This much for the general treatment of tabes. For cases recognized early nothing else will be required, and what has been considered will, if employed assiduously and with good judgment, be generally beneficial. In time it will arrest the progress of the disease, and will gradually lead to a practical, if not to an absolute cure, provided the treatment is carried on a few years, after all symptoms have disappeared. It is, however, generally necessary to give the patient, for one month or two, rest from the current, after forty to fifty treatments have been taken. During this period of rest the patient must be kept under control and observation, so that digestion, assimilation, favorable hygienic condition, and good spirits be maintained, and that no meddlers get a chance to interfere and to spoil what has been done. When the disease has already advanced so far as to give symptoms of disturbed locomotion and of ocular failure, we may still arrest the progress of degeneration, but when cerebellar and visceral symptoms appear, then all that we can hope to accomplish is to keep the patient comfortable, and to retard the progress of degeneration.

Besides the treatment outlined above, special treatment to oppose symptoms is required. When the lancinating pains in the lower extremities fail to yield to the current, and are taxing the patient's strength, ten grains of acetanilid, combined with powdered extract of digitalis, gives, as a rule, sufficient relief and cause no deleterious effects. Given at night, before retiring, it procures sleep. Opium or any of its derivatives must be avoided, as they have a paralyzing influence, which favors the progress of the disease.

In 1893 I concluded that the rest-treatment was an error, and I required my tabetics to walk as much as possible, and to aim or strike with their toes and fingers at objects, so as to engage the muscles of all extremities in all possible directions, and to exercise every muscle of the body. I also required bending of the spine in all directions. A few steps and a few exercises at short intervals are highly beneficial, but even the slightest degree of fatigue must be avoided. Standing with open and closed eyes and maintaining the equilibrium, without leaning on any object, must also be practised. All exercises must be carried out forcefully, with as much will power as possible. By bringing will power into play the efforts from the centers of volition tend not only to keep up life in the nerve cells and fibers, but also to generate new nerve tissues, and are, therefore, obviously, extremely important. Five years later Fraenkel published his views as to exercise in tabes, and since then exercise treatment is a matter of course. As long as the muscles, tendons, and ligaments of the lower extremities possess enough tone the walking and standing exercises can be taken up without delay. When, however, these structures have been permitted to lose the required tonicity, the peroneal muscles fail to act on the external sides of the feet and the patient shows a tendency to fall sideways. To oppose this tendency the patient throws his weight, with each step, on the inner side of the foot. The ligaments of the ankles and of the feet have also, by this time, lost normal tonicity, and the weight of the body, directed on the inner side of the foot, soon grows too much for them, and the plantar arch descends gradually more and more, till it rests on the ground. Now, while the descent of the arch is a pathological consequence, it is nevertheless a compensation which meets the failure of the peroneal tendons and muscles, and permits, to some degree, maintenance of equilibrium. The failure of the peroneal muscles and of the plantar arch, therefore, do not prevent walking. As, however, the process of degeneration in the ligaments of the ankle-joints increases in degree they fail to hold the tibia and fibula in place; and, as the tendons of the peroneal muscles have failed before this, the patient experiences, according to the degree of the hypotonia, difficulty or inability to maintain himself on his feet. This is the reason why walking becomes difficult or impossible. To enable the patient to walk shoes must be constructed which will at once elevate the external sides of the feet, support the plantar arches and hold the tibia and fibula on the tarsal bones. Various shoes have been ordered by various physicians, and much humbug and fraud have been and are being practised on the poor victims by enterprising imposters, and yet all that is necessary is a lace shoe with an elevated outside, having a strong steel spring or leather beam, to support the plantar arch, and a stout leather cuff, extending from the heel over the maleoli. The degree of side and arch-elevation must correspond to the needs of each case; too much of either causes pressure and renders the shoe useless.

To prevent, or to correct, ocular symptoms, thick absorbent cotton compresses, thoroughly saturated with glycerine, to which a little bicarbonate of soda is added, the latter to prevent irritation of the eyelids, are at night placed over the eyes, and covered with oiled silk to confine the glycerin. These compresses are very beneficial adjuvants to the current, especially against strabismus and diplopia.

To oppose the sensation of constriction on the chest, the girdle-feeling about the waistline, and the cramps in the bowels; to allay restlessness and to procure sleep, the acetanilid mentioned before, about ten grains, with powdered extract of digitalis according to necessity, is very useful. In some cases whisky or gin are more beneficial, and preferable to opium in any form. Opium and its derivatives must be used only when nothing else will allay suffering.

The more opiates the worse the tabetic lesions grow. When all hope for recovery or improvement is given up make the last days of the poor victims as comfortable as possible by every means. When the stomach grows irritable, water, decidedly acidulated with muriatic acid, is of great service. The patient sips of it off and on, according to his own judgment. When the bowels fail to digest and to absorb the food, decomposition with consequent diarrhea sets in. For this the acidulated water is also helpful, but more so the tincture of chloride of iron, used in the same manner as the acid. But when the iron solution disagrees, iron carbonate in pill form, in small quantities at frequent intervals, often prove very beneficial. When the kidneys act sluggishly and the bladder loses its sensitiveness, residuary urine remains in the bladder, which sets up a peculiar cystitis, without causing subjective symptoms, but which is decidedly detrimental to the system. To counteract this, drinking as much water as possible, with a little bicarbonate of soda, or with lemon juice is useful. One grain of methylene blue after each meal, for three days in succession, every fourteen days, counteracts decomposition of the residuary urine and cleans the blood.

When this disease is once well established all we can hope to accomplish then is to keep the patient comfortable and to prolong life. It is, therefore, of utmost importance to recognize tabes in its very incipiency. Judicious treatment will then check the progress of the disease and restore the involved structures to a normal, or to a practically normal condition. When the disease approaches its termination in cases due to traumatism, symptoms referring to the spine, by spastic or convulsive movements of the upper and lower extremities, and of the muscles of the abdomen and trunk, appear, and grow in intensity until the patient dies from exhaustion. But speech and reason remain clear until the end. In all other types, especially in the cerebro-cerebellar type, bulbar symptoms, which were present before, increase until speech is impossible, for which reason it is often so difficult to ascertain whether the patient is conscious or not. The death struggle, while resembling that of general paresis, appears even more horrible in tabes, because we cannot overcome a feeling which makes us believe that the patient is conscious of his agony. Tabes presents a great variety of symptoms, different in almost every patient, and most perplexing; the death scenes of tabetics present, however, a still greater variety, which writes large and indelible question marks on the brains of the observing physicians. But, however the last symptoms appear, they present a most striking and pitiful scene of suffering, which to prevent or to end as soon as possible, is the last and most substantial treatment a physician can give his departing patient.

1 West One Hundred and Second Street.

Appendicular Tuberculosis.—Verdelet gives an interesting résumé of Lacouture's recent thesis on this subject. This investigator shows that in a patient free from any other tuberculous focus, there sometimes develops a lesion of the appendix, due to the invasion of the tubercle bacilli. The evolution of this affection is sometimes slow, and it most often manifests phenomena resembling those of ordinary appendicitis. Besides these symptoms, there are the possible peritoneal complications from the invasion of the peritoneum and large intestine by this disease. The diagnosis is difficult to make. A study of the antecedents of the patient, of the clinical phenomena, and of the excreta in doubtful cases, must be fortified by the microscopical findings. Removal of the appendix is indicated. This intervention should be followed by a thorough examination of the neighboring organs, the condition of which may demand a more extensive operation than that of simple appendectomy.—*Journal de Médecine de Bordeaux.*

SANITARY SUPERVISION OF PULMONARY TUBERCULOSIS AND OTHER COMMUNICABLE DISEASES BY THE DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK.

By J. S. BILLINGS, Jr. M.D.,
NEW YORK.

The Department of Health exercises sanitary supervision over pulmonary tuberculosis, typhoid fever, cerebrospinal meningitis, pneumonia, malaria, puerperal septicemia, and erysipelas, by virtue of sections 133, 134, 135, 136, 137, 138, 139, and 144 of the sanitary code.

The general procedure is as follows:

1. All cases of pulmonary tuberculosis, typhoid fever, and cerebrospinal meningitis, occurring in the City of New York are registered at the Department of Health; and all necessary steps taken to render that registration as accurate and complete as possible.

2. Every person (or the family of such persons) suffering from those diseases is furnished instructions as to the measures to be taken to prevent its extension.

3. Bedding, etc., used by persons suffering from those diseases, is disinfected. All premises which have been occupied by persons suffering from pulmonary tuberculosis or cerebrospinal meningitis, on death, removal, or recovery of the patient, are disinfected with formaldehyde, or renovation is ordered.

4. Charitable assistance or hospital care is provided so far as is possible for all persons wishing or requiring such assistance or care.

5. The general public is educated as to the nature of the above diseases, the precautions to be taken against their spread, the advisability of institution and sanatorium treatment, etc.

6. *Pulmonary Tuberculosis.*—Patients with no attending physician are (*a*) visited at their homes by nurses and given necessary assistance and advice, (*b*) provided with extra diet (milk and eggs) when necessary, and (*c*) given free medical treatment at the Department Clinics.

7. *Typhoid Fever.*—Information as to the probable source of infection (water, milk, oysters, etc.) is obtained in every case, and suitable action taken.

8. *Cerebrospinal Meningitis.*—Quarantine of patients at their homes is enforced and other children in the family excluded from school.

TUBERCULOSIS.

Routine Procedure.—The sanitary supervision of pulmonary tuberculosis in the different Boroughs of the city is carried on by means of the same staff of inspectors who administer diphtheria antitoxin. The staff of nurses is apportioned as follows: Manhattan, seven; Brooklyn, four; Bronx, one, and Richmond and Queens, one. Each nurse has a certain section of the city assigned to her.

Notification.—Cases of tuberculosis are reported to the Department of Health by (1) private physicians, (*a*) on the postal cards furnished, (*b*) by the forwarding of specimens of sputum for examination to the Diagnosis Laboratory; (2) institutions (hospitals, sanatoria, dispensaries), on postal cards furnished; (3) death certificates, forwarded to the Bureau of Records; (4) complaints from lay individuals or organizations; (5) employees of this and other departments of the city.

The various records, files, indices, etc., of cases of pulmonary tuberculosis center around an alphabetical "name" index, in which the name, age, address, date, case number, and source of report of every living case are entered, together with the name of the sub-index in which the record card is filed. The

actual record cards are filed in different sub-indices according to circumstances, as follows:

1. "Private cases" (p. c. on name card), reported by private physicians and not visited by inspectors or nurses.

2. "At home" (a. h. on name card); cases at their homes under supervision by the Department (*i.e.* not under the care of a physician).

3. "Hospital" cases ("hosp." in the space for name of institution), reported as having entered a hospital.

4. "Not found" cases (n. f.); those not found at address under which reported.

5. "Dead" cases (name card is destroyed).

6. "Out of town" cases (o. o. t.); reported as having left the city.

7. "No case" and "Recovered" (n. c.); found on investigation not to be cases of tuberculosis, or reported as recovered.

General Routine.—On the receipt of report of a case, from whatever source, it is first searched for in name index. If it is a new (previously unreported) case, a record case number is assigned (beginning each January 1), which is written on the original postal card or report card from Diagnosis Laboratory in red ink. If an old case (a duplicate), the old number is written in black ink. A blue "record" card is then made out, on which all essential facts are entered, and (later) every official action and recommendation of the Department—dates of inspection and by whom, records of fumigation and renovation, forcible removal, etc. Changes of address, entrance into hospital, duplicate reports, etc., are also noted on this card. The original report is then filed in "report card" index, according to date of receipt. Only postal cards and sputum report cards are so filed; all other forms of reports are transferred to a postal card before filing. This index is kept for five years.

A record is kept of every case assigned to an inspector or nurse, by means of a "tally" index showing exactly what cases are being investigated by each inspector and nurse. A small "tally" card for each case is filed under the employee's name and is only removed on receipt from him or her of all cards, etc., relating to the case. This index is gone over once a week and any delays inquired into.

Private cases are not visited except at the request of the attending physician. A leter is sent to the physician, acknowledging receipt of report, calling his attention to the necessity for reporting any change of address or discontinuance of treatment on the part of the patient, and enclosing a circular of instruction, which (or its equivalent) the physician is requested to give to the family of the patient or to the patient himself. A card index is kept of the names of all physicians reporting "private" cases, together with names of cases. The large record card is then filed in the "private" case index according to patient's address. Once a year a letter is sent to the attending physician of every "private" case, asking for information as to outcome of case. If no answer is received, the case is followed up by the Department. Such cases, if found (also all "private" cases reported later by institutions) come under the supervision of the Department, the "p. c." on name card being stricken out.

At home cases are reported by (*a*) dispensaries and charitable organizations, (*b*) laymen, (*c*) physicians, with request that they be visited, and (*d*) hospitals, as having been discharged. Such cases are at once assigned for investigation and report to the nurse in whose district the patient lives. The date of assignment and name of nurse are entered on blue record card, which is mailed to the nurse. If the patient is found, a pink "observation" card is filled out, giving all essential data (if not found, that fact is noted on record card, which is returned). Record and observation cards are returned by mail on the day of inspection. Any recommendations (hospital, charitable aid, etc.) are indicated by writing date in proper space on record card. If case is kept under observation, a white "nurse's" card is filled out and retained, on same being entered all records of weekly visits. On termination of supervision (by death, improvement, removal to hospital, removal outside nurse's district, etc.) the nurse's card is returned. Recommendations by nurse during observation or on termination of case (for disinfection, forcible removal, etc.) are made on a special postal card.

On receipt of record at Borough office, (1) if tuberculosis case was "not found," that fact is indicated on name card and in book for recording number of "not found" cases, and card is filed in "not found" index. A letter is sent to individual who reported the case, requesting correct address. (2) If found, the record card is stamped "observation card" on left-hand margin, and filed in "at home" index. If not to be kept under observation by the nurse, the pink "observation" card is filed with it; if kept under observation the pink card is filed in the "tally" index under nurse's name, forming record of cases under her observation. Each week a record is kept of number of cases under observation in each district. On return of white "nurse's" card, it is attached to observation card and record card, and appropriately filed.

Cases needing charitable assistance are referred to the Charity Organization Society, Association for Improving the Condition of the Poor, United Hebrew Charities, Brooklyn Bureau of Charities, etc., by telephone and postal card, a card index being kept of all such recommendations.

Milw, two quarts daily for one month, eggs, three daily for two weeks, are issued in cases where such extra diet is called for as a part of treatment. On recommendation of the nurse, an order on the nearest depot is issued, a record being kept of all recommendations. The following are the depots:

Manhattan Diet Kitchen Association: Raymond Kitchen, 423 West Forty-first street; Rusch Kitchen, 146 East Seventh street; Freeman Kitchen, 335 East Twenty-first street; Wickham Kitchen, 137 Centre street; Gibbons Kitchen, 140 East Ninety-seventh street; Hackley Kitchen, 26 Barrow street; Anne Barbara Kitchen, 205 West Sixty-second street. Brooklyn: Brooklyn Bureau of Charities, 1600 Fulton street, 191 Marcy avenue, 69 Schermerhorn street, 174 Johnson street, 98 Sackett street, 255 Division avenue.

Sputum cups, both pocket and home (metal framed with removal filling), are issued by the nurses.

Instructions are given to the patient and his family both verbally and by means of the "Circular of Instruction to Consumptives and Those Living with Them," each circular being printed in English and one other language—German, Italian, Yiddish, Ruthenian, Slovak, Polish, Bohemian, and Chinese.

Cases of tuberculosis attending the dispensaries of Gouverneur, Bellevue, Presbyterian, and Harlem Hospitals, and the Vanderbilt Clinic, and kept under observation by the nurses of these dispensaries, are not visited. In order to avoid duplication of visits, these dispensaries are furnished with postals to notify the Department that the case is being kept under observation. These postals are filed under the name of the dispensary, forming a record. Twice a year this is compared with the records at the dis-

pensary. All cases must also be reported in usual way, but are held two weeks awaiting receipt of special dispensary postal. If not received, patients are visited.

All suitable cases are urged to enter a hospital; if consent is obtained, the recommendation is made on proper space on record card, date and name of institution preferred being given. If recommended to Riverside Hospital, the patient's name is placed on waiting list; when vacancy occurs, an admission card is made out and delivered by the district nurse, who obtains information called for on card and reports as to necessity for ambulance, coupé, etc. In emergency cases, when an ambulance is required, the hospital in whose ambulance district the patient lives is requested to remove the patient to Bellevue, whence he is transferred to the Metropolitan Hospital or to St. Vincent's Sanatorium.

Ambulance Districts in the Borough of Manhattan:

Gouverneur Hospital...	Houston to Front Sts., Bowery to East River.
Bellevue Hospital.....	Houston to 42d Sts., 4th Ave. to East River.
Flower Hospital.....	42d to 59th sts., 6th Ave. to East River.
Presbyterian Hospital...	59th to 96th Sts., 5th Ave. to East River.
Harlem Hospital.....	96th St. to Harlem River, Lenox Ave. to East River.
J. Hood Wright Hosp...	86th St. to Kingsbridge, Lenox Ave. to North River.
Roosevelt Hospital....	27th to 86th Sts., 8th Ave. to North River; 42d St. to 6th Ave. to 59th St.
New York Hospital....	14th to 27th Sts., 4th Ave. to North River; 27th to 42d Sts., 7th Ave. to Park Ave.
St. Vincent's Hospital...	14th St. to Canal St., 4th Ave. to North River.
House of Relief.....	Catherine St. to North River, Canal St. to Battery.

All requests for admission to the hospitals of the Department of Charities and also to St. Joseph's, Seton, and Lincoln Hospitals, are referred to the Department of Charities, by telephone, by a double card (one half being given to patient and the other being filed in borough office), and by postal card.

Forcible Removal.—When the necessary precautions cannot or will not be observed, and when others (especially children) are exposed to infection, a patient may be removed to Riverside Sanatorium by force if necessary, even if consent of patient or family is not obtained.

Notification of Employer.—When patients continue at work and may be sources of danger to their fellow workmen, the employer is visited and notified as to the danger of infection, and precautions to be taken. Placards forbidding promiscuous spitting are furnished free, to be put up in the work place.

Notification of Landlord.—When it is evident that premises will need renovation after removal of patient, the owner or agent is required to promptly notify the Department when such removal takes place, and also as to new address. A postal card is also left by the nurse with such patients, on which any change of address is reported.

Unsanitary Conditions.—All unsanitary conditions (bad drainage, leaky plumbing, etc.) are reported. If occurring in a tenement house, the complaint is referred to the Tenement House Department; if not, to the Division of Inspections of the Department of Health. (A tenement is any house containing three or more families.)

On death, removal to a hospital, or change of address of a case "under observation," the district nurse is notified by postal to return all cards, etc.

Treatment.—When patients are not receiving medical care, they are referred to one of the Tuberculosis Clinics of the Department of Health, a double reference card being used, one half being given to the patient, and one mailed to clinic.

Discharge from Hospital.—Every hospital must report all discharges and transfers of cases of tuberculosis. Every case returning home is at once visited to see if treatment is being continued, instructions observed, etc. Each morning a report is obtained by telephone from Seton, Lincoln, St. Vincent's, Metropolitan, St. Joseph's, and Riverside Hospitals of (*a*) all patients discharged the day before and (*b*) of all cases to be discharged three days later. The former (*a*) are noted on a "discharge card" and visited at once; as many of these patients remain at home only a day or two. The latter (*b*) are noted on a "nurse's discharge" card and each case assigned at once by telephone to the district nurse for investigation as to whether patient should be allowed to return home. She reports by telephone within twenty-four hours, her report being entered on card, which is filed, and hospital notified. Should a patient returning to unfavorable home surroundings, or giving wrong address, insist on being discharged, the patient can be transferred to Riverside Hospital.

"Suspected Cases" and Complaints.—All cases reported by lay individuals and organizations, and nurses, are classed as "suspected" cases and are visited by the district medical inspector, who reports results of physical examination and nature of ailment on observation card. The original report cards are filed separately until the case has been reported on, when person reporting case is notified of result. If case proves to be one of tuberculosis, the usual routine is followed, except that when inspector recommends that case be kept under observation, the record and observation cards are filed, and a white nurse's card filled out and sent to district nurse. If not tuberculosis, it is classed as "no case," so recorded in name index, and filed. All complaints by citizens (as to spitting, necessity for hospital treatment, etc.) are investigated by a district inspector, who submits a formal report. If there is a physician in attendance, he is visited and requested to see that nuisance is abated, if one exists.

Incipient Cases and Sanatorium Treatment.—All apparently incipient cases seen by nurses and inspectors, or calling at Borough offices, are referred by card to a Tuberculosis Clinic of the Department for examination as to their eligibility for sanatorium treatment. Very incipient cases are referred to the New York State Hospital for Incipient Tuberculosis. Suitable cases are also referred to the Stonywold, the Loomis, and the Adirondack Sanatoria.

School Children.—Only in the most exceptional cases are children with tuberculosis allowed to attend school. Such cases are excluded from school by medical school inspectors, pending their examination at one of the Tuberculosis Clinics of the Department, whence a report is sent to the Division of Contagious Diseases. Every effort is made to have such children enter a sanatorium or hospital.

Hospital Cases.—Every hospital in New York City is required to report all cases of tuberculosis within one week of their admission, using a postal card furnished. Each hospital and dispensary is visited once a month and their supply of the various reporting postal cards replenished. The larger hospitals (Bellevue, Metropolitan, etc.) report daily. A weekly record book is kept of the number of cases (new and duplicate) reported by each institution

throughout the year. When no report is received within two weeks, inquiry is made by telephone. The yearly totals are compared with the number of cases given in the annual report of each institution.

Census.—Twice a year (March 1 and August 1) a census is taken of all cases of tuberculosis in institutions in New York City, a special blank being supplied to each institution. These censuses are compared with the "hospital index," *i.e.* the cases supposed to be in each hospital, and all discrepancies investigated, the results for each institution being recorded. Every case reported as entering a hospital is assigned to a district inspector, who recommends the necessary renovation, fumigation, and disinfection of bedding, such recommendations being recorded in the proper spaces on the record card by means of the date. (It is also stated if patient will return to premises or not.) According to the condition of the premises, the inspector may recommend: (*a*) That nothing need be done. This is most exceptional, only obtaining in very clean apartments and those where the patient only spent one or two nights on the premises. (*b*) That the room occupied by the patient be fumigated with formaldehyde. (*c*) That the patient's room be thoroughly renovated, the walls and ceilings washed and rekalsomined, repapered or repainted, and the woodwork and floors be washed and repainted, the rest of the apartment being fumigated with formaldehyde. (*d*) That the whole apartment be renovated. Renovation of the premises (washing of floors and woodwork with antiseptic solution, repapering, painting and kalsomining) is recommended on a complaint blank, which, after being approved and journalized, is forwarded to the Sanitary Superintendent for enforcement. When cancellation, extension of time, or modification of order is asked for, the case is reinspected by the original inspector. When there is reason to believe that renovation will be evaded, or where the premises are vacated by the death or removal of the patient and renovation has been ordered, the inspector orders the premises placarded. A paster is then filled out at the Borough office, journalized, and forwarded to the Division of Inspections to be put up. When owner or agent, voluntary performs renovation, that fact is reported, a yearly record being kept of the number of such voluntary renovations. Fumigation with formaldehyde and disinfection of bedding is ordered on a card, on which number and size of rooms, date fumigation is to be performed, etc., are noted. All fumigation orders for the day are entered by inspector on a slip, which is forwarded with the fumigation cards to the Division of Contagious Diseases. In an emergency the fumigation order can be telephoned, but the card is also submitted. All bedding is fumigated before it is removed for disinfection, for the protection of the Department employees, and is returned in twenty-four hours. The tally card of the case is filed separately as a check on fumigation. The fumigation card is returned by Division of Contagious Diseases after its recommendations have been complied with, and the tally card is destroyed and fumigation card is filed according to date, being kept about four months.

On receipt of record card from inspector, it is filed in "hospital index" alphabetically according to name of hospital, which is written on small name card. In cases reported as having moved to a new address or having left the city, the same routine procedure is followed out. In cases living in private houses, disinfection can be done under the supervision of the attending physician, but he must submit a certificate. Lodging houses are not disinfected, that being the duty of the managers of such houses.

"Not Found" Cases. — When an inspector or nurse reports that no record can be found of a case at the address given, a letter is written to the person reporting the case, requesting the correct address. If this cannot be found, the name card is marked "n. f." and the record card filed in the annual "not found" index. These files are kept three years, when the record cards are destroyed and the name cards removed from the name index and filed in an "old not found name index." A daily record is kept of the number of "not found" cases reported.

Dead Cases.—All deaths from tuberculosis occurring during the preceding twenty-four hours are reported daily by the Bureau of Records. The record and name cards are stamped "Dead" and the former assigned to inspectors to order the necessary fumigation, etc., the latter being used as a tally card, and all cards of the case filed in "dead" index for the current year, which is kept for two years before being destroyed. Every previously unreported dead case receives a special serial case number, and a letter is written to the attending physician or institution calling his attention to the violation of the Sanitary Code and requesting an explanation. Should no answer be received, a second letter, signed by the Secretary of the Department, is sent, demanding an explanation on pain of prosecution. A record is kept under each physician's name of all such unreported cases, nature of explanation, etc. (unreported cases of typhoid fever, cerebrospinal meningitis, etc., are recorded in the same index). All deaths from pneumonia are daily compared with tuberculosis records. If case had been previously reported during life as tuberculosis, an inspector visits the physician who signed the death certificate and obtains an explanation of the apparent discrepancy, submitting a report on special blank. The same is done for all cases of tuberculosis reported as having died from some other cause. The Bureau of Records is also notified of any change of diagnosis and death certificate corrected.

Map.—Every new case of tuberculosis reported in Manhattan is plotted on a large map of the borough, which shows each house ("not found" cases, of course, excepted). The address is written on a small white card (of private cases, on receipt of postal or sputum report; of all others, on receipt of inspector's or nurse's report stating that patient did live at address given). In Richmond and Queens the cases are plotted on compo-board map by means of colored pins.

Riverside Sanatorium for Tuberculosis. — All cases are admitted through the Division of Communicable Diseases, the names and addresses of applicants being placed upon the waiting list. When a vacancy occurs, an admission card is filled out, for the first eligible case. ("Forcible removal" cases alone take precedence.) This is assigned to a nurse for delivery, who obtains data called for on card and leaves same with patient. If coupé or ambulance is necessary, the Borough hospital is requested to remove the patient. All patients must reach Reception Hospital, at East Sixteenth street, Manhattan, by 1 P. M., as the boat leaves at that hour. Walking cases may cross at East 132d street, whence a boat leaves every hour between 9A. M. and 5 P. M.

No patient is allowed out on pass or is discharged until the conditions at his home have been investigated and found satisfactory. A daily report of cases, deaths, discharges, and admissions is received by telephone each day and added to daily report to Sanitary Superintendent. Every case admitted, dis-

charged, or dead is reported daily on a special card, which is filed according to date.

Regulations.—All inspectors and nurses bear in mind that the Department of Health pledges itself not to interfere in any way with cases of pulmonary tuberculosis under the care of a private physician except where a complaint is made. Even then the attending physician, if there is one, is first visited. The source of complaint is never divulged.

The Inspector-in-Charge examines daily all cards, reports, etc., forwarded by inspectors and nurses, sees that the various recommendations are carried out, and various records, map cards, etc., are kept. When cards are incorrectly or incompletely filled out, the district inspector or nurse is summoned to the borough office.

All cases reported as living in other Boroughs are reported daily to the office of the Borough in which they live. When a patient moves to another Borough, all cards and records of the case are forwarded to the office of that Borough.

Inspectors.—Inspectors report at the Borough office every Monday at 9:30 A.M., bringing with them all cards, etc., in their possession, to be compared with tally index. All inspections are made within three days. Special assignments (forcible removals, diagnoses of suspected cases, etc.) are attended to immediately. Every entry on back of blue record card is dated. An observation card is made out for every case seen, whether tubercular or not, and the result of physical examination written in space "present condition."

In ordering fumigation, the date on which it is to be done is always given on card. Unless the premises are in very bad condition, it is usually sufficient to renovate the room occupied by the patient and to fumigate the rest of the apartment. Where the entire premises are probably infected, renovation should be complete. In cases where the premises are in very good condition, fumigation of the room occupied by the patient may be all that is necessary.

Great care and accuracy are necessary in recommending the kind and amount of renovation necessary, both for the sake of justice to the owner and because an error means a reinspection, probably rescindment of the order for renovation, and the submitting of a new complaint. The floor and position of premises are always noted on the blue card, complaint, fumigation card, etc. The full name of owner or agent is given in complaint; if it cannot be obtained, the fact is stated. All cards and reports, without exception, are mailed on the day the inspection is made. The regular blank is used for all reports.

Nurses.—All district nurses report at the Borough office at 9:30 A.M. on Tuesdays, bringing with them all cards, records, nurse's cards, etc., in their possession. Each nurse makes at least fifty-five inspections a week. All new cases are visited within three days, and all information requested on observation card obtained, special attention being paid to the physical condition of the patient, whether he is a menace to those about him, sanitary condition of the premises, domestic and financial circumstances, need of assistance, knowledge on the part of the patient of the nature of his disease, the care taken to prevent spread of disease, previous or simultaneous occurrence of other cases on the premises or in same family, and, if the case is under treatment, with the name and address of physician or institution. In giving instructions the nurse is guided by the patient's knowledge of the nature of his disease. When the patient knows that he is suffering from pulmonary tuberculosis, full instructions are given. In every case, however, the danger of promiscuous spitting and the necessity for the destruction of sputum is clearly pointed out, and the nurse leaves a copy of the "Circular of Information to Consumptives and Those Living with Them" printed in the language spoken by the patient. An observation card is forwarded for every case living at home, even if the patient is out or is to leave the premises at once. Where information cannot be obtained as to a particular point, a (?) is used. The name and address of the owner or agent of premises occupied by patient is obtained in every instance. Every observation card is dated, given the case number from blue card, and signed by the person filling it out, and it is stated if the patient is to be kept under observation (k. u. o.? yes or no). All cases under observation are visited once every week or ten days, the date of each visit and the condition of the patient being noted on the white card. These cards are gone over every two weeks by the Inspector-in-Charge.

Each nurse telephones the Borough office daily between the hours of 1 and 3 P.M., obtains names and addresses of patients in her district discharged from hospitals or to be discharged three days later, and reports on cases investigated the day before. These inspections are made within twenty-four hours. Cases under treatment at the Tuberculosis Clinics are visited and the large card of information as to home conditions filled out and returned, together with an observation card. (Instead of "yes" or "no" after k. u. o., the word "clinic" is written.) These cases are not kept under regular observation, being revisited only at request of clinic physician.

The following circulars, etc., are issued by the Department to physicians and others interested: Leaflet in reference to the reporting of cases of tuberculosis by physicians; Circular of Information Regarding Measures Adopted for the Sanitary Supervision of Tuberculosis; Circular Regarding Importance of Early Diagnosis of Tuberculosis.

Inspectors and nurses are supplied with pads of small cards forbidding spitting in cars, etc., which they use as occasion arises.

TYPHOID FEVER.

In Manhattan all hospital cases are under the supervision of a special inspector, all cases at their homes being looked after by the district inspectors. In Brooklyn, Bronx, Queens, and Richmond, the assignments of inspectors are the same as for tuberculosis. Cases are reported (1) by physicians and hospitals, on post card; (2) by the Diagnosis Laboratory, as results of examination of specimens of blood and urine; (3) by complaints from citizens and others, and (4) by death certificates. A complete history is obtained of every case reported, and filed according to address. Cases reported by hospitals are filed according to home address, and cross-referenced on a card for each hospital.

Dead cases, those living out of the city, and those not found at the address given are filed separately. On receipt of report, all records are searched to see if the case has been previously reported. If not, the data given on report are entered on a history card and a serial annual case number given.

For investigation, cases are divided into two classes: (*a*) those reported by private physicians; (*b*) those reported in any other way. In all cases reported by physicians, the history card and a stamped envelope for its return are sent to the physician, together with a letter requesting that he forward the desired information. A circular of information regarding the prevention of the spread of the disease, etc., is also sent him, with the request that he give it, or equivalent instructions, to the family of his patient. A record of such letters is kept by means of a tally card filed under physician's name. If, after fourteen days, no reply has

been received, the case is assigned to an inspector for investigation, the "tally card" being transferred to the inspector's record. All cases reported from institutions or by complaints are at once assigned to an inspector, who visits the houses of the patients, including those of patients in hospital, and returns the history with the required information. Every hospital receiving cases of typhoid fever is visited once a week by an inspector, and histories obtained of all new cases. If the patient is ill at home, the inspector makes certain that all precautions against the spread of the disease are being observed, and leaves a copy of the circular, "How to Avoid the Contraction and to Prevent the Spread of Typhoid Fever." When the diagnosis is uncertain, or when it is requested by the attending physician, the inspector obtains and forwards a specimen of blood to the Diagnosis Laboratory for examination for Widal reaction.

Disinfection of bedding is ordered on the termination of all "at home" cases, the same routine being followed as in tuberculosis (*q.v.*); but bedding is not fumigated before removal, premises being fumigated only on request.

All information given by the attending physician in his report having any bearing on the source of infection—namely, unsanitary conditions of premises, addresses of the stores whence the milk and food used by the patient were obtained, possible contamination of the water supply, exposure to other cases of typhoid, etc., etc.—are investigated by the inspector. In all cases where the patient is stated to have been an habitual drinker of milk, an inspection of the milk store is made.

A "milk store index" is kept, in which is recorded under the address of each milk store the date, name, and address of every case of typhoid fever in which that milk was used. The reports of inspection of each milk store or dairy are also filed in the "milk index."

Based on the inspector's reports, complaints as to unsatisfactory sanitary conditions, lack of milk permits, etc., are forwarded to the Assistant Sanitary Superintendent of each Borough for further action. Histories of cases in which such complaints have been made are filed separately, awaiting result. All deaths from typhoid fever are reported daily from Bureau of Records on special blank. Dead cases not previously reported during life are treated in exactly the same manner as similar cases of pulmonary tuberculosis (*q.v.*). Dead cases found on investigation not to be typhoid fever are reported to the Bureau of Records for change of diagnosis on death certificate. Each case on completion of record is plotted on a large compo-board map of the Borough by colored tacks indicating the *possible* sources of infection, as follows: White, no discoverable source (water?); blue, habitual milk drinker; green, habitual oyster eater; red, out of city during the two weeks preceding illness; orange, exposed to another case of typhoid fever.

Inspectors bring all histories, records, etc. (even if incomplete) in their possession to the Borough office every Monday morning.

The following circulars of information are issued and distributed: "Information Regarding Typhoid Fever," "Importance of Disinfection of Urine and Feces in Typhoid Fever," and "How to Avoid the Contraction and to Prevent the Spread of Typhoid Fever."

CEREBROSPINAL MENINGITIS.

This was declared a communicable disease by the Board of Health April 19, 1905.

The districts are the same as those for tuberculosis. Cases are reported by physicians and hospitals, on postal; by the Diagnosis Laboratory, from results of examination of spinal fluid; by death certificates, and by complaints. A full history is obtained of each case (home surroundings, symptoms, etc.), which, when completed, is filed according to address. Each new case reported is compared with this record; if unreported, the data on the report card are entered on the history card, and the latter is assigned to an inspector, a tally card being filed under the inspector's name as a record. The inspector visits the home of the patient within twenty-four hours, obtains all required information as to sanitary surroundings, past history of patient, exposure, etc. If the patient is at home, full instructions are given the family verbally and by circular as to the nature of the disease, isolation is enforced, and other tenants in house are notified. All children in the family are excluded from school, a postal being sent the school superintendent. The case is kept under supervision by the inspector, who sees that the rules of quarantine are being observed. If they are wilfully violated, removal to hospital may be recommended. If the patient is dead when inspector calls, or has been removed to a hospital, fumigation of premises and disinfection of bedding is ordered, just as in tuberculosis (*q.v.*); the same is done after patient has recovered. Certificates permitting children to return to school are then issued by inspector and left at the house. Deaths are reported daily by Bureau of Records. In all dead cases not previously reported during life, an explanation is demanded of the physician, as in tuberculosis, the same index being used (*q.v.*).

The clinical history of each case is obtained from the attending physician or hospital, the proper district inspector being assigned to that duty. All dead cases found not to be cerebrospinal meningitis are reported to the Bureau of Records, where diagnosis on certificate is changed.

Every fatal case of meningitis (tuberculous, etc.) in children is investigated and a history obtained.

Inspectors bring all cards, etc., (completed or not) to the borough office every Monday for comparison with the tally cards.

A circular is issued and distributed, entitled, "Circular of Information Regarding Cerebrospinal Meningitis."

MALARIAL FEVER, ABORTION, PUERPERAL SEPTICEMIA, ERYSIPELAS, AND PNEUMONIA.

While the above are reportable diseases, the patients are at present not visited, the report postal being simply filed for statistical reference and tabulation. History blanks have been prepared for pneumonia, abortion, and puerperal septicemia.

All cases of death from "malaria" are assigned to an inspector, who visits the attending physician to inquire if the case was not really one of typhoid fever, if blood tests were made, etc.

The following circulars in reference to malaria are issued on "Notification and Microscopical Diagnosis"; on "Prevention of Malaria"; leaflet.

32 East Fifty-third Street.

A CASE OF COMPLETE INVERSION OF THE UTERUS.

By J. SEYMOUR EMANS, M.D.,

NEW YORK.

INSTRUCTOR IN MEDICINE, AND ASSISTANT ATTENDING PHYSICIAN AT THE NEW YORK POST-GRADUATE HOSPITAL.

A CONDITION which arises but once in about 200,000 cases of confinement seems worth reporting. During 1904 there were 103,881 births reported in Greater New York. Thus, in a population of about 4,000,000 people, there should be but one case of inversion of the uterus in two years, or

about ten cases per year in the whole United States. The literature from 1803 to 1905 gives approximately these figures. About 570 cases have been reported; fifty per cent. were complete inversions, 140, twenty-six and one-half per cent., mostly recent cases, were reduced by taxis and mechanical means; 100, mostly chronic, were operated on; fifteen underwent spontaneous reduction; fifty per cent. became chronic, and twenty per cent. died.

M. H., thirty-six years of age, born in the United States, married, primipara. Her father, who was born in Portugal and reared in Spain, died of pleurisy in his thirty-seventh year. The mother, born in Ireland, is living. One sister died of phthisis in her forty-second year. Two others are living and well.

The patient had measles and false croup when a child, but has enjoyed good health ever since. Menstruation began at the fifteenth year, has been regular, lasted three days, flow moderate, no pain. From her eighteenth to her thirtieth year she worked in a tobacco factory. She then worked ten to thirteen hours a day as ironer in a laundry, up to the time of her marriage. After her marriage she menstruated but once, November 18, 1904, and then became pregnant. During this time she was perfectly well, until August 31, 1905, at 6 A.M., she had a discharge of blood, enough to soil three napkins. This continued more or less for five days, upntil she was delivered. Pains began, 6 P.M., August 31. The next day she had pains off and on, mostly in the afternoon. At times they came as often as every five minutes. The next two days, September 2 and 3, the pains continued. At 8 A.M., September 4, Labor Day, she had a chill. The doctor was sent for and he came at once, gave chloroform, put in forceps, and in a half-hour delivered her of an eight and a half-pound dead girl.

I have since called on the doctor, but he was not inclined to give any information, other than that the case was normal, and I must not take notice of what the family said, as they were not to be relied on. Therefore, I must give the statements of a sister of the patient who was present, and who has for the past fourteen years acted as an assistant at a large number of confinements, and is a truthful and competent person.

She said the physician had to pull very hard to get the child, and that the head was delivered with the forceps still applied. About five minutes later the shoulders and body were delivered by pulling on the head. The child had been dead but a short time. The cord was not about the neck or body, and was of normal length. After it was cut and tied, the child was taken into the next room, and immediately after, the placenta was delivered by massage of the abdomen over the uterus, and by pulling on the cord. This came away, but appeared small for so large a child. The doctor put his hand in the vagina as if looking for a part of the placenta, or membranes, and pulled out a round, red, body, around which he swept his finger. When asked what that was, he replied, "the uterus," and at once pushed it back.

The patient had much pain that day and night, and the following day expelled a large blood clot. After this she had scarcely any flow, but complained constantly of bearing-down pains and a feeling as if there was a lump in the vagina. For three days she had no movement; was then given citrate of magnesia, and the bowels moved several times. For three days again she had no movement, and was ordered three castor-oil pills by the doctor. While straining at stool on a pail, September 11, one week after the confinement, the uterus prolapsed inverted between the legs. The doctor was sent for twice, but could not be found, so I was sent for. Some bleeding had taken place, but it had stopped at the time of my arrival. By squeezing the uterus with both hands and making pressure, I was able with considerable difficulty to push it, still inverted, up into the vagina. Having relieved the patient's distress, I left, giving the family instructions to tell the doctor the patient's condition.

On September 17, four days after the patient had been discharged by her physician, I was called on account of burning on urination, constipation, and bearing-down sensations. On examination, I found the uterus still inverted in the vagina. Asking if her physician had done anything for her, she said no; he did not examine her and said it was nothing, also that it would have been a good joke on me if she had with her two fingers pushed the uterus up before I arrived. I told the patient her exact condition, and proposed to try and reduce the uterus under ether. This was agreed to, and on September 20, sixteen days after the confinement, at which time undoubtedly the uterus became inverted, the patient was given ether. After giving a hot bichloride (1-4000) douche, with the patient in the dorsal position, I introduced my right hand into the vagina and squeezed the uterus, making upward pressure. In the meantime the left hand, making pressure on the abdomen over the symphysis, felt the absence of the uterus, and the presence of a fleshy ring about two and a half inches in diameter, with a depression in the middle. Making no apparent progress, and my hand being cramped, I removed it, and a second time introduced it, grasping the uterus and trying with my fingers to push up the side of the uterus nearest the cervix. Again I was compelled to remove my hand on account of the severe pressure of the vaginal walls. After a moment's rest, I placed my right hand on the abdomen and introduced my left hand in the vagina, grasping the uterus and pressing up with the fingers along its side. Rather suddenly it yielded and slid in place. Following with my hand upward, I came to the fundus of the uterus which was still projecting slightly into its cavity. Pushing this in place, I withdrew my hand and gave a very hot bichloride douche, when the uterus contracted and remained in place. As soon as the patient came out of the anesthetic, a dram of the fluid extract of ergot was given, and she was ordered five grains of quinine sulphate every four hours to keep up contraction. The replacing of the uterus did not take more than ten minutes.

The patient was kept in bed ten days. At no time did her temperature rise above 99°. Two weeks from the time of the operation the patient was in my office feeling perfectly well. The uterus was in good position. A deep tear in the cervix, into the left fornix of the vagina, without doubt contributed to the inversion, and to the ease of its reduction.

February 21, 1906, the patient was in my office for ear treatment. An examination of the uterus showed it in proper position and she said that she had had no uterine troubles from the day it had been replaced to the present time.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, May 19, 1906.

THE GENEVA CONVENTION.

DURING the more than forty years that have elapsed since the first Geneva convention was held, largely, we are glad to remember, through the agency of a physician, Dr. Dunant, the beneficent operation of this international compact has accomplished inestimable good in alleviating the sufferings and dangers of the unfortunate common soldiers who form the helpless pawns in the game played by the diplomats. Well intended as were the provisions of the agreements ratified at the first convention, and carefully as they were remodeled and amended at the second, held four years later, in 1868, it appears that they are either not altogether adequate or are not explicit enough in form to eliminate all possibility of misapprehension. While there is no doubt that all of the powers that have signified their acquiescence in the Geneva agreements have intended to carry out the spirit as well as the letter of the law, misunderstandings and mutual accusations have nevertheless been not infrequent in most of the wars that have occurred since then.

The necessity for a revision, at least in some points, of the original understanding was emphasized at The Hague peace conference in 1899, and the Swiss government, both in 1903 and in 1904, extended invitations to the powers to take part in a conference for the purpose of readjustment. The first attempt failed through lack of interest, apparently, and the second was also unsuccessful, owing to the outbreak of hostilities between Russia and Japan. Switzerland has again issued an appeal to the nations to send representatives to consider the matter, in June of this year. One of the subjects suggested for consideration at this meeting is the adoption of measures intended to protect the wounded from robbery and maltreatment. A radical change is to be suggested in regard to the final disposition of the wounded, who on recovery are not, as formerly, to be sent home on parole but are to be held as prisoners of war. Soldiers are all to be provided with an adequate means of identification, which is always to be noted before burial, and the combatants are to furnish each other with lists of all the dead, wounded, and prisoners, as soon as possible after each engagement. The regulations regarding the members of the hospital corps are to be made more precise in their provisions, as also the directions concerning the ownership of hospital supplies, etc. The question of penalties for violation of the rules will come up, and the advisability of substituting for the conventional cross some other symbol, such as the crescent, for example, for the non-Christian nations, will also be discussed.

It is very much to be hoped that this effort of the Swiss government will meet with the cooperation it deserves, and that the success of the conference will be assured by a full attendance of the powers. The practicability of injecting this modicum of humanity into the anachronism of war has already been sufficiently well demonstrated to make it desirable to extend the field of mutual forbearance much further, and there is little doubt that if the conference is held it will be found feasible to introduce restrictions which originally would have been out of the question.

THE FEEDING OF POOR SCHOOL CHILDREN.

THE question as to the advisability, or rather as to the necessity, of providing free meals for those children attending the public elementary schools of England, whose parents are unable to procure them food, has been a subject of discussion now for some considerable time. The problem of physical, and to a lesser extent mental, degeneration which is threatening the inhabitants of the large cities of Great Britain is arousing widespread alarm, and it is fully recognized that the evil must be met, and steps to this end must be taken promptly. The proper nutrition of young children is, as a matter of course, intimately bound up with the question of degeneration; indeed it is, perhaps, the most important part of the entire subject. Underfed children cannot develop as they should develop, and will grow up deficient mentally and physically, and thus the race cannot but deteriorate rapidly. The British Parliament, which is now sitting, as might have been expected from its composition, is taking an active interest in all that concerns the poor, and consequently the feeding of poor school children has been brought into prominence in the House of Commons, and has been freely debated. On March 2 the Education (Provision of Meals) Bill passed its second reading and was referred to a select committee. This signifies that a measure will probably be enacted authorizing the supplying of meals to young children attending primary schools whose parents cannot afford to provide suitable food.

The whole matter was discussed at great length, many opposing the scheme for a variety of reasons. Some of those adverse to the plan pointed out that to make ratepayers pay for the meals of the children of their less fortunate brethren would be, in a very large number of cases, flagrantly abused. For instance, parents who are addicted to drink would hail the passage of the measure with delight, as it would apparently absolve them from parental responsibility, so far as feeding their children was concerned, and leave them with more money to expend on alcohol. However, it is hoped and expected that this would not be the case, as the intention of the framers of the bill would seem to be to feed the children and to pursue the parents. Whether it would be possible to carry out this intention effectively is altogether another matter.

After all, the main point, and the only one that really concerns a medical paper, is that young children who are compelled by law to attend school, in

the interests of public health should be properly nourished. A well-known English lady speaker made the apt remark a short time ago that "it would be better that children should not attend school at all, be well fed and grow up barbarians than that, ill-nourished, they should attend school and become anemic, puny, and weak sighted individuals." It may be taken for granted that ere long the law in England will be that the young school children whose parents are poverty stricken will be fed at the public expense. The method adopted will be, perhaps, in imitation of the Parisian system, as the new Minister for Education appears to be in favor of that mode of procedure. That the difficulties in the way of a successful consummation of the object in view will be very great goes without saying, but the situation is such that energetic action is urgently called for. Even if the experiment fails at first, something will have been learned, and when it is a question affecting the well-being of an entire country, no obstacles must be allowed to block the path. The progress of the movement in England to improve the race by insisting that the coming generation is given a fair fighting chance in the battle of life will be watched with interest by all classes in this country, and especially by members of the medical profession. The question of feeding poor school children has not as yet become pressing in America as a whole. There are, however, cities, among them New York, in which such a scheme has been suggested. With the continued influx of poor town dwellers into the United States it would seem that there might soon be need, at any rate in New York and certain other of the larger cities, of following the lead of England.

UNCURED GONORRHEA.

It is said that gonorrhea is the most widespread of all contagious diseases, with possibly the single exception of measles. Specialists all over the world and for centuries past have sought for a remedy which would surely cure gonorrhea, but up to the present without definite results. Whether it is ever radically cured has been discussed pro and con by those whose knowledge of the disease, acquired during years of experience in treating thousands of cases, gives their opinion great weight, but the question is not yet settled. Until recent years syphilis was considered the social scourge, while gonorrhea was thought to be of minor consequence. To-day the consensus of opinion is that the dangers from gonorrhea are of vastly greater moment than those from syphilis. If we are to believe reports, more than one-half of the population of European cities is affected with gonorrhea. This statement is appalling. Of the American army in the Philippine Islands, one-sixth of those treated in the hospitals were treated for gonorrhea; most of these returned to the United States, many uncured. One in 28 of the patients treated in a New York dispensary presents a case of venereal disease, there being four times as many cases of gonorrhea as of syphilis.

It is a matter of common belief that a large percentage of those infected with gonorrhea are not properly treated, and consequently remain uncured. The average physician does not know how to treat gonorrhea properly, and, moreover, many patients seek treatment from the druggist, who is necessarily incompetent to treat any, and more particularly this diseased condition. What may follow? Ophthalmia neonatorum; self-infection of the eyes; chronic gleet; stricture; sterility, 42 per cent of all affected becoming sterile according to various reports: gonorrheal rheumatism; kidney diseases; diseased prostate or bladder; gonorrheal endocarditis; peritonitis; septicemia; etc. The gonococci may remain quiescent for months or years, only to reappear in consequence of or following disease, intemperance, or unknown causes. Wilson reports a case in which a patient infected his own eye six years after he considered himself cured, no evidence of the disease having manifested itself during that time. In the woman, we may have infection of the pelvic organs, leading to the necessity for operative procedures. Price of Philadelphia declares that 95 per cent. of abdominal operations in women are the result of gonorrheal infection, while others declare that 80 per cent. of the deaths resulting from ovarian or uterine disease are chargeable to conditions due to gonorrhea.

How can we hope to avoid these conditions and results? Since we know that the gonococcus of Neisser is the sole cause of specific urethritis, it follows that the destruction of this germ should be the main object of treatment, and this is to be accomplished with as little injury to the tissues involved as possible. Germicides are used until repeated microscopical examinations determine the absence of the gonococcus—and this can be determined only by the microscope. To begin treatment with an astringent is to invite the multiplication of the gonococci and an invasion of the deeper-seated tissues, because of their protection in the folds of the mucous membrane, where astringents, which are seldom germicides, cannot reach them. After it has been definitely determined that the germ has disappeared, then astringents should be used, to close the crypts and stop the discharge. With all this accomplished, one is not yet justified in declaring the case cured, for the gonococcus may have invaded the prostate gland or the bladder. Prostatic massage, followed by a microscopical examination of the prostatic discharge, should be made several times after the urethral discharge has entirely ceased, to determine the absence of the germ, and the patient should be kept under observation for several months before he is finally discharged. Just so long as cases of gonorrhea are improperly treated will uncured gonorrhea prevail, and not only may the subject's wellbeing and life be endangered, but he or she may (given the opportunity) transmit the disease to others. This fact is one that should be impressed upon the minds of our patients and of the laity in general; it should be made plain that to stop a discharge is not to cure gonorrhea.

SOME STATISTICS OF SUICIDE.

An interesting study of this subject, based on official records on file in the Institute of Medical Jurisprudence of the University of Vienna, has been made by Pilez, who investigated 1,671 cases (*Jahrbücher für Psychiatrie und Neurologie*, vol. 26, Nos. 2, 3). Of this number there were about three times as many males as females, and their ages varied from

9 to 81. The prevalence of the male sex in these statistics is quite remarkable, although we also find this disproportion in other statistics. In both sexes suicide was more apt to be attempted during the period from 21 to 30 years of age than during any other time, and the maximum number of cases occurred during the month of May. The manner in which death was sought varied with the sexes. Thus poison was resorted to by about 20 per cent. of the men and by 55 per cent. of the women, and the bullet by over 25 per cent. of the former and only about 1 per cent. of the latter. About 20 per cent. of the women were pregnant, and in 22 per cent. affections of the sexual organs could be demonstrated. As regards the relations between suicide and mental disturbances, it was impossible to draw any definite conclusions. Only 42 men and 35 women were known to be mentally unsound, but an alcoholic history was present in 45 men and 7 women. This would apparently indicate that most of these suicides were sane in the ordinary sense of the term, and that the mental derangement which permitted the act could, if present, have been only a temporary one. One of the noteworthy features of this, as well as of other statistics of a similar character, is the age at which the greater number of these suicides occur. One would naturally suppose that the mind could overcome a suicidal tendency during the third decade of life much more readily than during the declining years. Or is it that the element of courage —designated, however, as cowardice by some—enters as a possible factor in the matter during this time?

The State of the Blood During Bier's Treatment.

The method of physical therapy to which the name of this well-known surgeon is attached has excited a great deal of interest, particularly as regards its mode of action. We have been favored during the last few years with numerous attempts to formulate some theoretical explanation of this method. When it was found that no factor could be demonstrated in the blood serum, E. Stahr, among others, turned his attention to the formed elements of the blood. He made a large number of blood examinations in ten cases in which the method was being used, his results being reported in the *Wiener klinische Wochenschrift*, No. 9, 1906. The number of the erythrocytes and the hemoglobin content remained entirely unchanged, or varied within very small limits. The leucocytes, in those cases in which the bandage was applied for a considerable period every day, showed a marked increase in number, which increase continued up to the third or fourth day of the treatment. This increase affected the lymphocytes, while the neutrophiles showed a decrease. In some of the cases in which the bandage was applied two hours every day, the decrease in the number of leucocytes was noted after the compression had been made, but the leucocytosis in the diseased extremity was always greater than in the healthy parts, so that we may say that localized leucocytosis occurred in the part under treatment. Stahr accounts for this leucocytosis by assuming that the blood current was slowed, or that there was an increased chemotaxis or an increased activity in the formation of the blood. This local leucocytosis probably accounts for the increased phagocytosis, and this, of course, is of importance in the curative process.

A False Note.

Among the sufferers from the San Francisco earthquake and fire was the *California State Journal of Medicine*, whose plant, we understood, was completely consumed. The May number has just appeared, a four-page folder only, showing admirable evidence of the determination of the management to keep its files complete. It is unfortunate, however, that this praiseworthy evidence of spirit is shadowed in one or two spots by a show of bitterness which it is not pleasant to see on such an occasion. We can hardly believe with this rancorous editor that "many participators in the nostrum business," whoever they might have been, could have felt anything but sympathy for the victims of the San Francisco disaster, nor do we believe there are many men so constituted as to have "rejoiced to think that we [the *Journal*] were wiped out"; or many, except those to whom such sensations are natural, who would have imagined such a feeling possible.

News of the Week.

Opening of the Rockefeller Institute.—The new building of the Rockefeller Institute for Medical Research was formally opened on May 11. Several hundred people were present and addresses were delivered by President Charles William Eliot of Harvard University, President Nicholas Murray Butler of Columbia University, Dr. William Henry Welch and Dr. L. E. Holt. Mr. Rockefeller was not present, but was represented by his son, John D. Rockefeller, Jr. The building stands on a plot which covers twenty-six and one-half city lots at Sixty-sixth street and Avenue A, and is five stories in height. The cost of the structure was about $350,000, and the effort was made to have it the most perfectly equipped laboratory building in existence.

The American Academy of Medicine.—An elaborate program has been prepared for the thirty-first annual meeting of this organization, which will be held in the banquet hall of the "Brunswick," Boston, on June 2 and June 4, 1906. At the executive session on June 2 action will be taken on several proposed amendments to the constitution of which one of the most important, regarding eligibility for membership, provides that "in lieu of the baccalaureate degree from a recognized institution, conditions of eligibility may be satisfied as follows: If the candidate is a medical graduate of at least twenty years standing, and has during that time made notable and scholarly contributions to medical science, and has been active along lines in harmony with the ideals of the Academy, he may be elected to fellowship in the Academy; provided that not more than ten fellows shall be elected under this provision at any one meeting." The secretary is Dr. Chas. McIntire of Easton, Pa., and the committee on arrangements consists of Dr. Augustus P. Clarke and Dr. Albert H. Tuttle.

The New Bellevue Hospital.—Progress on the new Bellevue Hospital building is being delayed through legal complications which have arisen in regard to the question of whether or not the State Board of Charities has jurisdiction in the matter and whether its assent to the plans would be required before the work could be begun. Dr. J. W. Brannan, President of the Board of Trustees of Bellevue and allied hospitals, maintains that Bellevue is independent of the Board's authority, while the members of the Board take the opposite view. In order to secure a settlement Attorney-

General Meyer has instituted mandamus proceedings against Dr. Brannan which are now pending.

For Our Medical Brethren in California.—The Medical Relief Committee appointed by the New York Academy of Medicine and the Medical Societies of the Counties of New York and Richmond has sent out a second appeal for funds for the relief of physicians in California who have suffered in the recent disaster. It is hoped that those who have not already responded will do so at once by sending their subscriptions to the Treasurer of the Committee, Dr. C. H. Richardson, 336 Lexington Avenue, New York.

"American Practice of Surgery" is the title of a new treatise in eight volumes, announcement of the early publication of which is made by William Wood & Company. The work is edited by Drs. Joseph D. Bryant and Albert H. Buck of this city, and the contributors are all representative surgeons of this country and Canada.

"The Paris Medical Journal."—A new monthly with this title has been started in Paris under the joint editorship of Drs. A. A. Warden and Edmund L. Gros. Its object is to provide English-speaking physicians with a monthly résumé of the work of French physicians and surgeons. The editorial committee includes some of the most prominent medical lights of Paris and the first number of the journal contains much interesting material.

Christian Science in England.—At the coroner's inquest a verdict of manslaughter was rendered in London against a Christian Science healer who was charged with having caused the death of Major John Nicholas Whyte. When the prisoner was searched there were found in his pockets a hypodermic syringe and tablets of morphine and strychnine. When pressed for an explanation of their presence he said he had been using them himself for indigestion.

Council on Medical Education.—The second annual conference of the Council on Medical Education of the American Medical Association was held at the Auditorium Hotel, Chicago, May 12. Dr. Arthur Dean Bevan of Chicago, Chairman of the Council, presided. The Chairman delivered a brief address, after which the Secretary presented a report of the work done in the past year. The subjects of the "Relation of the State Medical Examining Boards to Medical Education," and the "Relation of the State Medical Society to Medical Education," were discussed. Likewise preliminary education for medical students; also, "Shall advanced standing be allowed graduates of colleges of liberal arts?" The subject of what constitutes a proper medical curriculum was also discussed. Representatives from the various States, State medical societies, and delegates were in attendance.

Milk Licenses.—The Appellate Division of the Supreme Court has decided that the Board of Health has the power at any time on sufficient grounds to revoke a permit issued for the sale of milk. The question came up when a certain milk company sued the city to recover $30,000 damages for destroying its business by revoking its licenses. The Board of Health contention was that the company's dairies were found to be in a filthy condition and its milk adulterated and unwholesome. The court unanimously decided that licenses are revokable at the discretion of the Board.

Civil Service Examinations.—Examinations for the medical staff of the Illinois Charitable Eye and Ear Infirmary, Chicago, are to be held the latter part of this month by the Illinois Civil Service Commission. There are now the following vacancies: One assistant ear surgeon, one assistant eye surgeon, one assistant pathologist, three internes. Examinations for attendants in the hospitals for the insane will be held by the Illinois Civil Service Commission the latter part of this month in various parts of the State.

The Chicago Home for Destitute Crippled Children, of which Dr. John Ridlon is surgeon in charge, has outgrown its original quarters and a new building, the cost of which was about $40,000, has been completed. Twenty-five thousand dollars of this amount was donated by Mrs. R. H. McElwee for the erection of the out-patient department, which is to be a memorial to her daughter. At a recent meeting of the Board of Trustees, Dr. F. W. Belknap was appointed consulting pediatrician; Dr. Gilbert Bailey, assistant orthopedic surgeon, and Dr. C. G. Buford, attending surgeon. A resolution was adopted to the effect that ruptured children are to be considered crippled children, and that as soon as proper facilities have been added to the home for handling such cases, those needing operation will be admitted as house patients. An outpatient department for ruptured children was opened May 1 under the direction of Dr. Buford. A dispensary for orthopedic patients is open on Monday, Wednesday and Friday from 1 to 4 P.M., and for hernia cases on Tuesday and Friday from 9 to 10 A.M. The object of the latter department is to supply trusses to destitute ruptured children, and to educate parents in the proper application and maintenance of the trusses. It is estimated that under proper management about 75 per cent. of the patients under four years of age will recover from rupture without operation.

Resignation of Dr. H. P. Bowditch.—Dr. Henry Pickering Bowditch, George Higginson Professor of Physiology in the Harvard Medical School, who has been in the faculty of that institution for thirty-five years, has handed in his resignation, to take effect at the close of the present academic year.

New Tobacco Tax in Germany.—The Reichstag on May 7 adopted a new tax of $200 per metric hundredweight on fine-cut and cigarette tobacco. It also imposed a duty of $1.25 per 1,000 on cigarettes.

Mme. Curie has been appointed to the chair in the University of Paris occupied by her late husband with whom she was associated in the discovery of radium. It is stated that she is the first woman to occupy a position of this sort.

Japan's Halt and Blind.—According to the Nagasaki Press Her Majesty the Empress has presented 984 artificial eyes and 1,797 limbs to soldiers maimed during the recent war.

For a New Rochelle Hospital.—Mr. C. O. Iselin of New Rochelle has promised that city $40,000 for a new hospital, provided that the citizens will raise $60,000 more so that a $100,000 building can be erected. The gift is to be a memorial to the late Adrian Iselin.

The Code of Medical Ethics has been declared by the Medical Society of the State of New York to be merely a suggestive and advisory guide, and it therefore remains, as during the past quarter of a century, of no binding force in this State. This conclusion was reached by the substantial majority of 3,110, there being 3,307 affirmative to 197 negative

votes. Of the 6,352 members of the Society to whom the referendum ballots were sent, more than 2,800 refrained from voting.

American Climatological Association.—At the twenty-third annual meeting of this association, held in Atlantic City, May 12 to 14, the following officers were elected for the ensuing year: *President,* Dr. Thomas Darlington of New York; *Vice-Presidents,* Dr. Frank Fremont Smith of Washington and Dr. C. L. Minor of Asheville; *Secretary and Treasurer,* Dr. Guy Hinsdale of Hot Springs, Va.; *Representatives on the Executive Committee of the VII. Congress of American Physicians and Surgeons,* Dr. F. J. Knight of Boston, and Dr. R. G. Curtin, alternate. Dr. E. L. Trudeau, of Saranac Lake, and Dr. Leonard Weber, of New York, were elected Honorary Members. The next meeting will be held in Washington, D. C., in May, 1907.

Middlesex East District (Mass.) Medical Society.—On May 9 this society elected the following officers at Stoneham: *President,* Dr. Harrison G. Blake of Woburn; *Vice-President,* Dr. C. E. W. Harlow of Melrose; *Secretary,* Dr. H. A. Gale of Winchester; *Treasurer,* Dr. Charles Dutton of Wakefield.

Illinois State Medical Society.—The fifty-sixth annual meeting of this society will be held at Springfield on May 15 to 17. In addition to the scientific program a number of entertainments have been arranged for, including a reception held at the executive mansion by Governor and Mrs. Deneen to which all members of the society and the ladies of their families are invited.

Berkshire District (Mass.) Medical Society.—At the meeting of the society, recently held at Pittsfield, officers were elected as follows: *President,* Dr. Alfreda Withington of Pittsfield; *Vice-President,* Dr. G. L. Rice of North Adams; *Secretary,* Dr. I. S. F. Dodd of Pittsfield; *Treasurer,* Dr. W. L. Paddock of Pittsfield.

Windham County (Conn.) Medical Association.—The 113th annual meeting of this society was held at Putnam on May 3, and the following officers were elected: *President,* Dr. Robert C. White, Willimantic; *Vice-President,* Dr. C. J. LeClair, Danielson; *Secretary and Treasurer,* Dr. James L. Gardner, Central Village.

Franklin District (Mass.) Medical Society.—The following were elected as officers at the meeting of this society held at Greenfield on May 8: *President,* Dr. C. C. Messer of Turners Falls; *Vice-President,* Dr. B. P. Croft of Greenfield; *Secretary and Treasurer,* Dr. C. F. Canedy of Greenfield.

Norfolk District (Mass.) Medical Society.—Officers for the ensuing year were elected as follows at the meeting of this society held on May 7 at Dedham: *President,* Dr. Samuel Crowell of Dorchester; *Vice-President,* Dr. Arthur P. Perry of Jamaica Plains; *Secretary,* Dr. Jas. C. D. Pigeon of Roxbury; *Treasurer,* Dr. Edward G. Morse of Roxbury.

American Proctologic Society.—This society will hold its eighth annual meeting at the Hotel Vendome in Boston, Mass., on June 5 and 6. The program consists of eighteen titles comprising topics of much interest. The secretary is Dr. A. B. Cooke of Nashville, Tenn.

The New Jersey State Homeopathic Medical Society held its annual meeting in the Assembly Chambers at the State Capital, Trenton, N. J., on May 2. The following officers were elected for the ensuing year: *President,* Dr. Edwin De Baun of Passaic; *Vice-Presidents,* Drs. Ella P. Uppam of Asbury Park, and C. F. Adams of Hackensack; *Recording Secretary,* Dr. Carl H. Winch, of Newark; *Corresponding Secretary,* Dr. Alfred Drury of Paterson; *Treasurer,* Dr. R. F. Rabe of Weehawken.

The American Association of Physio-Medical Physicians and Surgeons will hold its annual convention in Chicago, May 22 to 24, at the Sherman House.

American Gastroenterological Association.—The ninth annual meeting of this society will be held in Boston, Mass., on Monday and Tuesday, June 4 and 5. The Monday meeting will take place at Sprague Hall, Boston Medical Library, and the Tuesday meeting at Harvard Medical School.

The Essex South (Mass.) District Medical Society at its meeting in Salem on May 8 elected the following officers for the ensuing year: *President,* Dr. H. W. Mitchell, Hathorne; *Vice-President,* Dr. P. C. Proctor, Gloucester; *Secretary,* Dr. G. K. Blair, Salem; *Treasurer,* Dr. G. Z. Godell, Salem.

Nebraska State Medical Association.—At the annual meeting of this society held in Lincoln on May 3 officers were elected as follows: *President,* Dr. J. L. Greene of Lincoln; *Vice-Presidents,* Dr. C. F. Burchard of Falls City and Dr. F. A. Long of Madison; *Secretary,* Dr. A. D. Wilson of Lincoln; *Treasurer,* Dr. A. S. Van Mansfelde of Ashland.

Obituary Notes.—Dr. Eliza J. P. Fountain of Newbury, N. Y., died on May 11, in this city after an illness of five months. She was sixty-nine years old and was one of the first graduates from the Women's Medical College in this city.

Dr. Philander Collard of Ossining, N. Y., died on May 7, at the age of sixty-one years. He was an ex-president of the Westchester County Medical Society, and a member of the staff of the Ossining Hospital.

Dr. Leroy D. McWayne of Hoosick Falls, N. Y., died on May 10, of heart disease. He began practice in 1879 and of late years had devoted himself to diseases of the throat.

Dr. Lawson A. Long of Holyoke, Mass., died on May 6, at the age of seventy-nine years. He was the son of Dr. Lawson Long, one of the earliest physicians to settle in Holyoke, and had been closely associated with the development of the city. He had practised for some years in Buffalo and New York City, but ten years ago returned to Holyoke. Of late years increasing deafness had forced him to give up active work. It is said that he was instrumental in foiling one of the earlier plots to assassinate President Lincoln.

Dr. James Osterman of Salt Lake City, Utah, died on May 2, at the age of thirty-three years. He was born at Granite, Utah, and was graduated two years ago from the Baltimore Medical College.

Dr. Esther H. Hawks of Lynn, Mass., died on May 6, at the age of seventy-two years. She was born in Hooksett, N. H., and was graduated from the New England Female Medical College. She had practised in connection with her husband, Dr. John N. Hawks, for many years, and she served through the Civil War as a surgeon together with him.

Dr. Louisa F. Parker of South Weymouth, Mass., died on May 9, at the age of ninety-three years. She was one of the first women in New England to study medicine, and was graduated from

the New England Female Medical College in Boston in 1861. She practised in Boston until 1897, when she retired to South Weymouth.

Dr. Edgar L. Draper of Holyoke, Mass., died on May 4, at the age of sixty-four years. He was a graduate of Amherst College in the class of 1864, and received his medical degree from the Harvard Medical School three years later. During the Civil War he was a surgeon in the navy.

Dr. F. E. Garlichs of St. Joseph, Mo., died on May 4, at the age of sixty-one years. After serving through the Civil War he took up the study of medicine and had practised in Buchanan County ever since.

Dr. L. B. Newton of North Bennington, Vt., died on May 2, at the age of sixty-seven years. He was graduated from Castleton Medical College in 1850, and had practised in North Bennington ever since. He had served as secretary of the Bennington County Medical Society almost uninterruptedly since its organization in 1873.

Dr. Onan B. Gross died at Camden, N. J., on May 9. He was graduated from the medical department of the University of Pennsylvania in the class of 1878.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENTARY VACCINATION ACTS — "RAGGING" CASE — ENDEMIC GOITER—INQUESTS—GUY'S HOSPITAL—OBITUARY.

London, April 27, 1906.

The threatened Parliamentary demonstration of the anti-vaccinationists came off on Wednesday, though without any immediate effect, except to illustrate still further the fears of the Government lest it should lose a few votes. It is curious that while boasting of being the strongest government of modern times it should display such hysterical timidity in the face of any faction among its followers. The anti-vacs are not numerous, but are noisy, so the Government tried to conciliate them and put them off with half-promises. The resolution brought forward by Mr. Lipton was that "in the opinion of this House vaccination ought no longer to be obligatory on those who regard it as useless or dangerous."

Mr. Robertson seconded the resolution and indulged in a tirade against magistrates and doctors. A few of the former, he suggested, should be sent to prison for not treating the "conscientious objectors" differently. As to the medical profession, it was always discovering that it was in error. The theory of the Jenner Society was a scientific importune. Hundreds had been killed by vaccination. Coercion was monstrous.

Mr. Pickersgill declared that the usefulness of vaccination had never been shown, and on every principle of criminal jurisprudence the grounds for compulsion had been cut away.

These three speakers are all members of the Labor party, to which the Government has promised so much. Sir William Collins, who professes to be of the party, remarked that as a member of the profession he did not think it necessary and compulsion made it unpopular.

Mr. Burns, as President of the Local Government Board, indicated the intention of the ministry. As "one who had not been vaccinated" he reminded the House that the Act of 1898 was not compulsory. Conscientious objectors were exempt, but lack of uniformity, capriciousness in administration, and sometimes the behavior of magistrates on the bench produced injustice, and it would be the duty of his department to prevent such inequalities. The House Secretary was about to issue a circular. The Local Government Board intended to take the whole question into consideration with a view to a reduction of cost, amendment of procedure for obtaining exemption, postponing vaccination to a later age, and in general inquiring into the working of the Acts. Upon these assurances the motion was withdrawn. Of course, no legislation can take place this session, at the close of which the Acts will expire unless they are included in the usual continuance list. There are those who think that a few more threats from the Labor party will terrify the Government into letting them lapse instead of repealing them by installments.

In the "ragging" case the Army Council has promptly pronounced sentence. The Colonel is put on half pay and the other officers concerned deprived of certain periods of seniority. "An expression of the displeasure" of the council is ordered to be conveyed to the Surgeon-Major. This last decision seems to be approved by the civil profession, many of whom are disposed to regard the reproof as too mild. It is well, however, that the army authorities should indicate thus their support of professional etiquette.

Endemic goiter, as observed in the Chitval and Gilgit valleys by Captain R. McCarrison, I.M.S., was the subject of a paper read for him by the secretary at the last meeting of the Medico-Chirurgical Society. The Chitval villages derived their water supply from the melting of the snows on the surrounding mountains. There were no wells, and, owing to the slope of the ground and the nature of the soil, the water could not stagnate. Its total solids and total hardness seemed to have no influence on the production of goiter. The ingredients differed a good deal in different parts. Goiter was common in children of all ages; even infants at the breast were not exempt. In one instance 18 per cent. of natives from nongoiterous regions developed the disease after residing four months in one of these villages. In another instance two out of ten young men from the plains became goiterous after two and a half months' residence. Symmetrical goiter diminished in size, except in old cases, on leaving the locality where it was acquired, and increased again on returning. In Gilgit and Nagar the geographical, physical and social conditions were the same, and the water came from a single source, flowing in open channels to the villages. At the source the percentage of goiter is 11.8, which increases in the villages along its banks until at the last it is 45.6 per cent. Near its source the water contained a quantity of diatoms, eucyonema and navicula being most common. At the terminus diatoms were fewer, but suspended matter increased. Up to six years ago Nagar had practically no communication with goiterous districts, but five years ago settlers from such brought the disease, which is now spreading. Captain McCarrison, noting the proportionate increase of the goiter in the downward passage of the water, says some poisonous element representing the differences at the several distances must be added; it must be in suspension, and either inorganic or microbial. The latter would explain those cases which cannot be accounted for by the former, and he thinks, though water is the chief vehicle of infection, it may not be the only one.

In discussing the paper Mr. J. Berry said the observations agreed with his own and with those of other investigators as to the main facts, such as the prevalence in limestone districts and the conveyance by water. Lime, magnesium, and iron had all been blamed, but none gave a perfectly satisfactory explanation. He believed the poison was in suspension, not solution, and that explained the increase in spring, when there was more suspended matter in the streams.

Dr. L. E. Stevenson said rain-water never caused goiter and recent cases soon subsided if only rain-water was drunk. Boiling the water prevented the disease, and filtering lessened the liability. There were also facts supporting the microbic origin of some cases. Captain Hugo, I.M.S., had found goiter in Nepaul affected goats, horses, pigs, also the poor people who got their water from the river or shallow wells. But the rich got water stored in tanks at a distance. In one station he found goiter in the rainy season, when the water was turbid, but it disappeared afterwards. In central India he had only met with two cases, and both had come from the hills.

Dr. Claridge said in West Africa the disease was only met with at Mampou, where there was limestone, and about 10 per cent. of the natives were affected. Mampou was on the trade route, but the other localities on that route were not affected—a fact against the microbe theory. He had never seen goiter where only rain-water was drunk.

A coroner's jury has added to a verdict of death from natural causes a rider to the effect that Guy's Hospital was greatly to blame for not having investigated the case more thoroughly and not having more experienced persons to examine such serious cases. It appears that the patient was taken to the hospital by her husband with a statement from the local doctor that she had a large abscess at the back of the right ear. After waiting some time they were told they could not have a bed that night. The husband went again next morning and was told to bring his wife in the evening. He did so, was kept waiting one and three-quarter hours, and then told the case was not urgent enough to have a bed. He then took her to St. Thomas's Hospital, where an operation was considered necessary without delay, but the patient died during its performance. The Guy's house surgeon considered the case one of enlarged glands. At St. Thomas's it was taken for mastoid disease. The coroner, Mr. Troutbeck, said it was very serious for a woman so ill to be brought to the hospital and not admitted, and surprising for a house surgeon to have the decision whether to admit or not. It was curious, too, that he should have

overridden the opinion of the practitioner who sent the case.

Of course, he had his brother-in-law, Dr. Freyberger, as the inevitable expert pathologist to give evidence, though one would have supposed that St. Thomas's could have supplied the necessary information. Dr. Freyberger said the cause of death was heart failure from acute inflammation of the valves while the patient was suffering from meningitis and suppurating middle-ear disease.

One of the oldest members of the profession in this country, John Scott, F.R.C.S., died on Tuesday night, in his ninety-fifth year. He was a well-known consultant in Harley street for many years and had been vice-president of the Pathological and Obstetrical Societies. He was one of the founders of the Women's Hospital, Soho Square, and surgeon to it, as well as to the Governesses' Home and other institutions. He retired in 1888. His first diploma, L.S.A., 1833, seems a remote date. The next year he took his M.R.C.S., and twenty years later became F.R.C.S. He recorded a case of enucleation of a large uterine fibroid in the *Lancet* of 1873, the last, I think, of his contributions to medical literature.

Dr. George Buchanan, Emeritus Professor of Clinical Surgery in the University of Glasgow, Consulting Surgeon to the Western Infirmary, died on the 19th inst., in his eightieth year. He took his M.A., Glasgow, in 1846, M.D., St. Andrews, 1849, and the latter university conferred on him its Honorary LL.D. in 1889. He served as a civil surgeon in the Crimea and wrote an account of "Camp Life" there. He had served as examiner at St. Andrews' and Durham Universities, as well as at the Glasgow Faculty of Physicians and Surgeons, of which he had also been vice-president (1872). He for some time taught Anatomy and edited the tenth edition of Wilson's manual, but his surgical skill and judgment naturally led to his becoming a clinical teacher of surgery. He was for some time on the staff of the *Glasgow Medical Journal,* to which he contributed, amongst other papers, "Cases of Ovariotomy," 1864-1868. He published in 1880 "Radical Cure of Inguinal Hernia in Children," and in the same year "Talipes Varus." The next year he wrote on the "Storage Battery and Electricity in Surgery." He contributed to the *Edinburgh Medical Journal,* in 1897, an essay on "Anesthesia: Jubilee."

OUR BERLIN LETTER.

(From Our Special Correspondent.)

OPENING OF THE KAISERIN FRIEDERICH HAUS—EXPOSITION ON INFANT HYGIENE—ANNIVERSARY OF THE SOCIETY FOR INTERNAL MEDICINE—MEMORIAL TO NITZE.

BERLIN, April 5, 1906.

THE Emperor rarely attends medical ceremonies, but he was present at the inauguration of the Kaiserin Friederich Haus, dedicated to the memory of his mother. This building is intended to furnish a center for postgraduate instruction, and through its architectural beauty and the extremely practical nature of its equipment deserves to be made the subject of a longer description, which I hope to give you in a later letter. Over two hundred military and civil medical functionaries of the highest rank were assembled in the great auditorium when the Emperor and the Empress, Prince Henry, and the court entered. Addresses were delivered by three speakers. Von Bergmann reviewed briefly the history of postgraduate medical work and eulogized the growth of medical science which had largely been fostered by technical methods. For this reason he said there was to be provided in the building a department for the exhibition of new clinical methods and technical apparatus. In closing he paid tribute to the part played by the house of Hohenzollern in the development of medical science. Löbker, the president of the Medical Chamber, dwelt on the difficult social position of the physician. Schjerning, the surgeon-general of the army, pointed out the interest that the royal house had always manifested in medical work. The Emperor then rose without announcement and spoke with evident emotion, saying: "I thank you for this beautiful ceremony and I thank you that we are able to unite to-day in honoring the memory of my mother. All of us, her children, her friends, and the whole of Germany still ask ourselves the question why that wonderful and illustrious woman should have been taken from us at so early an age and by so painful a malady. I feel that her own sufferings inspired her to plan for diminishing the pain of others, and the consequence of this thought was the establishing of this beautiful building. And so the Providence which always determines the results of the physician's efforts regardless of his science is to be directed by the plans of my departed mother, and I hope that her name will be a blessed one for centuries. If that end be attained I shall be grateful to all who have helped to build this house."

The Empress in March opened a small but very instructive exhibition devoted to the subject of infant feeding and hygiene. In the well-arranged catalogue Heubner answers the question, "What is the purpose of the exhibition?" by saying that it is intended for the instruction of mothers and nurses, to show to physicians the value of institutional treatment, and to teach the hygienists and administration officers what still remains to be done. The exhibition was divided into six departments, of which the first was devoted to statistics. Diagrams and charts were displayed showing the mortality of infants, social classes, etc. The second department concerned the etiology of disease, and in the third and fourth sections exhibits relating to infant feeding were on view, including von Behring's investigations and those of the bacteriologist Flügge. Apparatus and appliances from dairies and children's hospitals were used to illustrate the various processes of sterilizing, cooling, and handling the milk, together with the means employed to detect adulteration. The fifth and sixth sections contained exhibits relating to the general hygiene and care of infants.

On February 19, the twenty-fifth anniversary of the Society for Internal Medicine was celebrated. The first paper was read by von Leyden, who gave a review of the history of the association. The principal paper, by A. Fränkel, was devoted to a consideration of the means of dissemination of tuberculosis from the clinical standpoint. He said that tuberculosis entered the body by three channels, through respiration, through the lymph vessels, and through the blood-vessels. Hematogenous infection through the placenta seemed of importance since Schmorl had found evidences of tuberculosis in nine out of twenty placentas from tuberculous women. Von Behring especially advocated the lymphatic mode of infection and believed that the tubercle bacilli go from the site of infection through the lymphatic channels to the bronchial glands. The speaker himself had seen three cases in adults in which the cervical glands were infected before the lungs. He believed that primary bronchial tuberculosis in adults was an inhalation disease. Evidence that tubercle bacilli may easily be aspirated by the lungs was furnished by the occurrence of pneumokoniosis, and the aspiration of bacilli into the bronchi caused most cases of pulmonary tuberculosis. Three forms of acute pulmonary tuberculosis might be distinguished: one form begins with a hemoptysis, another is peribronchial, and a third type, occurring chiefly in diabetes and pregnancy, leads to very rapid destruction of the lung. The third paper was read by Goldscheider and related to the natural treatment of disease. He contended that all the researches of scientific medicine were meant to discover the natural means of combating disease and to lead the body back to health by natural processes.

On April 1 a memorial meeting in honor of Max Nitze, the inventor of the cystoscope, who died suddenly in March, was held in the beautiful auditorium of the Kaiserin Friederich Haus. Four speakers paid tribute to the merits of the great investigator, who died at a comparatively early age. Von Bergmann referred to Nitze's perseverance, which enabled him to surmount successfully obstacles which seemed almost insuperable. His greatest achievement, the cystoscope, was the result of years of effort, and he did not cease trying to improve the instrument until he finally saw the realization of what he had planned for in the beginning. Professor Posner, one of our ablest speakers, in an admirable paper discussed the advantages accruing to medical science through Nitze's invention. He compared the cystoscope with the laryngoscope and the ophthalmoscope, the inventions of Garcia and Helmholtz, but while these latter were only the inventors and had to relinquish to other men the fame of the practical application of their ideas, Nitze himself was able to develop to the full the capacities of his appliances. Professor Kutner, one of Nitze's old pupils, gave an interesting picture of Nitze's labors, and showed that only through his invention had urology been put in a position to become a separate specialty. Finally, Nitze's qualities as a man were eulogized by his friend, Professor Heymann, who said that Nitze was of a very sympathetic disposition and was always ready to help his friends. He was interested in many subjects outside of medicine, especially in sculpture and architecture. A complete series of Nitze's instruments, showing their development from the beginning to the perfected form, was exhibited, as well as a set of the latest models in which his principles were used.

OVARIAN GRAFTING.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your issue of May 5 there appears an article by Dr. R. T. Morris concerning "A Case of Heteroplastic Ovarian Grafting," in which both ovaries of Mrs. W. were totally removed by the angiotribe, and at a subsequent operation two new ovarian grafts, taken from Mrs. P., were successfully implanted within the abdominal cavity of Mrs. W., the latter eventually becoming pregnant and giving birth to a healthy child. Two considerations pertaining to the subject suggested themselves: first, the origin of sexual

cells, and second, who was the mother of the child? According to Ernst Haeckel ("The Evolution of Man," edition of 1905) both the ovaries and testicles are evolved from the sexual plates, or layer of cells situated on the ventral celoma. The celom pouches arise from behind and subdivide into a posterior and an anterior section. The anterior sections on each half of the body form the two gonocels, or ventral celomas, which by union in the median anterior line, and the absorption of the dividing partition finally develop into the peritoneal cavity. A cluster of cells, or cell plates, on the internal layer of the ventral celoma, on each side, develop into the sexual glands. So that in simple language it may be said that the sexual cells of the ovary are but the specialized cells covering the peritoneal coat of the broad ligament. In lower forms of life these "peritoneal" cells, or primitive sex cells, are given off directly from the primitive peritoneum (or wall of the celoma) long before such a complicated thing as an ovary has been evolved, and these "peritoneal" sex cells are discharged through the common ejection opening or cloaca and, if fertilized, proceed to develop just as the highly evolved ovum does. Now it has happened that certain women, whose ovaries have been removed, have subsequently conceived and borne children. The usual explanation is that a thorough and complete excision of the ovaries was not actually made, and that some minute portion of the ovary had been left, possibly on the stump at the seat of ligation. May it not be that sometimes a compensating proliferation of cells of the peritoneal covering of the broad ligament may have supervened, due to operative irritation, so that one of the primitive peritoneal sex cells, capable of fertilization, might have passed into the Fallopian tube and there matured into an ovum? When one makes a study of comparative embryology, and the early evolution of all the bodily organs, this idea of a compensating reversion of sex-cell proliferation does not appear altogether imaginary.

As to the second question, Who is the mother of the child in a case of heteroplastic ovarian grafting? to the writer there seems but one answer. In the case of a fetus we know that it is evolved from the fusion of two cells, a maternal cell (or ovum) and a paternal cell (or ciliated spermatozoon). The heredity of the mother is passed down through the maternal cell, not through the nourishing pabulum. It is the nucleus, or caryoplasm, which has to do with heredity, while the outerplasm or cytoplasm has to do with adaptation and perception. Now in the case of Mrs. W., if this child which she bore subsequently to the implantation in her abdomen of the ovarian graft from Mrs. P. did actually arise from the graft instead of from the peritoneal cell covering of Mrs. W.'s broad ligament, then it was Mrs. P.'s maternal sex cell which developed parasitically in the body of Mrs. W. The child, then, was formed by the fusion of Mrs. P.'s sex cell and Mr. W.'s sex cell in the body of Mrs. W. There is no doubt, perhaps, that the blood and nourishment of Mrs. W.'s organism did modify the ova developed from Mrs. P.'s graft. But the life was in the cell, and when the cell was transplanted it did not forfeit its ancestry, however much it may have adapted itself to its environment in its new hostess. According to the legal aspect of the case, this child, now living, might be considered Mrs. W.'s child, because she gave birth to it; but in this artificial maternity "birth" is far different from "origin." As a matter of fact, the child was adopted in embryo instead of post-delivery. The line of descent, therefore, is through Mrs. P. In connection with this exceptionally interesting subject the pathology of cancer throws some light. The cancer cell is now believed to be the product of the leucocytes. A cancer growth is a morbid and excessive proliferation of cells which under some stimulus have reverted to their presanguinary life. It appears that the blood was evolved from the primitive fluid of the celom cavities, and the leucocytes descended from the cells of the celom walls. Thus is seen how nearly the white blood corpuscles were originally related to the sex cells. If an unduly stimulated leucocyte may revert to its primitive method of excessive proliferation in a foreign soil, thus giving rise to cancerous tissue, it ought not to be beyond the limit of possibility for its near relative, the sex cell of the peritoneal coat of the broad ligament, to develop by a natural evolutionary process into an ovum, under the stimulus following an operative procedure at the site of the ovary. Embryology teaches us that every cell, or sex cell, of the ovary in every fetus came from the lining of the celum wall, what is later the peritoneal coat. How many of the peritoneal cells in the region of ovary, but outside the ovary, may be in fact dormant sex cells we may not know; but that certain of the lining cells of the broad ligament near the implantation of the ovary may be scattered undeveloped sex cells is a possibility. Possibly the rise of dermoid cysts may be accounted for in this way. There may be also some causative factor in this relation between the leucocyte and the sex cell which would explain the sterility following the injection of male blood in a female abdomen.

The Treatment of Ununited Fractures of the Neck of the Femur by Operation, with Report of a Case.—Farrar Cobb's case was that of a boy of 18 years, whose accident occurred nine weeks before operation, and is fully described by the author, who refers in commendatory terms to the work of Nicolaysen in this line of operative procedure. He presents the following conclusions: (1) Fractures entirely intracapsular are very rare. (2) When they do occur and are unimpacted, the obtaining of union by any form of fixation apparatus is exceedingly doubtful. (3) The operation of nailing the fracture with or without open incision is to be adopted whenever possible. (4) In the young and middle-aged, when no contraindications to operation are present, such as obesity, general debility, marked arteriosclerosis or complicating disease, the method with open incision is more accurate and preferable. (5) In persons of advanced age and those with definite contraindications to surgical interference, the direct method without incision, as practised by Nicolaysen, should be used in all cases if seen sufficiently early. (6) In employing the method of Nicolaysen, a general anesthetic should be given.

A Dietetic Study.—From personal observation of his own dietary, A. L. Benedict analyzes the proteid, carbohydrate, and fat amounts in the diet of a man living in good circumstances. He believes that the only method of making trustworthy observations along this line is actually to weigh the food taken. He says, however, that a very important basis for clinical dietetic study is the ability to gauge by the eye the amount ingested. For this purpose, food must be prepared in homogeneous form; *e.g.* meat must be hashed and thoroughly mixed. Many ingredients, however, of ordinary diet occur in the form of units which do not vary much from an average. For instance, ordinary lumps of sugar average 6 gm.; small round "Jersey" crackers, 5 gm.; standard soda crackers, 23 gm.; a fair sized lamb chop weighs 60 gm. gross.; the round muscle, 20 gm., and other available muscle, 10 gm. An ordinary cut of prime rib roast of beef with the bone removed weighs about 25 gm., and two of these are equivalent to an ordinary serving of almost any meat. Much larger portions are served *à la carte* at first-rate restaurants. Shredded wheat biscuit, the ordinary serving of other cereals, an ordinary slice of bread and the half of a hard roll amount to 30 gm. each. When it is necessary to keep close account of the nutrition of a patient, it is well to reserve for him a loaf of bread, a special sugar bowl, a package of cereal, etc., and to obtain the amount used in a certain period by subtraction.

New York Medical Journal, May 5, 1906.

The Use of Rubber Gloves in Medical Wards.—T. W. Clarke discusses this matter under the threefold heading of the protection of the patient from the physician, the protection of the physician from the patient, and the protection of the patient from his fellow. The physician should wear gloves for infusions, venesections, intravenous injections, paracenteses and lumbar punctures. Any procedure which will tend to lessen the danger of infection under these circumstances is certainly worthy of being followed. As to the protection of the physician, the gloves should be worn during vaginal and rectal examinations. Interference with the tactile sense is so slight as to be disregarded. Moreover, the disagreeable clinging odor which at times no amount of washing will remove is entirely obviated. As to the protection of one patient from another, the use of gloves by nurses when handling stools of infectious diseases is most commendable; the same precaution is applicable in case of outbreaks of vulvo-vaginitis in the children's wards of hospitals. Of course, it has never been found that a nurse's hands have been the medium of conveyance of this malady, but it seems unlikely to the author that air contagion is the cause of the spread of the infection. In one institution in which the author has served the use of gloves by the nurses in handling typhoid stools has been made obligatory.

What Medical Subjects Can Be Taught Efficiently in the Literary Schools?—F. S. Lee believes that the medical schools of the present day should not be called on to give instruction in general physics, general chemistry, or general biology. Their proper habitat is the college. The office of the latter is to teach general information, while that of the medical school is to impart exact information, information which is abundant, specific, and always at the immediate service of the individual. Anatomy, physiology, physiological chemistry, pathology, bacteriology, and phar-

macology should be considered for purposes of medical instruction as applied sciences. Anatomy cannot be taught in the college as it is taught in the (medical) school. Physiology can be so taught and ought to be, but it should always be taught with its direct bearing on the practice of medicine strongly in view. The same general conditions apply to physiological chemistry. With pathology, bacteriology, and pharmacology, the case appears too obvious to require consideration. The elements of bacteriology can be taught in the college, but nothing more. There is no sense in attempting to have the two classes of institutions complete in any of these directions, but the author does not believe that except in occasional specific instances and for unusually cogent reasons, the schools should allow credit for strictly medical work done in the colleges.

The Causes of Injuries Among the Insane.—J. T. W. Rowe makes a plea for the attendants in insane asylums who are periodically attacked by the yellow journals and accused of every sort of brutality. Such abuse he considers as wholly unmerited. The most frequent instances in which these attacks arise are in cases of brain softening. Fractures and injuries occur among such patients despite every precaution. The reasons are that in cases of dementia paralytica the bones undergo rapid decomposition, the inorganic constituents are reduced, and the organic increased; the ribs, especially, become very brittle, due to great deficiency of osseous tissue; in the bony structure the Haversian canals may be almost obliterated by an oily deposit; in addition to the sudden reckless violence of this class, there is a diminished reflex activity and diminished sensibility in the limbs, with a contributory factor of the inattention of the patient; he makes a false step or lunges abruptly against another patient, due to his ataxia, the nervous current is dull and sluggish; excitomotor acts are tardy, therefore the muscular contractions are too late to guard against the injurious falls and blows. Under these conditions the dullness of common sensation lessens the pain of fractures and masks their presence.

Journal of the American Medical Association, May 12, 1906.

Fluid Extract of Squill.—E. M. Houghton concludes, from a number of experimental tests here detailed, that the acetic acid menstruum adopted in the 1900 edition of the Pharmacopeia, is not so satisfactory as alcohol in making the fluid extract of squill. The therapeutic results, he thinks, will be less marked and more variable than with the alcoholic preparation of the 1890 Pharmacopeia, and there will be not only a difference of degree of effectiveness, but also a different kind of action, as is shown by the comparison of the effects of the two preparations injected into the circulation. He suggests that it would be advisable for physicians to specify the 1890 preparation in their prescriptions when they desire to obtain the usual therapeutic action of squill.

Gastric Hemorrhage from Hepatic Cirrhosis.—W. J. Taylor gives the detailed history of a case of gastric hemorrhage due to atrophic cirrhosis of the liver, in which gastroenterostomy was performed on the diagnosis of gastric or duodenal ulcer. The operation was followed by great relief of the symptoms and apparent recovery, but the hemorrhage recurred ten weeks after the operation and the patient succumbed. The cause of the condition is not clear. The man was 40 years of age, of exemplary habits, never used alcohol, and with no syphilis or acquired or hereditary tendency to tuberculosis or other constitutional disease. Two cases similar in this respect and in their diagnosis are mentioned by Dr. R. B. Preble in his review of the literature (*American Journal of the Medical Sciences,* March, 1900), in which the autopsy showed no ulceration of the stomach or intestine. In this case, however, there was a probable incipient ulcer of the duodenum about an inch and a half from the pylorus, the probable site of the hemorrhage.

Kidney Fixation.—J. H. Carstens concludes that movable kidneys can be permanently fixed by proper technic. Many disturbances of digestion are due to this cause, probably by the effect on the sympathetic system and, possibly, on the solar plexus, and some of these may be relieved by fixation. Many of the nervous symptoms also can be relieved. A correct diagnosis must be made prior to operation, and any reasonable doubt as to the kidney being the cause of the trouble must be removed. Of course operation cannot relieve such organic conditions as gastric cancer, bowel obstructions, etc. He gives a condensed report of twenty-five cases occurring in his practice which he thinks ought to give a fair average of general results. In all cases the kidney remained in place. He has also found that fixing a loose kidney and decapsulating it pretty thoroughly, relieves, even cures, the early stages of Bright's disease. He has never lost a case, and thinks the mortality should be absolutely *nil*. He keeps the patients in bed fifteen or sixteen days and allows them to leave the hospital in three weeks.

Clean Milk.—J. Roby demonstrates from the experience of the Rochester health authorities that a remarkably clean milk can be secured without an expensive plant, and points out the way. The essentials are: First, the protection of the milk from any possible infection by disease, such as scarlet fever, diphtheria or typhoid. Second, cooling the milk and keeping it cold, or at least below 50 degrees. Third, keeping the utensils clean, or, better, sterile. Fourth, milking directly through sterile cheesecloth into a pail with a small (five-inch) opening. Fifth, keeping the milk tightly covered. These five points are absolutely necessary. Unless they are followed, milk with a low bacterial content cannot be produced. With the following also carried out the proportion can be still further reduced so that in well-equipped and managed dairies it can be kept at 1,000 or below: Sixth, discarding the first-draws from every teat. Seventh, keeping the cow absolutely clean. Eighth, keeping the milker's hands and clothes clean. Ninth, keeping the ceiling clean and free from dust; preferably it should be lathed and plastered. Tenth, keeping the barn clean and using shavings instead of straw for bedding. Eleventh, being careful not to stir up the dust before milking. He suggests that cities have a municipal sterilizing plant where the cans and cloth strainers can be sterilized and thence, with everything in place ready for milking directly into the can, be sent out to the farms. After they are filled, all the farmer would have to do would be to seal the can after removing the strainer, put it into an icewater trough, and then send the whole outfit back to the city, where the milk can be bottled or delivered directly. This plan was tested, and bacteriologic examination showed a milk with less than 500 bacteria.

Treatment of Bites of Copperhead Snakes.—C. W. B. Crum has had an average of two cases of bites by copperheads to treat every year for a number of years, and finds the following method to give incomparably better results than any other he has tried: He first freezes the area around the bite with ethyl chloride spray, then incises through the wound, usually making two parallel incisions an inch long through the two fang wounds. He then soaks the parts for a few minutes with a strong permanganate solution and applies dressings wet with this solution. The edge of this dressing is raised up every hour or half-hour and fresh solution applied. The trifling incisions usually heal in a day; an incision in an area poisoned by snake bite will heal with extraordinary rapidity, even if no effort is made at asepsis. He is inclined to attribute some virtue to the ethyl chloride beyond the anesthesia it causes. The extension of the poison seems to be very quickly checked by this treatment. If the patient is seen within an hour after the bite he is usually all right in two or three hours except for a trifling swelling. Internally, he gives a few doses of strychnine, sometimes also, in deference to popular prejudice, alcohol and ammonia. According to his observation, the bite of small snakes is likely to be more dangerous than that of larger ones. Three cases are reported illustrating as many different types of poisoning by copperhead bites.

The Lancet, April 28, 1906.

Obstruction of the Submaxillary Duct.—Three cases are reported by O. Eichholz. In the first instance the obstruction came on suddenly and the mass was expressed, it being of a putty-like odor and offensive. In the second case a salivary calculus had formed around a hair which had penetrated the orifice of Wharton's duct and passed along it for about half an inch. The symptoms of obstruction here also came on suddenly. In the third instance the only symptom was swelling, with some tenderness of the gland. The skin over the latter was painted with glycerine-belladonna and a fomentation applied; and the symptoms quickly abated. No plug or calculus appeared in this case. It is possible that the obstruction may have been spontaneously extended. The blockage may have been the result of inflammation.

Volvulus of the Cecum Treated by Reduction and Appendicostomy.—The patient of C. B. Mannsell was a woman of 77 years, always subject to obstinate constipation. She was seized with violent pain about the navel, and the abdomen speedily became hard and swollen. She was removed to hospital, and, as enemata failed to relieve her, it was decided to operate. At no time had there been any vomiting. When the abdomen was opened a tensely distended cecum and ascending colon were seen filling the lower abdomen and pelvis. These were deflated and withdrawn, when it was found that the cecum and portion of the ascending colon had made a complete turn from below upwards and from right to left. The lower portion of the ileum, having been carried in front of the colon, was tightly wound around the neck of the strangulated large intestine. The twist having been reduced, it was found that the cecum and colon had a well-formed mesentery, thus rendering volvulus a possible and likely accident.

Having closed the incision which had been made for deflation, the operator determined to fix and to drain the cecum by performing the operation of appendicostomy. In this instance he had to ligate and to divide a portion of the mesoappendix, but took care to leave sufficient blood-supply to the portion near the cecum. A stab wound was made at the outer border of the rectus and the appendix was drawn through and fixed by two sutures, its distal end was amputated, and its lumen was dilated with sinus forceps. A gum elastic catheter was then passed through it into the cecum and fixed in position by an encircling ligature. The after-history of the case was uneventful except for some slight suppuration which occurred in the abdominal wound about eight days after operation, evidently due to infection of the incision when the intestine had been opened for deflation.

Acute Meningococcal Septicemia.—F. W. Andrews reports the case of a man of 53 years without exposure so far as was known to any similar case. He was in a moribund condition when first seen by the author, with a profuse hemorrhagic purpura covering the entire body. He died in about twenty-four hours from the onset of his initial symptoms without any definite meningeal symptoms. The condition was evidently one of profound septic poisoning, though its nature could not be made out. About half an hour before death a syringeful of blood was withdrawn from the basilic vein and submitted to the usual examination methods. A large coccus was found, which was identified as that of Weichselbaum. The autopsy revealed no meningeal inflammation, though all the other organs showed evidences of a profound sepsis with hemorrhagic tendencies.

Recent Advances in Surgery of the Blood-Vessels.—The paper of D'Arcy Power opens with a review of the work of Crile of Cleveland on the subjects of surgical shock and collapse. It is familiar to American readers and need not be reproduced here. Power then discusses in turn the ligature of arteries in their continuity, the treatment of aneurysms by other methods than ligature, including the diagnosis by the *x*-ray, injection of gelatin, introduction of foreign bodies into the sac, acupuncture and wiring, electrolysis, and the Moore-Corradi method, which is a combination of wiring and electrolysis. All these questions are considered in the light of results actually obtained by different surgeons. Surgery of the venous system, the author thinks, is still in a very unsatisfactory state.

British Medical Journal, April 28, 1906.

Pneumococcic Arthritis.—G. D. Trevor-Roper reports the following case: A woman, about three months pregnant, was at a working party when she suddenly noticed that her neighbor was blessed with two thumbs on one hand. This, she declared, was a deformity which she had never ever heard of before, and it made a great impression on her. Her child, born six months later, had a very perfect supernumerary thumb on the right hand.

Pneumococcic Arthritis.—G. D. Trevor-Roper reports the case of a woman of 47 years with acute lobar pneumonia with crisis on the seventh day. On the next day there was some pain in the left hip and down the thigh. The same evening there was severe pain in the left shoulder and wrist, and she was quite unable to move the arm; temperature 100°. Next day the right shoulder, elbow, and wrist were painful and swollen; temperature 101.6°. Afterwards the left knee and ankle became affected and extremely painful, but no distinct evidence of fluid could be made out. The temperature, which never rose above 102°, fell to normal on the eighth day after the joint symptoms first appeared, the swelling and pain rapidly subsiding, and the case going on to complete recovery.

The Incubation Period of Malta Fever.—From observations of a case occurring in a British sailor, E. H. Ross is convinced that the period may vary from two to nineteen days. When the disease is naturally contracted the period is from eight to eleven days. In the case above referred to, the mode of inoculation was probably a mosquito bite.

Pleuritic Effusion Treated with Adrenalin by the Preliminary Intraserous Injection Method.—W. Ewart and F. Murray report one case. A boy of ten years was admitted to hospital with a pleuritic effusion of five days' duration. Paracentesis was performed by siphonage, and then air was allowed to enter by thoracic suction. The secondary effusions which ensued were treated by preliminary intraserous injections with a view to eventual paracentesis, but this was not required, as the fluid was completely absorbed. The injection consisted of ten minims of a solution of 1-1000 adrenalin. This was repeated four times in all, at intervals of from two to three days. Eventual recovery ensued. Care was taken to inject into the pleural cavity and not into the lung. After the second injection the accumulation of fluid seemed to diminish and its reabsorption proceeded rapidly. There is no positive proof, however, that these injections had any share in promoting the absorption. The authors are inclined, however, to attach importance to the procedure and think that in the more favorable cases of absorption somewhat larger injections might do away altogether with the necessity of paracentesis.

Bradycardia with Arrhythmia and Epileptiform Seizures.—J. M. Fainy's patient was a woman of 42 years whose pulse beat was only 22 per minute. There was no cyanosis, dyspnea, or hurried respiration. The heart was slightly enlarged and the *x*-ray showed that it lay in a very horizontal position. The auricles could be seen beating between the ventricular pulsations and seemed slightly larger than normal. Two auricular beats could be counted between the beats of the ventricles. The patient was subject also to seizures of an epileptoid nature, during which the face became flushed and her hands shook. The iodide and bromide of potassium were given with a view of lessening these seizures, but they seemed to aggravate the bradycardia and were soon discontinued. Finally the seizures became more prolonged and ended in sudden death. The question arises, says the author, were the earlier fits examples of epilepsia mitior (*petit mal*) occurring in a woman, in whom were present cardiac infrequency and cardiac arrhythmia, simply as a coincidence? or were the cardiac affection and the fits in direct relation to one another as cause and effect, and, if so, did the fits cause the cardiac phenomena, or vice versa? The author is inclined to think that the cardiac arrhythmia was the cause of the seizures, the cerebral anemia from the prolonged cessation periods of cumulation producing the syncopal and convulsive attacks.

Berliner klinische Wochenschrift, April 23, 1906.

The Value of Unstained Blood Preparations for the Practitioner.—Krönig is of the opinion that for the purposes of the practitioner it is preferable to make use of unstained blood preparations for diagnostic purposes. He believes that with a little practice it is possible to distinguish the diagnostic features with perfect satisfaction, while the saving in time and trouble is very great. He believes that many practitioners are deterred from making blood examinations by the complicated technique necessary, and that by examining unstained preparations directly they would be encouraged to study blood conditions more carefully. In courses of instruction he advises drilling the students first in the appearance of the stained smear, and of then demonstrating the blood of similar conditions in the fresh state and from the same patient if possible.

A Case of Cardiac Neurosis and Arteriosclerosis Following Trauma.—Goldscheider reports the case of a man of 26 years who had never been ill and was very slightly alcoholic. There was no history of venereal infection. In 1904 a brick fell on his head and he was unconscious for a time. He was kept under observation in the hospital for some time and was then dismissed, although headache, tremor, and general weakness persisted. About a year later he was seen again and was found to exhibit marked cardiac hypertrophy, rapid heart action, and pronounced thickening of the superficial vessels. The author considers that in this case a condition of arteriosclerosis, cardiac hypertrophy, and arrhythmia and increased pulse rate was the result of the original trauma, probably through the setting up of a vasomotor neurosis and general nervous and psychical irritability which reacted on the circulatory system.

Münchener medizinische Wochenschrift, April 24, 1906.

The Graphic Depiction of the Percussion Sound.—May and Lindenmann, in the course of investigations on the physics of the tympanitic and nontympanitic percussion sounds, have developed a method for securing graphic representations of the phenomena. The principle involved consists in recording on a photographic film fixed on a revolving drum the oscillations of a beam of light reflected from the surface of a delicate membrane which is set in motion by the vibrations produced by the sound to be studied. The membrane found most suitable for this purpose was a soap film. The authors present specimens of the photographic records obtained of normal pulmonary resonance and of abdominal tympanitic resonance, and state that they hope by these means to obtain a better insight into the nature of the sounds produced in this way.

Punctate Red Cells.—Meyer and Speroni, in discussing the nature of the erythrocytes which exhibit the minute basophilic granulations that are ordinarily spoken of as granular degeneration, take sides with those authors who consider that cells of this sort represent a regenerative and not a degenerative process. One of the arguments that has been used by the opponents of this view is that in cer-

tain conditions, notably lead poisoning, punctate cells appear in great numbers, while nucleated red cells are almost or quite entirely absent. The authors believe that such a conclusion is the result of inadequate observation, for if the blood in such a case be examined every day at certain periods nucleated red cells will always be discovered. Evidence in favor of the view that the granulations are regenerative in character, that is, due to the disintegration of the nucleus of normoblasts, is furnished by the observation of the authors that when warm-blooded animals having nucleated red cells, such as fowls, are subjected to poisons like lead which give rise to granular degeneration in the blood of animals whose erythrocytes are normally nonucleated, no basophilic dots appear in their blood cells. On subjecting the blood of fowls to the action of .5 per cent. salt solution in the incubator, at the end of twenty-two to twenty-four hours very marked evidences of karyorhexis are produced resembling the fragmentation of the nucleus seen in connection with basophilic granulation in the blood of anemia and leukemia, but nothing resembling granular degeneration is observed when human corpuscles are caused to degenerate in the same way.

The First Heart Sound.—Geigel says that there are two diastolic heart sounds formed respectively at the aortic and pulmonary valves and two systolic ventricular sounds. In addition there is always to be heard somewhere about the heart a systolic vascular sound which follows the first sound by a very minute interval. Over the aortic area there is usually to be heard the first heart sound together with the following aortic sound, which in some instances may be a short aortic murmur. There is always in the normal heart a point somewhere to be found at which the first sound may be heard split into its two components. The author considers it very unlikely that the first sound at the apex should be divided in any way other than this, as for example, through lack of synchrony in the action of the right and left sides of the heart. In the case of the divided second sound the conditions are very different, however.

Deutsche medizinische Wochenschrift, April 26, 1906.

Therapeutic Pneumothorax.—Brauer recounts at considerable length his observations on a case of pulmonary tuberculosis in which artificial pneumothorax was induced and the pleural cavity was inflated with nitrogen. The patient was a girl of 18 years having a very extensive lesion with cavity formation involving the entire left lung. Four injections of nitrogen were made at intervals of several weeks, the effect being each time very marked in causing reduction of temperature. No undesirable symptoms attended the collapse of the lung, and the author considers the effect on the temperature more pronounced than that to be secured by any other means. The technique of carrying out the procedure is described very fully. The first injection is the most difficult one. The skin is incised under local anesthesia and the intercostal muscle is divided by blunt dissection until the costal pleura is reached. This is then perforated with a blunt trocar and cannula, through which the nitrogen is allowed to flow in as the lung collapses. Considerable judgment is necessary in selecting the site for the puncture in order to avoid striking adhesions. The effect of the pulmonary collapse is to effect condensation of the lung tissue so that it no longer consists of numerous tense cavities, filled with infectious material and favoring progression of the process, but is squeezed out like a sponge, the softened areas being evacuated. The rest secured and the effect on the blood and lymphatic circulation also contribute to the favorable result.

The Gastric Juice in Chlorosis.—Arneth presents a table showing the results obtained in the examination of the blood and gastric juice in twenty-three cases of chlorosis treated in von Leube's clinic at Würtzburg. From these figures he shows why it is that such discordant conclusions have been published in regard to the behavior of the gastric secretion in this disease. The results of the analysis of the test meal appear to vary considerably in different stages of the malady, so that according to the period of treatment at which Arneth's cases were examined very different conclusions regarding the proportionate distribution of cases with very high, moderately high, or approximately normal values for the total acidity might be drawn. Arneth himself is of the opinion that in the milder and moderately severe cases of pure chlorosis there is usually a condition of hyperacidity, but that in general the acid values are in the neighborhood of the normal limit. The presence of marked hyperacidity is the rule for cases of great severity, but subacid values never occur. The treatment employed in these cases did not differ in any essential feature from that usually resorted to. The iron given was administered in the form of a pill composed of 7.5 grams of reduced iron made into 90 pills with equal parts of glycerine and gelatin. One or two of these pills are given three times a day, after meals.

The Action of Iodine on the Arterionecrosis Produced by Adrenalin.—Koranyi describes experiments made on twenty three rabbits, in the course of which twelve of the number were given subcutaneous injections of adrenalin and the remaining eleven received adrenalin and also an iodine preparation. The animals were kept under similar conditions, and one of each group was killed at definite intervals. The result showed well-marked arterial degeneration with plaque formation in the animals that had been treated with adrenalin alone, while those that had received iodine in addition presented normal aortas in almost every instance. It therefore appears that the arterial changes produced by adrenalin may be avoided by the simultaneous injection of iodine.

French and Italian Journals.

Mixed Tumors of the Breast.—P. Lecène concludes that there exist in the mammary glands, as in the peribuccal salivary glands, tumors characterized histologically by a special structure. Tissues are found here which do not form a part of the normal structure of the adult mammary gland. They may be osteo-, chondro-, or myxo-, sarcomata, pure or associated with epithelial formations (adenoma, or more rarely atypical epithelioma); they may be sarcomata, containing cystic cavities lined with stratified pavement epithelium with the structure of epidermis. These tumors may be called mixed tumors, according to Wilms, that is to say teratoid tumors developed from intraglandular embryonic inclusions (ectodermic or mesenchymatous débris according to the case). Again, very rare are those tumors which resemble clinically the common encapsulated tumors of the breast (adenofibroma, cystic adenosarcoma). In evolution, physical signs, and prognostic significance, the resemblance is striking. Careful histological examination of the tumor is necessary in all cases to make the diagnosis.—*Révue de Chirurgie,* March 10, 1906.

A Case of Subacute Meningitis of Saturnine Origin Ending in Recovery.—Oettinger and Malloizel report this case. The patient, a man thirty-four years old, a plumber, had been exposed to lead intoxication. Rather quickly there developed cerebral manifestations with mental depression and confusion, cephalalgia, vomiting, constipation, and slowing of the pulse. These symptoms were like those accompanying a lesion of the cerebrospinal meninges. Emaciation, anemia, and functional insufficiency of the liver made the patient very cachectic. Gradually these phenomena became less severe and finally almost completely disappeared. Such occurrences are not very rare in lead poisoning. The symptomatology in this case was clearly meningitic.—*La Tribune Medicale,* March 10, 1906.

Alimentary Levulosuria in Infectious Diseases.—S. Rebaudi tells us that the reaction showing levulosuria is the most delicate and exquisite that we know for demonstrating even slight functional disturbances of the hepatic cells. In febrile and afebrile infectious diseases there is always a functional alteration of the hepatic cells more or less severe according to the intensity and duration of the disease or the special conditions of the soil on which the germs grow. These functional alterations of the liver cells as soon as the infectious process is past gradually disappear, according as the gravity and duration of the infective process and the special conditions of the individual have diminished the vitality, or according to the condition in which the liver was when attacked by the infection. Bacteriological infections may bring out latent liver disesases.—*Clinica Medica Italiana,* November, 1905.

Influence of Hereditary Syphilis on the Heart.—De Chiara insists on the importance of the infective factor as a cause of the maladies of the heart in congenital cases. Such factors are rheumatism and hereditary syphilis. He describes a family in which one child showed the typical symptoms of mitral stenosis. The father was affected with syphilis, and there were luetic manifestations in all the members of the family. In the child described there had never been any other sort of infection up to the time when she was examined, which was at the age of twelve years. One year after the heart symptoms were recognized the child had chorea, and a year later she died suddenly. The author believes the heart lesion to have been the result of hereditary syphilis, since it appeared before the chorea. He advocated mercurial treatment of the pregnant mother throughout pregnancy in cases in which the father is syphilitic as a prophylactic measure to be used for the benefit of the child.—*Rivista di Clinica Pediatrica,* January, 1906.

Book Reviews.

The Medical Diseases of Egypt. By F. M. Sandwith, M.D., F.R.C.P., Part I. London: Henry Kimpton, 1905.

The writer, who has practised his profession in Egypt for a period of more than twenty-one years, has undertaken to present an account of the peculiarities of the diseases found in this country, without claiming for his work, however, the character of a treatise. The history and geographical distribution of each disease are fully considered, but the discussion is not limited to the so-called tropical diseases only, the infections, the exanthemata, the continued fevers, plague, ankylostomiasis, etc., being also taken up. The book is intended by the author for three classes of readers: the Egyptian student of medicine, the newly-settled foreign doctor who is suddenly charged with the responsibilities of many things unknown, and the physicians of other countries who may be interested in these types of illness. As the work is essentially an amplification of lectures to students, the colloquial style has been retained in many places, and the only fault to be found with the book is a consequent lack of system. Otherwise it constitutes very interesting reading and will undoubtedly prove of value to those for whom it is intended. Another favorable departure in book making may also be here recorded—the paper is of a very light weight, and this contributes to the easy handling of the volume—a great desideratum and worthy of imitation.

Nasal Sinus Surgery with Operations on the Nose and Throat. By Beaman Douglass, M.D., Professor of Diseases of the Nose and Throat in the New York Post-Graduate Medical School and Hospital; illustrated with sixty-seven full-page half-tone and colored plates, including nearly one hundred figures. Philadelphia: The F. A. Davis Company, 1906.

The relatively prominent part sinus disease has come to play in modern rhinology is evidenced by the title of this book. Formerly the various works issued on this subject devoted most of their space to general nose and throat operations, while their statements of sinus disease were compressed into one short chapter. The present volume opens with a general anatomical review of the nose; then follow chapters on respectively the frontal, ethmoidal, maxillary, and sphenoidal sinuses, deflections of the nasal septum, operations for nasal deformities and paraffin injections, external operations for the relief of deformities, turbinectomy, tonsils, adenoids and uvula, exostoses and synechiæ, laryngotomy and tracheotomy. The anatomical relations suggested by these headings are exhaustively discussed and modern methods of surgical relief explained in detail. Concerning the now popular operation of submucous resection for deflected nasal septum, we note the author's statement that the objections to it are the length of time required to accomplish it and the fact that perforations often result from sloughing or from instrumentation. While an occasional sacrifice of clearness of expression is noted, the general appearance of the work is most commendable, and it is one that can be cordially recommended to students and practitioners.

Die Krankheiten des Beckenbindegewebes. Unter Mitwirkung von J. A. Amann, München, O. Busse, Posen, und Ph. Jung, Greifswald. Herausgegeben von A. Martin, Greifswald. Berlin: S. Karger, 1906.

The present constitutes the third and concluding volume of Martin's elaborate and extensive work on the diseases of the female adnexa, the first installment of which appeared over ten years ago. The first portion of the book deals with the anatomy and physiology, the second with the pathology of the pelvic cellular tissue. The various chapters contain, in addition to the regular material, numerous references to the personal researches of the associated authors, many of which are of great interest and value. Thus mention may be made of the injection experiments of Jung in which he showed that the subserous parauterine, vesical, and rectal spaces are not always separated by connective tissue septa, but very often communicate with each other. Considerable importance also attaches to the statement of Busse, p. 168 *et seq.*, that pelvic peritonitis may be produced by lesions in organs higher up, such as the stomach and gall-bladder, which find their way downward without noticeably involving the intervening segments of peritoneum. Neoplasms of this region are fully considered in the concluding chapter, which has been written by Amann. Many excellent illustrations are presented. There is no book in the English language which can be compared with the present volume in scope.

The Strange Story of the Quillmores. By A. L. Chatterton. New York: Stitt Publishing Company, 1905.

This is a well-written story of a mysterious happening in an Indiana town. The story need not be recounted here, for it can be learned in the reading; but the manner of its telling is good; it is not "literature," but it is entertaining and presents an entertaining picture of life in a dull town—life more interesting in the telling than in the living. Some of the characters are well drawn, especially that of Uncle I', short for Irenæus, who followed the callings of keeper of the country store, undertaker, and postmaster, and that of Doc. Gus, the kindly country doctor, trained to self-sacrifice in the pursuit of his humanitarian calling and hard-headed withal, though deceived in common with his fellow-townsmen by appearances and led to do injustice in thought, if not in deed, to the two persons about whom the tale hinges. Another finely depicted character is that of the priest, who was in the secret, but prevented by the rule of his church from violating the confidences of the confessional. The book will not be one of the "best sellers," but it is as good as some that are, and its reading will fill a leisure evening pleasantly.

The Food Factor in Disease, Being an Investigation into the Humoral Causation, Meaning, Mechanism, and Rational Treatment, Preventive and Curative, of the Paroxysmal Neuroses (Migraine, Asthma, Angina Pectoris, Epilepsy, etc.), Bilious Attacks, Gout, Catarrhal and Other Affections, High Blood-Pressure, Circulatory, Renal, and Other Degenerations. By Francis Hare, M.D., late Consulting Physician to the Brisbane General Hospital; Visiting Physician to the Diamantina Hospital for Chronic Diseases, Brisbane; Inspector-General of Hospitals for Queensland. London, New York, and Bombay: Longmans, Green & Company, 1905.

The argument of this interesting treatise is that many of the ills of mankind, those especially which are mentioned in the subtitle of the book, are dependent upon an accumulation of carbonaceous materials in the blood and tissues of the body—a condition termed by the author "hyperpyremia." The writer's views are already familiar to readers of the Medical Record, wherein he has presented them in several well-reasoned articles, but in the present work he has expounded them at length, starting with an exposition of the theory and then making particular application of it to its causation of the various affections mentioned. To those who have followed Haig in his denunciation of the proteid elements of food, and have been half-persuaded that health is to be preserved or restored only by abstinence from these elements, the doctrine of Hare that carbon rather than nitrogen is the poison, comes as a shock and an upsetting of dietetic faith. Both cannot be right, else we must starve to death. Which is right, if either, must be left to the future to determine. The arguments of both are seemingly sound and well-nigh convincing, but perhaps neither is wholly right or wholly wrong. We suspect the evil lies in the consumption of too much food of both kinds, nitrogenous and carbonaceous. Man is rightly omnivorous, but he is wrongly multivorous; it is not so much from what he eats, but from how much he eats, that his ills arise. Dr. Hare's book is of great size, comprising two thick octavo volumes, and the reading of it grows rather tiresome after one has gone through a few hundred pages and finds the same ideas repeated over and over again in practically the same words. His theory is, as we have already said, that the obnoxious elements of the food are the carbonaceous—the starches, sugars, and fats—and that little or no harm can come from the consumption of proteid—the nitrogenous element. The arguments put forth in support of these statements are strong, and the reasoning is cogent; but "the proof of the pudding is in the eating," and a few practical demonstrations are worth a cloud of theories and unproved assertions. Most practitioners will admit, we believe, that a conscientious trial of the no-meat, no-fish, no-tea regimen has not always been followed by the brilliant results that are claimed for it by Haig and his followers. Neither is an exclusive or nearly exclusive nitrogenous diet regarded by the majority of medical men as either safe or curative. Hare regards gout, epilepsy, hemorrhages, pyrexia, and many other disturbances of the economy as efforts on the part of nature to effect a purification of the blood surcharged with carbonaceous material, hence these are salutary in their intent; but, like many of nature's efforts, they constitute a rather clumsy means of bringing about the healing process, and the remedy may in the end prove to be worse than the disease. Hence the task of the therapeutist is to restrict the carbonaceous intake or to prevent both the "carbonization" of the blood, or "hyperpyremia," and the attempts of nature to relieve it. Among the existing causes of these "decarbonizing" attacks are many factors, prominent among which is eyestrain, and the author quotes with approval several of the statements of Gould regarding the evil results of uncorrected astigmatism. We wish Dr. Hare had condensed his work into smaller compass, for he would thus have had many more readers and could have preached to a wider circle. As it is, numbers will doubtless be turned away from a careful study of his theory by the apparent formidableness of the task.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, held March 26, 1906.

Dr. Floyd M. Crandall in the Chair.

A Case of Rhinoscleroma.—Dr. William S. Gottheil presented this case. He said that when Hebra, in 1870, described a case of rhinoscleroma, he regarded the lesion, from its hardness and insensitiveness, as a chancre; but its persistency and unchangeableness, the non-appearance of other symptoms of syphilis, and the total inefficacy of antiluetic treatment soon made him change his opinion. A little later Kaposi made a histological study of a case, and concluded that the tumor was sarcomatous. Mikulicz, in 1876, discovered the peculiar cells that bear his name. It was Frisch, however, in 1882, who described the rhinoscleroma bacillus, an organism hardly distinguishable from the ordinary pneumococcus, which was generally recognized as the cause of the disease. The malady was quite rare; Wolkowitsch, in 1889, could find only 86 cases, 52 of which occurred in Western Russia and Eastern Austria. Since the immigration from Southeastern Europe had set in an occasional case was seen here. The lesion was a chronic tumor of the connective tissue type caused by the growth of the specific bacteria in the tissues. In the first cases observed the nose was especially affected; hence the name. With the development of rhinolaryngology in the 80's cases in which the palate, pharynx, and larynx were chiefly or even exclusively affected were recorded; and it was the opinion of some observers that the affection usually began in these structures, rather than in the nose itself. Scleroma had, therefore, been proposed as a more fitting designation; but the old name was still generally employed.

The patient, Mrs. R. H., aged 29, Russian, was sent to him by Dr. J. Frankel, of this city, July 17, 1905. The tumor had been growing for four years; it appeared first in the nares, and later spread into the mouth. Increase in size had been steady, though slow, ever since; besides the deformity, the condition of her throat interfered seriously with deglutition, and the complete stenosis of the nasal passages caused great discomfort. Her general health was good; she had several living children, and was then nursing a three-months infant. There were two large tumor masses occupying the external and lower borders of the nares, the columella, and the palate bone, causing marked projection of the upper lip and great dislocation upward of the entire nose. The tumor mass was hard and wooden, absolutely insensitive, and slightly reddened and marked with dilated vessels on its surface. Inspection of the mouth showed that the entire hard palate was infiltrated and thickened; the uvula was gone, and the soft palate shriveled up into a cartilaginous mass. The fauces were deformed with cicatricial bands, and both they and the posterior pharynx were ulcerated in places. The nares were completely occluded throughout their entire length on both sides, posterior rhinoscopy showing only the tumor masses projecting into the pharyngeal cavity. The larynx was free. She had had a good deal of treatment of various kinds, including arsenic, antiluetic medication, and parenchymatous injections of unknown nature. Her main difficulty being the nasal stenosis, he succeeded finally in passing a fine probe on each side, and attempted dilatation with small hard rubber dilators on several occasions. In spite of the utmost care and delicacy in the manipulations, violent and almost uncontrollable hemorrhage was always set up; on one occasion she had to remain at his office with the anterior nares and the upper pharynx tightly plugged for four hours before he could send her home. This was not a feature usual to these growths, and undoubtedly pointed to the presence in some degree of the hemorrhagic diathesis. It caused him to give up all further attempts at instrumental dilatation, and rendered hope of operative relief very faint. He was therefore confined to the use of topical applications for the pharyngeal and nasal symptoms. There being no radical treatment for this condition known, he turned to the *x*-ray. Being by no means an enthusiast for this remedy, he promised the patient nothing. From October 30 to date she had had twenty-six sessions of ten minutes duration at intervals of two or three days, with a medium tube placed as close to the nose as possible. Every four or five sessions she would get a mild but well-marked reaction; treatment would then be suspended for a week or so, until the inflammation subsided. To his astonishment and gratification there had been a marked change in the external tumors. They had diminished greatly in size, being one half what they were at first; both the patient and her friends noticed the change. On the other hand there had been no improvement in the palate infiltration, the nasal stenosis, or the condition of the throat. He attempted to apply the ray intrapharyngeally, and would continue to do so; but as the condition there was one of cicatricial band formation and ulceration, and effective application of the ray to the body cavities was difficult and unsatisfactory, it was very doubtful whether any amelioration would result. He added that, in spite of the patient's statement to the contrary, the cicatricial and ulcerative lesions of the throat were of a later stage of the disease than the tumor formations of the nose; the disease probably began in the palate, and spread anteriorly and posteriorly. In connection with this he showed a photograph of a case of fifteen years' duration that was in his Lebanon Hospital service some time ago. The ulceration and cicatricial contraction had caused a loss of tissue in the lip and anterior palate closely resembling the deformity of hare-lip.

Report of a Case of Complete Inversion of the Uterus.—Dr. J. Seymour Emans reported this case (see page 795).

A New Instrument for Measuring all the Diameters of the Pelvis in the Living Woman.—Dr. Sidney D. Jacobson presented this instrument (see Medical Record, March 31, page 489).

The Clinical Manifestations of the Toxemia of Pregnancy.—Dr. J. Clifton Edgar read this paper. He said that his object was merely to make a preliminary statement of the results of his study of this subject during the past year. The belief was slowly but surely gaining ground that while it was undoubtedly true that various toxemias might occur in pregnancy, still a special autotoxic state of pregnancy existed, or the pregnant state predisposed or favored a condition of toxemia peculiar to pregnant women. This toxemia might be defined as a state of the blood due to faulty metabolism, and *possibly* arising from hepatic insufficiency. It showed itself most commonly in trivial ailments, but exceptionally by serious, severe, and even pernicious affections, as acute yellow atrophy of the liver, pernicious vomiting and eclampsia, conditions which were now believed to be closely related. We were to-day practically ignorant of the origin of the poisonous material or materials causing pregnancy toxemia. There was a growing belief among those who had given the subject the most study that these substances were metabolic in origin; that there was a direct connection between these metabolic changes and the pregnant condition itself, and that these toxic substances in the blood were more or less identical in pernicious pregnancy, vomiting and eclampsia alike, and that they caused in some cases first lesions in the liver, and subsequently in the kidneys, the kidney changes being secondary in character. The time would probably come, if it was not already here, when we would be able to detect an autotoxic state by the detection of marked changes in metabolism from a chemical examination of the urine, before the presence of albumen and casts pointed to the

secondary changes in the kidneys. Within the past two years we had had another clinical index of the autotoxic state of pregnancy proposed by Dr. Ewing of the Cornell University Medical College. This clinical index was based upon the supposition that even mild cases of pregnancy toxemia caused errors in metabolism possibly due to lesions in the liver cells, and as a result various unoxidized compounds were formed in place of nitrogen, which were in themselves poisonous in character, and were found in the urine in various percentages of the total nitrogen as urea nitrogen, ammonia nitrogen, amino acid nitrogen, uric acid nitrogen, creatin nitrogen, creatinin nitrogen, etc. As a danger signal the most important seemed to be the ammonia nitrogen and the amino acid or undetermined nitrogen. He did not believe that as yet sufficient material had been collected to permit us to formulate from the percentages of total nitrogen excreted as urea nitrogen, ammonia nitrogen, etc., any rule to guide us in the determination of the severity of the pregnancy toxemia. These relations varied in the normal individual and were dependent upon the intake of nitrogen, and many other sources of error were possible. In order to reach a definite conclusion, it was necessary to tabulate a large number of urinalyses, both of those who did and those who did not show clinical symptoms of toxemia. For nearly a year he had had examinations made in both toxic and non-toxic cases in his private practice, and of the suspected cases in two hospital services. While he hesitated to formulate rules for diagnosing an impending or existing pregnancy toxemia, he would state that in most of the cases examined in which the clinical picture of a toxic condition was present, such as headache, excessive vomiting, slight jaundice, mental and physical torpor, high arterial tension, itching of the skin, etc., the complete chemical examination of a twenty-four hour specimen of urine showed errors in metabolism. Sixty-two chemical analyses were made in twenty-four patients. The analyses included, in addition to the total nitrogen and the nitrogen percentages or coefficients, the reaction, specific gravity, tests for albumen, sugar, indican, urobilin and casts, and in most of the specimens for acetone and acetoacetic acid. The character of the urine indicating normal metabolism depended upon the relation of the nitrogen of the nitrogenous compounds of urine to the total nitrogen. Thus, broadly speaking, when the total nitrogen ranged from three to fifteen grams per day the normal extremes of the percentages of total nitrogen excreted as urea nitrogen, ammonia nitrogen, creatinin nitrogen, uric acid nitrogen, and undetermined nitrogen were as follows: Percentage of total nitrogen excreted as urea nitrogen, 61 to 88 per cent.; percentage of total nitrogen excreted as ammonia nitrogen, 13.6 to 2.9 per cent.; percentage of total nitrogen excreted as creatinin nitrogen, 17.2 to 2.7 per cent.; percentage of total nitrogen excreted as uric acid nitrogen, 2.5 to 0.7 per cent.; percentage of total nitrogen excreted as undetermined nitrogen, 11.1 to 40 per cent. Abnormal metabolism was indicated by a urine which deviated from the generally accepted normal standard for the given quantity of total nitrogen excreted in the twenty-four hours. The twenty-four cases were readily divided into four classes, as follows: 1. Non-toxic pregnancies, consisting of those in which both the clinical symptoms and the chemical analyses were in accord with what could be considered a normal standard. 2. Toxemic vomiting, in which class were included cases of persistent pregnancy vomiting, due to some poison of unknown origin and accompanied by symptoms of toxemia. In four of the six cases in this class the percentage of total nitrogen excreted as ammonia nitrogen ranged high, reaching 48.4 per cent. in one case. Of sixteen analyses albumin appeared as a trace four times and casts only twice. 3. Preeclamptic toxemia, in which class were the cases in which the clinical picture of pregnancy toxemia was present, but persistent vomiting was not a symptom, although appearing intermittently in most of them. Of the nineteen urinalyses the percentage of total nitrogen excreted as ammonia nitrogen only reached 10 in one instance. The percentage of nitrogen excreted as undetermined nitrogen ranged high throughout the series, and in twelve urinalyses of the first three cases albumin only appeared as a trace once, and in no instance were casts found. In four of the cases in this series the kidneys seemed to be at fault. 4. Eclamptic toxemia, in which class he reported three cases, in which eight urinalyses were made. Two classes of eclamptic toxemia were recognized, an eclampsia of nephritic origin or renal insufficiency, and an eclampsia resulting from a neglected toxemia of the kind peculiar to pregnancy. A case illustrative of each class was cited.

The Chemistry of the Toxemia of Pregnancy.—Dr. C. G. L. Wolf presented this communication with a lantern-slide demonstration

The Medical and Surgical Treatment of the Toxemia of Pregnancy.—Dr. George L. Broadhead presented this paper. After reviewing the recent ideas in regard to the etiology of this condition he spoke of the great practical value of urinalyses in this class of cases. For convenience all cases of toxemia were divided into three classes: (1), toxemia with persistent vomiting; (2), toxemia without persistent vomiting, and without convulsions; and (3), toxemia with convulsions, or eclampsia. The subject of treatment was divided into (1) gynecological, (2) hygienic and dietetic, (3) medicinal, and (4) obstetrical. The gynecological treatment consisted in the correction of some abnormal condition of the genitals. In regard to hygiene and diet it was necessary to have cheerful surroundings, freedom from worry, and such hygienic measures as facilitated elimination of the poison. In severe cases rectal enemata were resorted to. The following formula gave good results: The whites of two eggs, whiskey or brandy ℥ss, a pinch of salt, and peptonized milk to make ℥vi. In addition to enemata a saline infusion of one pint should be given each day. In speaking of medicinal treatment, he reviewed the measures usually employed for the relief of the vomiting of pregnancy. The bromides, with or without chloral, given per rectum had been of advantage at times. Morphine should be reserved for very severe cases. Calomel was superior to any other drug in its action upon the liver and bowels, and should be used frequently in the toxemia of pregnancy. Prolonged irrigation of the colon with physiological salt solution was of great benefit; it should be followed by the retention of a quart. The heart action should be sustained by the use of stimulants. The obstetrical treatment consisted in the dilatation of the cervix, and second, the emptying of the uterus. In regard to the latter procedure he thought that if it was to be followed by good results it must be done early. In presenting the second division of the subject, toxemia of pregnancy without persistent vomiting and without convulsions, he thought the chief treatment must be eliminative. The diet should be modified by taking away the red meats and reducing the ingestion of nitrogenous foods to the minimum. In severe cases the diet should be chiefly milk. The kidneys might best be stimulated by copious draughts of water. The bowels should be kept open by the use of cascara, podophyllin, aloes, the laxative mineral waters, or calomel in small doses, followed by a saline. In the severe cases calomel with compound jalap powder, or in the form of compound cathartic pills, acted well. Colonic injections and intravenous infusions should be given in severe cases. Venesection had its place in certain cases. If medicinal treatment failed, labor should be induced, and it had been his experience that labor should not be prolonged in this class of patients. In considering toxemia with convulsions or eclampsia, he concluded that during the eclamptic seizure chloroform should be administered and oxygen, if possible. The patient should be protected from injuring herself as far as possible. If the pulse was full and strong with tension the fluid extract of veratrum viride ♏x-xx should be given hypodermically, and repeated in doses ♏v every half hour until the pulse was reduced to 60. In case of collapse, whiskey, morphine, and atropine hypodermically

should be used. If the pulse was weak and feeble we should rely chiefly on chloral and bromides by the rectum in doses 3ss-3i. Where the pulse was strong we should use veratrum viride as indicated, combined with chloral by the rectum. If the patient was unconscious the bowels should be moved by croton oil ♏i-ii given with olive oil 3i on the back of the tongue. If this was not effective a high enema of sulphate of magnesium and castor oil should be used. The colon should be irrigated with one gallon of hot saline solution, and several quarts should be left to be absorbed. If the patient was conscious 3ii magnesium sulphate should be given every fifteen minutes until one ounce had been given. Intravenous infusion might be reserved for very severe cases. Venesection, when labor had not yet begun, might be used to advantage in robust patients with a full pulse, twelve to sixteen ounces of blood being removed. To decrease arterial tension, and as a heart stimulant, diuretic, and diaphoretic, nitroglycerin was of great value, while caffeine and strophanthus were second. If labor had not commenced a dilating bag should be introduced, and when the cervix was softened and well dilated delivery should be accomplished by forceps or version. The bags might be used to hasten labor if it had already begun. If the cervix could not be dilated by ordinary methods cesarean section should be resorted to; but unless the operator was perfectly able to perform these operations he had better rely upon medical treatment alone. The one fact to be kept in mind at all times was that in elimination lay the hope of the patient's salvation.

Dr. Egbert Grandin opened the discussion on these several papers and said that the keynote of the conclusions reached regarding the management of the toxemias of pregnancy was to be found in prophylaxis; treat the case before the toxemia developed. But, unfortunately, in these days obstetrics was not recognized as a branch of medicine remunerative enough to warrant the general practitioner giving the pregnant woman the care she should have. The prophylactic treatment of toxemia of pregnancy was too often neglected. If the intestinal tract of the pregnant woman was kept free, if the kidneys were sufficient, she would not suffer from the toxemias of pregnancy. The average medical man was unable to give the proper amount of time for the proper care of these cases; if he examined the urine for albumin he thought he was doing his duty. Not only should the condition of the kidneys be learned, but the condition of the liver as well. The laity should, in his opinion, be taught that the obstetrician was entitled to as remunerative a fee for the work he should do as the gynecologist secured for doing the work the obstetrician left undone. When the toxemia was imminent, with the pulse rapid, with some temperature, with vomiting, etc., the average man waited and the patient died. No woman should be allowed to die from the vomiting of pregnancy. The late Professor Lusk stated that those who died, died because they were compelled to wait too long. These cases should be tamponed, and, after waiting twenty-four hours, the uterus should be emptied with the hand, or with the curette if necessary. In the treatment of toxemia, when eclampsia was imminent, the medical man who folded his hands and waited was scarcely entitled to his title. In such a case the thing to do was to empty the uterus. The treatment of toxemia of pregnancy was eliminative. Calomel was too slow in its action, and Dr. Grandin preferred elaterium in big doses. He did not depend upon veratrum viride; he had seen eclampsia with a pulse of 60; therefore, what good would veratrum viride do under such conditions? Empty the uterus. If the pulse was tense, he relied upon glonoin, and in large and often repeated doses. The effect of nitroglycerin was evanescent and must be repeated often if the internal congestion was to be relieved. The colon should be irrigated, and with plenty of fluid. In these cases there was the element of spasm to be dealt with, and he did not know what it was due to. But the best results seemed to him to come from the use of hyoscine hydrobromate in big doses given hypodermically. Give until the pupils were dilated. This relaxed the spasm of kidneys and intestinal canal as no other drug would. Morphine he believed to be the invention of the devil in these cases. Venesection was recommended when the pulse was full and bounding. If the patient was bleeding from the uterus he believed it should not be interfered with; let her bleed. If an anesthetic was to be used, give chloroform, and not ether. The vaginal cesarean section had a new field in these cases.

Dr. S. Marx considered the clinical aspect of toxemia of pregnancy and said that, from the standpoint of the clinician, we should remember that we were speaking of gentlemen in general practice, and not of the wonderful laboratories, and that we must depend upon the simpler tests. There was no better simple test, one which would place a man on guard, than a study of the quantity of urine plus the specific gravity. When in doubt, have the case examined by experts. He divided the cases into two classes: first, those with true kidney lesions or conditions, and, secondly, the intoxications depending upon intestinal or liver conditions. If one waited for the presence of albumin, urea, or casts, often, when found, the patient would be beyond hope or dead. The toxemia due to liver or intestinal conditions was evidenced by estimating the amount of urea or nitrogen derived from urea. When the nitrogen partition was below 60 uremic convulsions were likely to occur. The patient was in danger, too, when acetonuria appeared Regarding treatment, not much was to be said in regard to the medical treatment; the safety of any patient who was threatened with eclampsia rested in immediately emptying the uterus. No other form of treatment should be entertained for a moment, such as the use of veratrum viride, chloral, bromides, etc., when the symptoms were on the increase, as manifested by the general symptoms and changes in the urine, which should be examined day by day. The next most important treatment was by bleeding. If the woman was beginning to twist, or to convulse, he said he preferred to bleed the woman, a distinct indication in his opinion. The surgical treatment, however, was the most important form. Empty the uterus. For dilating purposes he believed the hand to be the best instrument, although other instruments might be used, because sometimes it was impossible to empty the uterus with the hands alone. The vaginal cesarean section was an operation of election under certain conditions. The Bossi dilator was a brutal instrument and should never be used.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 20, 1906.

Dr. Arnold Sturmdorf, Chairman.

Presentation of Specimens.—Dr. George Gray Ward, Jr., showed a small metal appliance which he had removed from the uterus of a woman 22 years old. She had long suffered from dysmenorrhea, and was referred to a New York physician, apparently in good standing, who had told her that in order to relieve her symptoms it would be necessary to insert into the uterus an instrument imported from France which would cost her $50. This was done, and she was instructed to return in six months. Following the insertion of this appliance, she suffered excruciating pain, especially at each menstrual epoch, until she finally applied for relief. An examination revealed a marked anteflexion, with a good deal of endometritis and discharge. She was admitted to the Post-Graduate Hospital, and when Dr. Ward curetted her he found this instrument, which was deeply imbedded in the uterine tissues. It was apparently made of two different kinds of metal wires, fitted together, and each terminating in a ball point. The impression that it was intended to convey evidently was that it had some magnetic influence.

Treatment of Uterine Retrodisplacements.—The

Chairman, Dr. Sturmdorf, said that recorded observations on uterine retrodisplacements antedated the writings of Hippocrates, and, although one of the most ancient and clinically familiar of gynecologic topics, its etiology, pathological significance and correction still presented obscure and much-disputed elements. The early writers attributed the gravest significance to the condition, and laid proportionate stress upon the necessity for its correction. Whenever views supposed to be false were authoritatively repudiated the disciples of the new conceptions usually rushed to the opposite extreme. Thus came a period during which it was claimed that retrodisplacement, as such, was entirely unproductive of symptoms or consequences unless complicated by uterine or adnexal disease, and it was to the correction of such complications that all therapeutic efforts were directed. To-day we recognized that while many cases of uncomplicated retrodisplacements were unproductive of disturbance, there were many more that called for correction. Such correction should be based upon a clear conception of the nature of normal uterine support, and the elements involved in the disturbance of normal support. Unfortunately, there was no unanimity of opinion as to the relative importance of the various supporting elements involved in maintaining the normal anteverted position of the uterus, and it naturally followed that many of the operative measures in vogue, especially the so-called fixation methods, only succeeded in substituting one uterine malposition for another. It should be borne in mind that the free mobility of the uterus was essential to its own structural and functional integrity, as well as to that of its contiguous viscera, and any method immobilizing the uterus could not be accepted as rational or curative. It was not a question of correcting the displacement, but of curing the patient. Operative differentiation between ventrofixation and so-called suspension was purely visionary; no one could predetermine the amount of reactionary agglutination that would occur between visceral and parietal peritoneum in a given case; we had all seen a thin filamentous attachment follow a broad sutural coaptation, while on the other hand extensive agglutination might result from the merest contact. The extraabdominal attacks on the round ligaments had been followed in a number of reported cases by mishaps and failures; furthermore, it was claimed that while the round ligaments held the uterus in anteversion, they could not elevate it into its normal plane, yet numerous were the recorded and unrecorded successes following that method of operation. The intraabdominal and vaginal methods of shortening and fixing the round ligaments, the vaginofixation, the shortening of the uterosacral ligaments, like the classic pessary, massage, the tampon, and postural treatment, all had their field of usefulness, their advocates, and their adversaries. These methods could not be all wrong nor all right, for each counted its successes and its failures, and it became evident that each of these procedures must be adapted to certain forms or phases of the condition under consideration. It was with a view to the elucidation of that point that the present discussion was introduced.

Dr. Egbert H. Grandin said that by logical sequence the treatment of uterine displacements had resolved itself practically into a surgical one. With the development of abdominal surgery came the new pathology and the modern treatment, which aimed at a cure rather than mere palliation. It had been learned that the mere fact of version did not cause symptoms, but that another factor, downward sagging, was the essential element. It had been found that it was not cellulitis, but peritonitis, which was the complication. Thus, of necessity, all but those who would not see, recognized the futility of the pessary, tampon, etc. In dealing with cases of movable, uncomplicated uterine displacement the patients should always be given the choice between palliation and cure; if they preferred the pessary, with all its annoyances, it was their right, since any operative measure carried with it a certain risk. In discussing the operative treatment of these cases, Dr. Grandin said it was necessary at once to rule out any procedure which resulted in fixation of the uterus, for it did not advantage the subject in the least to substitute one pathological position for another. He considered fixation justifiable only in women with prolapse after the child-bearing period. There remained, therefore, three methods of approach: through the inguinal canals, through the vaginal vault, and through the abdomen. The inguinal canal route he had long ago rejected because it subjected the woman to the risk of double inguinal hernia, and also because, while such an operation might draw the uterus forward, it did not lift it upward—a *sine qua non*. Furthermore, he had seen a number of instances in which operation through the inguinal route had resulted in the uterus being placed so closely against the pubes that the bladder could not fill upwards, bladder symptoms being substituted for back and for bearing-down symptoms. The speaker said that fixation by dissection through the vagina never had logical grounds for existence, and he mentioned it only for renewed condemnation, nor could he accept infolding or shortening of the round ligaments through the vagina, because it required considerable mutilation of the vaginal vault for performance, because he did not think the uterus was lifted up thereby, and because the technique might be followed by fixation. Coming to the abdominal route, Dr. Grandin said that formerly suspension was practised by the posterior or the anterior fundal wall, but it had been found that such a procedure was apt to be a cause of dystocia in the event of subsequent pregnancy. Those who were expert might shorten the posterior ligaments of the uterus, although it appeared to the speaker that while this method would maintain the uterus forward, it would not keep it at a higher level. His own method, preferably, was to suspend the uterus by the round ligaments to the parietal peritoneum, without, however, buttonholing the fascia. This kept the organ forward and upward; it did not interfere with the normal sphere of motion, nor did it cause dystocia at the ensuing labor. In cases of complicated uterine displacement the problem was a complex one, as one had to deal not alone with backward displacement, but also with peritoneal bands binding the uterus backward and downward, and, in addition, frequently with tubal and ovarian disease. Also, in many cases, the intestines, omentum, or appendix were adherent to the uterus or the broad ligaments, and in some instances no one could tell the extent or the nature of the complication. This emphasized the fact that the abdominal route should be that of election in the cases under consideration.

Dr. J. Riddle Goffe said that in order to discuss the subject in a broad and comprehensive way, it would be necessary to review somewhat the dynamics of the female pelvis, and especially the forces that were at work in maintaining the uterus in its normal position. From that we could learn what would remove it from its normal position, and what tissues should be utilized to restore it when it had become displaced. He was a believer in the view that the uterus was supported absolutely and entirely by its ligaments. Opposed to this theory was the idea that the perineum supported the uterus; but this seemed to be disproved by the fact that when the perineum was torn through into the rectum and absolutely destroyed, so far as any probability of support was concerned, the uterus still remained in place. That was the experience of all observers. In such cases what held the uterus in position? Naturally its ligaments. If the uterus is compared with other organs in the body, weight for weight, it is found to have more ligaments than any other organ. These ligaments, we were told, act as guy-ropes, but the speaker said he did not believe that six or eight different guy-ropes were necessary simply to regulate the oscillations of the uterus. On the contrary, he thought they were there for purposes of support, and that they actually did support the uterus. In cases in which the perineum was not absolutely destroyed.

but torn through to the rectum, the idea of restoring the perineum would be to prevent a retrodisplacement and descent of the uterus. The explanation of this is that the condition was complicated by a retrocele; we had to deal with a pulling force on the uterus which was not there before, and when this dragging force had become sufficient to overcome the resisting power of the ligaments, then the uterus descended, and finally retroverted. Dr. Goffe said he did not assume that all the ligaments of the uterus exerted an equal force or resisting power to the descent of the organ. He regarded the uterosacral ligament as the principal sustaining power, and as long as that maintained its tone and proper length it was impossible for the uterus to descend or become retroverted. The first step in the process was always a relaxation of the uterosacral ligament. The round ligaments he believed were the guy-ropes, acting to maintain or limit the excursions of the uterus in the filling and emptying of the bladder. The broad ligaments were there very largely to act as viaducts for the great blood-vessels that nourished the uterus, and he knew of no better illustration of the economy of nature in adapting means to needs than we had in the broad ligaments, sustaining and giving passageway to the great blood-vessels, and lengthening as the demands of pregnancy were made upon them. In the uterosacral ligament we had a muscular structure, which, as a rule, was sufficiently powerful to lift the cervix high in the hollow of the sacrum, which was its normal position. Dr. Goffe said, to his mind, the chief cause of retrodisplacements of the uterus was lack of involution of the ligaments after parturition. These ligaments were muscular in structure, becoming hypertrophied during parturition, and when the uterus involuted after parturition it was just as important for the ligaments to involute as it was for the uterus itself. The treatment for this condition, as it was in other troubles to which flesh was heir, was prophylactic, and should be carried out directly after parturition, while involution was going on. It consisted, essentially, of stimulating the circulation by lifting the uterus up in the pelvis, so that the circulation be kept to as high a degree of perfection as possible. It was at this stage only that the pessary could be regarded as a means of cure. Dr. F. Davenport of Boston, who had carefully investigated this subject, had made the statement that most of these cases were cured by the prompt insertion of a pessary after parturition, in order to hold the uterus high in the pelvis, thereby stimulating circulation and aiding involution. In chronic cases the pessary had to be worn continuously; here it did not effect a cure, but simply acted as a crutch did for a person with a short leg. Coming to the surgical treatment of retrodisplacements, Dr. Goffe said that as he maintained that as inefficiency of the uterosacral ligament was the chief cause of their occurrence, it was only logical to look upon its utilization as the best method for their correction. While this method was not applicable to all cases, it was in the majority. The ligament could be shortened either through the vagina or the abdomen with very satisfactory results. The speaker said that in some cases in which it was difficult to reach the uterosacral ligament he had utilized instead the round ligaments, but the support thus given to the uterus would not be permanent unless at the same time it relieved the strain on the uterosacral ligament, and allowed the latter to recover its tone. In shortening the round ligaments, Dr. Goffe said he preferred to operate through the anterior vaginal vault, and he had found that many patients would consent to such an operation who would refuse to submit to the abdominal operation.

Dr. S. Marx said that if the gynecologist could view these cases from the standpoint of the obstetrician he would doubtless change his opinion regarding the advisability of performing some of the operations that had been discussed for the relief of uterine retrodisplacements during the child-bearing period. The gynecologist, after operating on these women, perhaps kept them under observation for a few weeks and then lost sight of them. He was satisfied as long as his patient made a good recovery from the operation, and with the apparent restoration of the abdominal relations. It was left to the obstetrician to undo a good part of the work done by the gynecologist. The work of the gynecologist and the obstetrician, Dr. Marx said, should be more closely affiliated. At present there was entirely too much operative work done in connection with uncomplicated retrodisplacements of the uterus, and as a result of this so-called surgical correction some of the worst cases of dystocia had resulted. The speaker said he agreed with Dr. Goffe that most of the early cases of uterine retrodisplacement could be cured by the temporary use of the pessary and tampon. Among the operative procedures for the correction of this condition that were apt to have a deleterious influence in case of subsequent pregnancy, the speaker particularly condemned the vaginal method of fixation of the uterus. He recalled one such case in which an operation on the round ligaments had been done by the vaginal route, with resulting distortion of the cervix, and at a subsequent pregnancy the forceps brought away not only the fetus, but also portions of the vagina, cervix, and uterus. In another case, in which a fixation operation had been done through the anterior fornix, the woman subsequently became pregnant, and at the time of delivery an obstetrical operation was necessary, from which she barely escaped with her life. The operation for the correction of uterine retrodisplacements through two openings in the abdomen, as advocated by Goldspahn of Chicago, the speaker said he regarded as scientifically incorrect and absolutely unnecessary. The methods he favored personally were the various suspension operations by the abdominal route. No single operation was suitable to all cases. In many cases the displaced ligaments had become thin and elongated, and were no longer strong enough to support the uterus, and under such conditions he resorted to anterior suspension. When he found the ligaments still thick and muscular, he contented himself with a simple reduplication of the ligaments, *plus* peritoneal suspension. By doing this one did not create a fixation operation, nor was the capacity of the bladder limited. The speaker mentioned three cases in which he was obliged to do a cesarean section after an abdominal fixation had been done through the aponeurosis of the abdomen by excellent men, and yet in all three instances it was absolutely and utterly impossible to deliver through the vagina. Abroad the fixation operation from above had been generally discarded, simply because of the fearful dystocia it had given rise to. His own experience with the after-effects of that operation had convinced him that it should never be done; and while an entirely satisfactory operation for the correction of uterine retrodisplacements had not yet been devised, he believed that suspension by the broad ligaments, or, if that could not be done, anterior suspension by the intraabdominal route offered the best and safest expedients.

Dr. Hiram N. Vineberg said that after listening to the rather dogmatic statements of those who had preceded him in the discussion, he was inclined to take a middle ground. He did not think the gynecologist, in the treatment of any particular condition, should be wedded to any one system or method, and cases of uterine retrodisplacement were not infrequently observed which should be left alone entirely. For example, in women with nursing children in whom the uterus was small, perhaps two-thirds its normal size. Such cases were simply instances of lactation atrophy, and they usually got along perfectly well without having the position of the uterus changed. The same was true of another class of women, either married or unmarried, with a small and partially retroverted uterus—probably a congenital condition. Dr. Vineberg said he did not entirely agree with Dr. Goffe as to the functions of the uterine ligaments. He had time and again seen cases of completely retroflexed uteri in which the uterosacral ligaments were found to be in an entirely normal condition. Take, for example, those

cases which were the result of subinvolution. A month or six weeks after confinement the uterus, instead of being reduced to its normal size, still remained large and subinvoluted, but in spite of this it might remain in good position for six months or a year; then, when changes in the uterine tissues had occurred, retroversion would follow. In these cases the normal position of the uterus was maintained on account of the tissues of the uterus itself, and the speaker said he did not believe there was any particular ligament or set of ligaments that kept the organ in its normal relations. Certainly the round ligaments had nothing whatever to do with holding it in position. In some cases the uterus would remain in position after perineal rupture; in others it would not. It would depend whether this pelvic fascia of the cellular tissue surrounding the cervix had been torn away from their attachments by the fetal head crowding all the pelvic tissues in front of it. Dr. Vineberg said he did not quite agree with Dr. Marx that there was such a wide breach between the work of the obstetrician and that of the gynecologist. Most of the latter practised more or less obstetrics, and kept their cases under observation. He had operated on between fifty and sixty cases by vaginal fixation methods, and while, among those who had subsequently become pregnant, at least five or six had suffered from early miscarriage, there were quite a number that went on to a complete and uneventful pregnancy. He had heard of no instances of dystocia in any of his cases, although he had frequently asked his colleagues to inform him if they met with any. Certain cases, he thought, could be best treated by the vaginal route; others by the abdominal. In dealing with patients who had passed the child-bearing period, or who were not likely to conceive, and in whom the retrodisplacement was complicated by a large rectocele or cystocele, he had obtained his best results by doing a regular vaginal fixation. During the child-bearing period, on the contrary, he had entirely discarded the vaginal fixation operation, substituting instead suture of the round ligaments directly to the vaginal wall—an operation he had devised several years ago. This procedure could be carried out only in a limited number of cases, and when it was done any abnormal condition of the adnexa could be attended to just as well through the vaginal vault as it could be through the abdomen, even when there were adhesions of the sigmoid. The gynecologist, he thought, should be able to work from below if it was necessary. Coming to the abdominal route of treating retrodisplacements, Dr. Vineberg said his favorite procedure was to suture the round ligaments to the abdominal wall. By that method he could depend upon securing over 95 per cent. of permanent cures; he might add say almost 100 per cent. of anatomical cures. While he had had relapses after the vaginal operation and after Alexander's operation, he could only recall one or two cases in which failure had followed suturing the round ligaments to the abdominal wall. At least eight of the cases in which he had done that operation had become pregnant, and the progress of their pregnancies and their labors were normal in every respect. In some of his cases the patients went through two normal pregnancies and the uterus remained in good forward position. Of all the round ligament operations done through an abdominal incision the method he practised was the simplest; was attended with the least traumatism.

Dr. Leroy Broun said the uterus possessed two sets of ligaments, the true and the false. The latter were made up of folds of the peritoneum, and their duties, as supports of the uterus, were secondary to those of the true ligaments, which contained not only muscular tissues, but also dense, connective tissue. The true ligaments were the uterosacral, the uteropelvic, and the round and the ovarian ligaments. Dismissing the ovarian ligaments from consideration, the three others sprang from the uterus; they were composed of tissues of the same character as that of the uterus itself, and each one was attached to some fixed point—the uterosacral to the sides of the sacrum, the uteropelvic at the base of the broad ligament to the pelvic fascia overlying the internal obturator muscle, and the round ligament over an angle as it passes through the internal abdominal ring. The uterosacral ligaments were retractors, pulling the cervix backward and upward, while the uteropelvic ligaments helped to support the organ in an upright position. The round ligament had no influence upon the position of the uterus while that organ was in a quiescent state, since it is a lax cord while it is in this normal position, but it restrained the motions of the fundus with the filling and emptying of the bladder. The ideal treatment of uterine retrodisplacements, Dr. Broun said, would be not only to shorten the uterosacral ligament, which pulled the cervix backward, but also to take up the slack in the round ligament, which helped to restrain the excursions of the fundus of the uterus. Shortening of the uterosacral ligament alone had never given him very satisfactory results. The operation of shortening the round ligament through the external abdominal ring was very simple; it had entailed no death rate in his hands, and no hernia should follow. In doing this procedure care should always be taken to see that the fundus was well up, and that there were no intestines in front of it. The result of the operation was uniformly excellent, not only anatomically, but also clinically. The Alexander operation was applicable only to those cases in which the uterus was freely movable, and where there was no disease of the adnexa or appendix. The fundus of the uterus being large did not interfere with the excellence of the clinical results following this operation. Dr. Broun agreed with some of the speakers that it was a comfort to look into the abdominal cavity and see that the pelvic organs and appendix were in a healthy state; he, however, maintained that in uncomplicated retrodisplaced uteri with the symptoms of backache and bearing-down pains we were not justified in subjecting the patient to an abdominal section, when a simple procedure such as Alexander's operation would relieve all symptoms, and could at all times be relied on to give an admirably anatomical result in maintaining the uterus in an anterior position. He further called attention to the fact that there had never been reported any complications in subsequent pregnancies following Alexander's operation attributable to the operation.

Dr. Austin Flint, Jr., said that a uterine retrodisplacement could usually be traced to subinvolution of the uterus and its supports. When in that condition any unusual strain upon it might tilt the organ backward. One of the most common causes was straining at stool. Dr. Flint said that his experience with the pessary in these cases, used soon after labor, had been excellent. Before the sixth week the tissues were not quite firm enough to hold the pessary, but after that the insertion of the pessary, combined with a certain amount of postural treatment, would effect a cure in from 50 to 75 per cent. of cases. The form of pessary he preferred was a simple round ring. The postural treatment to prevent posterior displacement was commenced about three or four weeks after confinement, and consisted in having the patients turn on their abdomens morning and night, in order to give the large, subinvoluted uterus a chance to fall forward. Avoidance of straining at stool was also insisted upon, and tampons should be used much more frequently after confinement than they were at present. Nothing would drain a uterus more certainly after parturition than the glycerine tampon, and even in cases of long standing its use would minimize the degree of operation that might subsequently become necessary. Surgical treatment was the only curative method in the chronic cases, and of the various operations that had been advocated, that of Alexander was one of the most satisfactory in the simple, uncomplicated forms of retrodisplacement. It was not a difficult operation, and its results were uniformly good. In complicated cases the abdomen should be opened.

Dr. James D. Voorhees, in speaking of the preventive treatment of uterine retrodisplacements, said he tried to educate the patient to sleep on the stomach, commencing about four or five days after confinement, and also to take the knee-chest position for five or ten minutes each morning and evening. A large percentage of these cases could be cured by the proper application of a well-fitted pessary. Many women, Dr. Voorhees said, developed a retrodisplacement before becoming pregnant from overindulgence in athletic sports. In the radical treatment of this condition there were two operations that could be undertaken by the gynecologist with impunity, so far as their effect of future pregnancy and labor was concerned: One was Alexander's operation, and the other was a true ventral suspension, such as the Gilliam operation. He recalled a number of cases of uneventful pregnancies at the Sloane Maternity in women who had been operated on by the Alexander method or by ventral suspension. In one case the woman was successfully delivered of twins. It was after vaginal or ventral fixation that trouble was likely to occur. Rühl has collected nine cesarean sections after vaginal fixation. Dr. Voorhees recalled a number of ventral fixation cases where a miscarriage or premature delivery resulted. When labor started in the pains were apt to be irregular, the cervix failed to dilate properly, and many such women had to be delivered by forceps or version on account of uterine inertia. The first case of cesarean section ever done at the Sloane Maternity was on a young woman upon whom a ventral fixation for uterine retrodisplacement had been performed before marriage. Dickinson, Noble, and others had reported similar cases when cesarean section was necessary after ventral fixation. This major operation was necessary because the anterior uterine wall was bound down, and in the enlargement of the uterus during pregnancy it formed a hard, muscular tumor about the size of the child's head which blocked the pelvic brain. Another possible danger connected with the fixation methods was severe post-partum hemorrhage on account of the uterine inertia. Slow involution of the uterus was also likely to follow.

Dr. Augustin H. Goelet said that posterior uterine displacements were to be divided into three classes, namely, reducible retroversions and retroflexions, and fixed displacements of both kinds. The treatment, to be most effective, should be begun very shortly after labor or abortion, when the uterus and its supports were in a condition that would permit restoration to their normal condition. Non-operative treatment was applicable mainly to cases of freely movable retroflexed uteri. The retroverted uterus was seldom amenable to non-operative treatment, especially if the condition had existed for any considerable length of time. If the treatment was instituted sufficiently early after labor or abortion many of these cases would never require operation, and this should be impressed upon the family physician or accoucheur. In the application of a pessary to a retroverted uterus the fact should be borne in mind that the bar of the pessary presses against the uterosacral ligaments and tends to stretch them still further, hence preventing their retraction. The pessary was incapable of curing the displacement unless the underlying cause of the condition was corrected (namely, the pathological changes that the uterus and its supports had undergone), and for that purpose he had found negative electrolysis a very effective agent, applied through the canal of the uterus to the walls of the organ and its supports. Dr. Goelet said that movable retroflexions were almost always curable by means of a properly adjusted pessary and negative electrolysis. Movable retroversions were sometimes amenable to cure also by the same means, but fixed posterior displacements of both kinds demanded operation.

Dr. George H. Balleray emphasized the value of conservative treatment in these cases, and expressed the opinion that in uncomplicated cases of uterine retrodisplacement, whether chronic or otherwise, 25 per cent. could be cured by the application of a proper pessary. In speaking of the forces that maintained the uterus in its normal position, Dr. Balleray said he thought some support came from the perineum, and another factor was the retentive power of the abdomen. A frequent cause of uterine displacements was the wearing of corsets and tight skirts, which certainly tended to crowd the organ into an abnormal position.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Burdett's Hospitals and Charities, 1906 Year Book of Philanthropy, and the Hospital Annual. By Sir Henry Burdett, K.C.B. 12mo, 1,055 pages, muslin. The Scientific Press, London, England. Price, 16, net.

Chemistry of the Proteids. By Gustav Mann, M.D. 8vo, 606 pages, muslin. Macmillan & Co., New York. Price, $3.25.

Reference Handbook of the Diseases of Children. By Prof. Dr. Ferdinand Fruhwald. Edited, with additions, by Dr. Thompson S. Wescott. 8vo, 533 pages, illustrated, muslin. The W. B. Saunders Company, Philadelphia. Price, cloth, $4.50; half morocco, $5.50, net.

Manuel Pratique pour le Choix des Verres de Lunettes et l'Examen de la Vision. Par le Docteur Scrini et le Docteur Fortin. 12mo, illustrated, 233 pages, flexible muslin. Vigot Frères, Paris, France. Price, 4 francs.

The Examination of the Function of the Intestines by the Means of the Test Diet. By Prof. Dr. Adolf Schmidt; translated by Charles D. Aaron, M.D. 8vo, 91 pages, illustrated, muslin. F. A. Davis Company, Philadelphia. Price, $1, net.

Affektivität, Suggestibilität, Paranoia. By Prof. E. Bleuler. 8vo, 144 pages, paper. Carl Marhold, Halle a. S. Price, 3 Mark.

The Medical Diseases of Infancy and Childhood. By Alfred Cleveland Cotton, A.M., M.D. 8vo, 670 pages, illustrated, muslin. J. B. Lippincott Company, Philadelphia.

The Treatment of Gonorrhea in the Male. By Charles Leedham-Green, M.B., F.R.C.S. 8vo, 151 pages, illustrated, muslin. William Wood & Co., New York. Price, $2, net.

Gynecological Diagnosis. By Arthur E. Giles, M.D., B.Sc., London, F.R.C. S.Ed., M.R.C.P., London. 8vo, 212 pages, illustrated, muslin. William Wood & Co., New York. Price, $2.50, net.

Nineteenth Annual Report of the State Board of Ohio for the Year 1904. 8vo, 618 pages, paper. The Springfield Publishing Company, Springfield.

Psychotherapeutische Briefe. Von Prof. Dr. H. Oppenheim. 8vo, 44 pages, paper. S. Karger, Berlin.

Clinical Applied Anatomy. By Charles R. Box, M.D., B.S., B.Sc., London; M.R.C.P., London; F.R.C.S., England; and W. McAdam Eccles, M.S., London; F.R.C.S., England. 8vo, 471 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $4.

Recent Advances in Physiology and Biochemistry. Edited by Leonard Hill, M.B., F.R.S. 8vo, 740 pages, illustrated, muslin. Longmans, Green & Co., New York. Price, $5, net.

Nature and Health. By Edward Curtis, A.M., M.D. 12mo, 313 pages, muslin. Henry Holt & Co., New York.

Chemistry of the Albumens. By B. S. Schryver, D.Sc., London; Ph.D., Leipzig. 8vo, 102 pages, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $2.

The World's Anatomists. By G. W. H. Kemper, M.D. 32mo, 79 pages, illustrated, paper. P. Blakiston's Son & Co., Philadelphia.

Third Treatise on the Effects of Borax and Boric Acid on the Human System. (With Diagrams.) By Dr. Oscar Liebreich. 4to, 70 pages, paper. P. Blakiston's Son & Co., Philadelphia. Price, $1.75, net.

Sex and Character. By Otto Weininger. Translation from the Sixth German Edition. 8vo, 356 pages, muslin. G. P. Putnam's Sons, New York. Price, $3, net.

Transactions of the American Gynecological Society for the Year 1905. Volume XXX. 8vo, 518 pages, illustrated, muslin. Wm. J. Dornan, Philadelphia.

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Minnesota reciprocates, under certain conditions, with the following States: Illinois, Iowa, Kansas, Maine, Maryland, Michigan, Missouri, Nebraska, Nevada, New Jersey, Ohio, South Carolina, South Dakota, Wisconsin, Wyoming.

New York.—The University Regents on April 26 made the following appointments to the New York State Board of Medical Examiners: From the State Medical Society Dr. William W. Potter of Buffalo, Dr. William S. Ely of Rochester, and Dr. Maurice J. Lewi of New York, all reappointed, and Dr. Arthur W. Booth of Elmira, to fill the unexpired term of Dr. George R. Fowler, deceased; from the Homeopathic Medical Society, Dr. J. M. Lee of Rochester, Dr. J. W. Candee of Syracuse, and Dr. G. E. Gorham of Albany, all reappointed; from the State Eclectic Society, Dr. L. H. Smith of Buffalo, Dr. G. W. Sutton of Bath, and Dr. M. H. Nichols of Worcester, all reappointed. Miss Anna L. Alline of New York City was appointed a member of the State Board of Nurses' Examiners.

The American Confederation of Reciprocating, Examining, and Licensing Medical Boards met at Columbus, Ohio, on April 25. The following States are members of the Confederation: Michigan, Wisconsin, Indiana, Iowa, Kansas, Kentucky, Nebraska, Maryland, Georgia, Illinois, Ohio, North Dakota, Nevada, and Oklahoma.

Wyoming reciprocates, under certain conditions, with Colorado, Georgia, Illinois, Iowa, Kansas, Maine, Michigan, Minnesota, Missouri, Nebraska, North Dakota, South Carolina, Vermont, and Wisconsin.

Ohio reciprocates, under certain conditions, with Illinois, Indiana, Maine, Maryland, Michigan, Minnesota, Nebraska, New Jersey, and Wisconsin.

HEART FAILURE AS THE RESULT OF DEFICIENT FOOD.

By ALEXANDER HAIG, M.D.,

LONDON, ENGLAND.

I often have the opportunity, as a teacher of diet, of observing the results of the diets I have myself prescribed, of those prescribed by others, and finally of quantities of food which I regard as insufficient. So common is the latter error that in the last few years I have seen many instances in which deficient nourishment had led directly or indirectly to more or less marked heart failure. It is known that a well-nourished patient may starve for thirty, forty, or even sixty days without serious signs of collapse if due care is exercised; the physiology of this apparently being that the essential structures—the muscles of the heart and cells of the brain—are nourished at the expense of the other structures from which a definite daily quantity is taken to provide their supplies of albumin. This may be called acute starvation, and if its duration is brief, it does little harm, because the heart muscle and brain cells are sufficiently provided for meanwhile. But if a condition of slow, steady, and constant deficiency of food is substituted, there comes a time when not only do the less important tissues suffer, but the heart muscle and brain cells begin to suffer with them to some extent. No doubt before this occurs many other tissues of the body, especially the muscles, have been largely drawn upon to provide the necessary nourishment. But after this has lasted for weeks, months, or it may be a year or more, there comes a time when the muscle of the heart participates in the general malnutrition and anemia, and this (as any physiologist may easily understand) is, or may be, a rather serious condition, because the actual continuation of life depends from moment to moment upon the entire functional integrity of that organ. I see not infrequently people who have from various causes—misunderstanding, wrong information, distaste for new foods, and so on—broken through my rules of quantity or dieted themselves in ignorance of the rudimentary principles of nutrition, and it thus comes about that I have observed some very marked cases of cardiac failure as the result of the debility and anemia produced by prolonged underfeeding. Knowing the opinion is gaining ground that it is desirable to live on a smaller quantity of albumin than has hitherto been generally acknowledged as sufficient, I feel it my duty to draw attention to these experiences because I believe that (owing to what I consider erroneous teaching) people may be led to underfeed themselves, and thus enter the danger zone where their hearts may either fail directly or do so when exposed to special strain or stress.

First, then, as to the signs of heart failure. There are so many instruments for measuring blood pressure and other circulation conditions that these signs are perfectly definite and distinct, and those who know how to look for them can scarcely miss them. In my previous writings I have been careful to point out that a distinct ratio exists between the capillary circulation as measured on the skin at the heart level on the front of the chest and the blood pressure; that given the capillary circulation rate in half seconds and the fact that the heart is normal in strength, it is possible to tell with very great accuracy what the blood pressure is, but that when the heart is weak this ratio is definitely and distinctly broken through. It would lead me too far to give full particulars here, but I may mention one or two of the common ratios and show how heart failure alters them. The capillary reflux on the front of the chest is commonly found to be six half seconds, and with a normal heart the blood pressure will be 120 mm. of mercury. If the capillary reflux is seven half seconds the blood pressure will probably be 130 or slightly more, and if the capillary reflux is eight half seconds it will probably be 140 or even 150. Now if the heart fails, you get a capillary reflux of seven, eight, or more, with a blood pressure of only 110 or 120, or at the most 130, and this is a very marked and easily obtainable sign of failure. The other signs are those long known, namely increased action of the heart, showing anything from 5, 10, 15, or even 20 or 30 beats extra in a minute, and some decided increase of the cardiac dullness as measured on the front of the chest, with more or less displacement of the apex beat to the left. There is also a prolongation or may be a reduplication of the first sound over the septum between the ventricles and to the right of the apex beat. I will now shortly mention one or two cases.

A man between 30 and 40 who had been strong and athletic, had adopted an altered diet for a year or two without sufficient care about quantities, being under the impression that if he ate to the limit of appetite he would probably take enough. This is an absolutely unfounded assumption; a man who has been accustomed to a diet of small bulk, such as meat, cannot all at once take the increased bulk of breadstuffs, rice, etc., necessary for his nutrition. After a year or more of this defective nourishment he one day exerted himself more than usual in lifting a heavy weight. He was seized with a sudden pain in the epigastrium and with more or less serious and prolonged collapse, from which, however, he gradually recovered. When I saw him a few days later he had all the signs I have mentioned: there was distinct quickening of the pulse, the capillary reflux pointed to the probability of a blood pressure of 140, but the blood pressure was only 100 to 110. His contention was that though for some months he had been underfeeding, he ought still to be able to perform feats of strength, but this was evidently not the opinion of nature. He was put on

an ample diet, while fluids were reduced to a minimum so as to diminish the driving work of the heart. Rest was advised and a slow increase of exertion, and it suffices to say that in the course of a few months he recovered and had good normal (or almost normal) blood pressure in relation to the capillary reflux. But there must be, I think, some doubt whether a heart which has been strained like this is ever quite as good as it was before.

Another case is that of an anemic woman who had altered her diet without sufficient supervision, and, owing to general delicacy of health and distaste for food decidedly underfed herself. On more than one occasion she had feelings of impending collapse. While in this condition and still defectively nourished, she became pregnant, and then during pregnancy she very unwisely undertook considerable exertion in house hunting and furnishing. Here again the result was strain on the heart, and throughout the later stages of the pregnancy there were very decided signs of this in more or less marked dropsy. No doubt pregnancy is always a strain on the heart, but what I wish to point out is that in this case the heart would probably not have failed even though severe exertion had been added on to the condition of pregnancy, if she had not been defectively nourished for some years.

A third case was that of a man who had placed himself on an approximately uric-acid-free diet without definite medical advice. He suffered slightly from rheumatism and deliberately underfed himself that the rheumatic poisons might, as he thought, be the more quickly eliminated. Here again all went fairly well for about a year or eighteen months, but at the end of that time he had marked signs of collapse after taking some depressing drugs and became extremely nervous, suffering also from insomnia. He then came to me and I found the following conditions: The pulse was 96, on some occasions being as low as 88 and on others as high as 100. The capillary reflux on the chest was 7 to 8 half seconds and yet the blood pressure was only 110 to 120. The first sound of the heart was prolonged and at times reduplicated, and the area of the heart dullness was slightly increased. The treatment here was the same as in previous cases, the three chief indications being to diminish the work of the heart, to increase its nourishment, and for a time the administration of a tonic.

If a patient in this condition has suffered from migraine the headache disappears while the heart is weak, for there is no longer power to keep up the necessary pressure; but it returns as the heart recovers itself. An interesting instance of this was a doctor who went some years ago to the Lahmann Institute, near Dresden, to try and get relief from headache. He was entirely successful in his quest, as the headaches took their departure in one or two weeks, but he got in their place very marked signs of heart failure, for which I had to treat him with considerable care a little later. In this case the blood pressure was only 90 to 100, with capillary reflux of 6 or 7. Later on, with the same capillary reflux, it rose as he got stronger to 120 and later even to 130 or 140. The pulse at first was 72, but it dropped one beat in every 5 or 7, and if these were added the rate would be above normal. From his history it appeared that during the "cure" he had lived largely on salads, which by their bulk prevented him from taking sufficient of the more nourishing foods; and it is evident that by so doing he merely exchanged a slight illness for a more severe one, as high blood pressure headache is rarely dangerous to life while heart failure is so.

So far as I know, these patients eventually recovered, but the signs were for a time sufficiently threatening to cause considerable anxiety to their friends and to their doctors. In another case I have seen more or less decided irregularity of the heart arrising under similar conditions of defective nutrition, but here the problem was complicated by the presence of some excess of uric acid in the blood, which, with a slight debility of the heart muscle, accounted for irregular action. I myself used to suffer from irregular action of the heart in bygone years when I had excess of uric acid in the blood, but in that case there was little or no quickening of the pulse, rather some slowing, and no marked difference between the blood pressure to be expected and the blood pressure I found. In one such case where the chief characteristic was irregularity of the heart action, the capillary reflux on the chest was 6 to 7 half seconds and the blood pressure 140, and though in this case anemia and defective nourishment had probably something to do with the matter there was no definite sign of heart failure, for the blood pressure was about normal in relation to the capillary circulation.

More or less alteration of the first sound of the heart is a common symptom in all cases of raised blood pressure, especially where the heart is beginning to fail; and where it is failing owing to defective nutrition we may find a very decided reduplication of the first sound over the septum of the ventricles.

These cases all occurred in people who had not underfed themselves from want of food but from misunderstanding, or ignorance of physiological facts, or, in some cases, mere indifference and inattention to details, as in the case of the busy man who is unable to give the necessary time to insure the right quantities of food.

Debility from underfeeding may come on so insidiously that it is often far advanced before it is in any way recognized by the sufferer. It is only when he compares himself as he was at some definite date—for instance, the ride of yesterday with the ride of last month and the relative fatigue—that he realizes he is probably not so strong as formerly. This condition is insidious also because, with the decline of strength, there is very often a decline of appetite, which leads to a further loss of both, and when in this condition and weaker than he suspects the sufferer undertakes some unwarranted or violent exertion, such as running for a train or lifting a heavy weight, there may follow a more or less decided collapse. A result somewhat similar to this is not infrequently produced by those who treat gout by low diet together with an excess of fluids, for the purpose of washing out urates from the body, and it is still more likely to occur if while attempting to flood out the poison, they do not stop its introduction in flesh, tea, coffee, etc., for the uric acid which causes the resistance in the circulation is thus constantly poured into the system, while the excess of fluid maintains a very high blood pressure and increases the work of the heart and its tendency to dilate.

There is also a problem of some interest in relation to a portion of our population—I refer to the condition of the poorest classes and the chronically unemployed—for if people who are well provided

with food occasionally suffer from heart failure from defective nutrition, how much more must those suffer who for weeks and months in the winter are on the verge of starvation, though not actually starving. This consideration explains, I think, a fact of some interest with regard to these people, since it is said by observers that after a certain length of time they "lose heart" and are then and afterwards practically unemployable, becoming chronic loafers, beggars, or thieves, or absolutely starving. I believe the condition of these men is probably akin to that which I have described as occurring in the cases which come under my notice, and that when they "lose heart" it means that the heart muscle is at last sharing with the other muscles in the general malnutrition. As the result of this the heart probably fails and dilates and is perhaps never again able to keep up the same blood pressure, to produce the same muscular nutrition, and the former strength of muscle and nerve or of will-power. No doubt if such a man were carefully dieted and rested for months, he would, as in the cases I have mentioned, return to his normal or approximately normal condition. These poor people, however, practically never have this chance, the most they can hope is that as spring comes round a small increase of work may lift them a short distance above the verge of starvation, and their hearts therefore never have an opportunity of completely recovering. Thus these men are permanently debilitated, lethargic, deficient in muscle and mind, and are just the people to be driven to the use of stimulants whenever they can lay hands on them. For debility and underfeeding, especially on wrong foods, create a craving for stimulants to replace even momentarily the feelings of strength. It is small wonder that in winter the public houses are full of those on the verge of starvation, though drink of course ultimately makes things worse and can but increase the debility and malnutrition.

It behoves us as physiologists to point out to the governments of our respective countries that when men and women remain for months at this starvation level, physiological change may occur debarring them from any further fitness for useful work, and that in permitting a section of our population to drop into these conditions we are condemning them to a moral and physical shipwreck of which they can neither avert the inception nor escape the consequences.

Another sign of deficient nourishment is anemia. The ordinary blood color of meat-eaters who drink tea and coffee is about .8 to .85,* while those who have lived for some years on correct diet obtain a blood color of 1.0 to 1.10 and upwards. Yet another danger signal is more or less subnormal temperature. The fire cannot burn up because there is a deficiency of fuel and consequently not enough to maintain the temperature of the body, which is generally from a degree to a degree and a half below normal. Underfed persons commonly have all these signs and symptoms together, and the patients who present themselves with failing hearts and abnormally low blood pressure, are also more or less markedly anemic with a chronically subnormal temperature. There are consequently plenty of signs of the condition under discussion, and it is unnecessary to fall into the error of mistaking it for a normal one. For these reasons I consider it dangerous for anyone to produce less than three grains of urea per pound of body weight per day, or to take less than the albumin requisite for this production, namely, nine grains per pound daily. Sooner or later all who attempt a lower standard develop anemia, debility, subnormal temperature, and, in some cases, added to these, various degrees of heart failure and collapse. The body weight to be used in this calculation is that of the original structure of bone and muscle; therefore, if several stones weight of adipose tissue has been added to this it should be deducted before multiplication by nine. Those who lead a decidedly active life may, however, require a little more than nine grains per pound per day, and they will generally find their appetite leads them to take a somewhat larger amount. On the other hand, the very sedentary, whose existence consists of some fifteen hours' daily resting, and who take only a gentle saunter once or twice a day, may require less than this quantity. But none, active or sedentary, should display constantly anemia, subnormal temperature, unduly quick pulse, and a wrong relation between capillary reflux and blood pressure, and all who on any diet become progressively paler and weaker with subnormal temperature, *even though there is no loss of weight,* are underfeeding and risking heart failure and a condition of debility from which it may be difficult to rescue them.

They are also (as I have elsewhere* pointed out) exposed to considerable danger of microbic invasion and therefore to boils or carbuncles, catarrh, influenza, tubercle, or diphtheria, and have no reserves of strength and endurance for times of stress or strain should these unfortunately come upon them.

In practice I give all adults who consult me nine grains of albumin per day for each pound of body weight, and though this is only a rough guide, it is decidedly better than none. But because it is a rough guide I watch also the temperature of the body, the condition of the blood, the ratio of the capillary reflux to blood pressure, and the other circulation signs above mentioned, and I look upon these taken together as safe and certain guides to a condition of satisfactory nourishment and nutrition.

Far be it from me to assert that there are no exceptions and that no one can live on less than nine grains of albumin per pound daily, but those who do so must demonstrate that all these conditions remain normal, week after week, month after month, and year after year, or they will fail to persuade me that they are not underfeeding and courting danger.

* Medical Record, August 26, 1905.

* It is necessary to add .3 to my old figures to make them comparable to present standards, thus .5 becomes .8. The present standard is about .15 below the color of normal blood and the other .15 is accounted for by my having worked with a color standard this much too dark.

To Remove Foreign Bodies such as calculi impacted in the urethra Schroeter advises the following procedure. If any urine can be made to dribble out past the obstruction the meatus is compressed with the fingers and the patient is directed to continue his efforts until the portion of the canal distal to the obstruction is well dilated; the fingers are then suddenly removed, and in many cases the foreign body will be expelled with the emerging stream. If no urine can be forced past the obstruction a ligature is placed about the penis on the vesical side of the obstacle to prevent its retreat toward the bladder, and the necessary dilation of the anterior urethra is effected by injecting water into it with a syringe; the expulsion is then carried out suddenly as before.—*Centralblatt für Chirurgie.*

SYPHILITIC LESIONS OF THE JOINTS IN HEREDITARY AND ACQUIRED INFECTIONS.*

By ROBERT W. TAYLOR, M.D.,

NEW YORK.

CONSULTING GENITOURINARY SURGEON TO BELLEVUE AND TO CITY (CHARITY) HOSPITALS, NEW YORK.

Syphilitic affections of the joints present many and varied peculiarities in their evolution, course, extent, and ultimate results. In the early stage of hereditary syphilis the gravamen of attack does not, as a rule, expend itself on the joints, but upon the shafts of the bone, and their terminal portions or epiphyses. In the growing bone the length is accomplished by true increase in size of the shaft or diaphysis into the cartilaginous layer which exists at its end between the terminal portion or the epiphysis. This part is called the diaphyso-epiphyseal junction, and it is here that in hereditary syphilis the morbid process is developed in any of the long bones. In the early days this lesion, known as osteochondritis, is the predominating morbid osseous change. As a rule there is no synchronous or complicating joint involvement, except in the parts where the epiphysis is very narrow and the synovial membrane very near or contiguous to the seat of inflammation. As a rule, therefore, we do not find articular lesions in recent hereditary syphilis. As the disease grows older we lose the early osteochondritic changes and observe features in the course of syphilitic osseous lesions which resemble those of the acquired infection. Then we encounter periostitis, osteitis, inflammatory and gummatous, with more or less typical synovitis.

In the acquired infection we find early and late joint inflammation or synovitis, which may be mild and transitory or severe and chronic. In the two cases which I now detail the condition of the knee-joint in early secondary and intermediary syphilis is well shown, and I think they can be accepted as typical in nature and course. The knowledge offered by these cases makes the subsequent development of more accentuated syphilitic joint lesions very easily understood.

Female, aged 22, never having had rheumatism or gonorrhea, nor had her family suffered from rheumatism, had the initial lesion of syphilis several years before, which was followed in a little more than a month by a roseola and a general papular syphilide, and severe rheumatoid pains. These manifestations yielded to treatment in about a month, and she had no other symptoms, to her knowledge, until two years after, when she complained at first of pains along the subcutaneous surface of the tibiæ, the pain being more severe in the left tibia. At the same time also she had pains in the vicinity of the larger joints. There was no febrile movement, and the pains were very much worse at night. In a short time she noticed that the pain became excessively severe in the left knee, and that, although it was somewhat painful during the day, it became of an excruciating character at night. When she moved the leg she said that the pain was not increased, nor did slight concussions, which brought the articular surfaces in forcible contact, cause any unusual uneasiness. At the same time she noticed that the tibia of the left side was more tender to slight than to firm pressure. The knee-joint gradually and slowly enlarged, the process being, however, unaccompanied by any appreciable heat. This effusion lasted several months, and then somewhat subsided, and finally was not to be noticed. The pain remained in the joint for some time, when it again slowly enlarged. The swelling was of an intermittent character, and within a month it could be observed, according to the statement of the patient, that the circumference of the knee varied within considerable limits. The swelling sometimes became acute, then again it would follow a chronic course. When the knee became acutely swollen, she observed distinctly that it was much more tumefied on each side corresponding to the inner and outer borders of the rectus tendon and corresponding borders of the ligamentum patellæ. During the whole time, which was in all six months, she was not confined to bed, but could walk with more or less difficulty, and did not use any local applications, but took some medicine internally.

When she came under my observation she complained of rheumatoid pains in the tibia and a swelling and pain in her left knee. Upon examination I found that there was considerable effusion into the joint, but with no tendency to flexion, however slight. The articular surfaces could be crowded together without pain, and when pressure was made upon the outer surface of the heads of the femur and tibia, a very slight pain was felt. Spontaneous pain was felt during the day, but worse at night. I could not discover, even though I carefully sought for it, any evidence of thickening of the synovial membrane described by Richet, though I thought that although there was no marked tendency to gummy deposits, the chronic course of the lesion might have produced that result; still it is very difficult, in the tumefied state of a joint, to determine this fact, and the thickening would necessarily have to be very considerable in order to be discovered through the integument. Taking into consideration the history of the case, I concluded that it was that form of white swelling described by Richet and Follin, as produced by syphilis, and placed the girl immediately upon antisyphilitic treatment, giving her twenty grains of the iodide of potassium, with the eighth of a grain of the bichloride of mercury three times a day. She used daily inunction of strong mercurial ointment. The immediate result was to alleviate the rheumatoid pains and allow the patient to sleep comfortably at night. Very gradually the swelling subsided, and in three months after, the knee had resumed its natural size, and locomotion, which had been slightly interfered with, was again perfect. During the whole time she had simply used internal and local treatment, and did not, although advised to do so, spare the knee at all. She remained free from any syphilitic symptom for fully three years, when she again had rheumatoid pains through the body, and in the fibrous tissue, with others of an osteocopic character along the tibia, which was slightly swollen upon its internal surface. She was again placed upon the same treatment as before, and very soon lost her pains, and the node upon the tibia subsided. She had also had fugitive pains in the knee and hip, but neither joint was at all impaired.

The lesion in the knee-joint of this patient was evidently in the synovial membrane, as evidenced by the effusion and pain; and from its distinct

* Read before theAcademy of Medicine, New York, in the Section on Orthopedic Surgery, January 19, 1906.

syphilitic history there could be no doubt that its origin was in syphilis. This lesion occurs late in the secondary or any time in the tertiary period, and is due to inflammation or gummy deposits, or both, beginning in the vessels in the synovial connective tissue. This deposit may be very copious, as shown by Richet, Follin, and Lancereaux, and then it will so much thicken the synovial membrane that the fact is readily perceived upon clinical examination. When the deposit occurs in the ligamentous fringes of synovial membrane of this joint, its integrity might be compromised if a proper treatment were not instituted. Follin refers to a case in which the deposit was so copious that it was mistaken for one of fungous disease of the joint, and a surgeon proposed an operation; but as an antisyphilitic treatment was adopted, the lesion in the joint was cured. There can be no doubt that, although in the tertiary period the lesion is a deposit of gummy material, the same effusion may be due to the simple inflammatory action of the syphilitic virus in the later portions of the secondary period, producing an effusion into a joint, in the same manner as it does in the synovial sheaths of tendons. This simple inflammatory action of the syphilitic virus, unattended with gummy deposit, probably also accounts for the rheumatoid pains, they being produced by inflammation of the fibrous structures of joints, muscles, or bones. Then in cases of the tertiary or gummy period we have a regular deposit; as a result of either the membrane may be thickened. The lesions are in the main readily amenable to treatment. The same lesion is said by Richet to coexist sometimes with an osteitis, but in the majority of cases there is no lesion of the bone near the joint, although it may coexist with periosteal thickening elsewhere, as it did in this case, and in others with true nodes. The symptoms of my case are similar to those considered by Richet and Follin, as diagnostic, viz., slow and intermittent effusion, dull pain, not increased upon pressure, but worse at night, and not materially increased upon locomotion, with absence of any change in the integument, and any preternatural heat. In cases observed by Richet, Follin, and Lancereaux, the lesion has always attacked the knee-joint. Other minor joints also are not infrequently attacked.

Case II.—A man, aged 36, had the initial lesion of syphilis many years before, which in due time was followed by regular secondary lesions. These latter persisted for about one year, when they disappeared and he had a respite for several years. In the interval he does not know that he had any cutaneous eruption, and did not suffer from pains. Later he was attacked by rheumatoid nocturnal pains in various parts of the body, which were very persistent. He had also mucous patches upon the lips, which yielded to treatment. Later he was again attacked by the pains, which finally located themselves in the shafts of both tibiæ. The patient described his suffering as being boring and terrific, especially at night. He came under my observation at this juncture, and was then suffering from pains of an osteocopic character in the tibiæ, upon which I discovered several large, hard nodes. At this time the pains had fixed themselves in these bones, and were not of the fugitive rheumatoid character. Besides these nodes I found that the right knee-joint was very much swollen, and there was evidence of considerable fluid in the joint. He stated that the knee had swelled gradually within two months, and that his attention was first called to it by the pain, and in a week or two he discovered that it was slightly swollen. There was then an entire absence of heat, and after remaining slightly swollen it gradually swelled again a little more, then remained a short time in that condition, and then swelled again; and when first seen by me the swelling was very extensive. Firm pressure upon the articular surfaces in any direction did not produce acute pain, but still gave rise to an uneasy sensation. Though the joint was so much tumefied, the patient, who was engaged in mercantile pursuits, went to his business daily, and hobbled around with the aid of a stick. The pain was of a dull character during the day, and was not much, if at all, aggravated by walking, but became intense at night. Careful palpation plainly showed that the synovial membrane was much thickened; this could be well noticed over the four cushions, or those more prominent portions of the tumor on either side of the rectus tendon above, and on either side of the ligamentum patellæ below. The knee was very slightly flexed. Besides the articular and osseous lesions he had an extensive and well-marked palmar psoriasis and a large mucous patch upon the left labial commissure. He had been taking, as I ascertained by seeing the prescription, five grains of the iodide of potassium, with about the thirty-fifth of a grain of the bichloride of mercury. I increased the dose of the iodide to thirty grains, and the mercury to one-sixth of a grain, thrice daily. He also kept a plaster of strong mercurial ointment on the parts continuously. The mucous patch was penciled with nitrate of silver, and the nodes rubbed every night with an ointment of iodide of potassium. The patient experienced immediate relief of his pains by taking the medicine, but fully four months elapsed before the knee-joint became much reduced in size. The nodes gradually subsided. The palmar psoriasis was especially inveterate, but finally yielded to the mixed treatment which I had placed him upon, and also to the topical use of an ointment of nitrate of mercury of one-half the officinal strength, with which was combined oil of cade in the proportions of two drachms of the latter to one ounce of the former. The patient, when I saw him last, was much improved, and he then passed from my observation for two or three years, when I found that his knee was in its normal condition, and had been so for nearly a year, and that he attributed it to the persistent use of the medicine which I had prescribed and of which he told me he had taken increased doses, so that he took about forty grains of the iodide and one-fourth of a grain of the bichloride three times daily. He had not had any syphilitic manifestations in the meantime. He never had pains of rheumatic character until after he contracted syphilis, and his family never was troubled either with rheumatism or gout, nor had he suffered from gonorrhea for many years prior to the appearance of the synovitis in the knee.

In this case the usual clinical history of syphilitic synovitis is well shown. The lesions in the bones and joints were more profound than in the first case, and it is probable that there was gummy deposit in the subsynovial connective tissue, but the synovial ligaments of the joints were probably not much infiltrated. The early and active antisyphilitic treatment probably modified the course of the lesion very much for

the better. The appearance of mucous patches in the tenth year of syphilis is interesting, as showing the inveterate character of these contagious lesions.

While in hereditary syphilis tuberculosis complications are very frequent in the bones, viscera, and the cerebrospinal axis, in the acquired disease this morbid symbiosis is far less frequent, and it is less prone to complicate syphilitic joint and bone structure early in their morbid course. As the disease becomes chronic, particularly when the health of the patient is deteriorated, the tuberculosis bacillus may appear on the scene and produce a mixed and virulent complication.

142 West Forty-eighth Street.

SYPHILITIC ARTHRITIS.*

By HENRY W. FRAUENTHAL, A. C., M.D.,
NEW YORK.
PHYSICIAN AND SURGEON IN-CHIEF OF THE JEWISH HOSPITAL FOR DEFORMITIES AND JOINT DISEASES.

In presenting the subject of syphilitic arthritis before you this evening, it was with the intention of showing:

1. That no doubt many of the cases of acute arthritis in congenital and acquired syphilis, occurring in what is known as the early second stage, are treated as simple rheumatism.

2. The failure properly to diagnose the true pathology of the lesion as syphilitic and treating it as such, may result in a later secondary invasion of the tubercle bacilli or other bacteria, with their comitant sequelæ.

3. That late secondary and tertiary arthritis may be polyarticular and bilateral.

In reviewing the literature of the past twenty years of American medicine, I am convinced that syphilitic arthritis has not received the consideration to which it is entitled, if the observations and statistics of the most eminent Continental observers are to be accepted as accurate, nor does there seem to be such relative proportion of cases as one would expect, if we accept (with allowance) the estimate of cases of new infection accredited by leading syphilologists of this city.

It is claimed by Sturgis, and indorsed by Bulkley and others, that we have 50,000 cases of new infection in the city of New York alone. Admitting that there is a relatively small percentage of offspring from these cases, if their sequalæ correspond to those on the Continent, what are these syphilitic arthritis cases that do occur treated for? It is claimed by Fournier that 39 per cent. of all cases of congenital syphilis have arthritis, and by E. von Hippel that 56 per cent. of all cases of congenital syphilis have arthritis. It is estimated by Schuller that 7 per cent. of all joint diseases in children are syphilitic.

In the late congenital joint manifestation and in the arthritis of late secondary and tertiary origin, we have another form of joint disturbance which is quite frequent in occurrence, but not often diagnosed, and bad results frequently attend the failure correctly to determine the nature of the process, which is often unsuccessfully treated for tuberculous arthritis.

Our actual knowledge of syphilis dates from the time of Columbus, to whose followers is credited the blame of introducing the disease into Europe, where it spread with great rapidity and virulence through the various European countries.

*Read before the Orthopedic Section at the Academy of Medicine, January 19, 1906.

Previous to this, and in the early writings, is abundant evidence of the existence of syphilis.

In an article by Parrott in the *Revue Scientifique* 1882, the author produces some incontrovertible facts in support of the antiquity of syphilis. Baldwin and Tarney ("Syphilis in Dentistry," page 16) say that upon the teeth the imprints of congenital syphilis are tenacious and characteristic. They often preserve their original appearance, not only during the life of the individual, but after death. No other disease, says Parrott, can produce them so that their existence justifies us in affirming that the subject, if affected with such remains, was a syphilitic. He then speaks of the lower jaw of a young Frank of the Merovingians found in a sepulchre at Brenor. The teeth clearly showed lesions such as are produced by hereditary syphilis, and hence this disease existed in France before the seventh century.

In the celebrated medical treatise, "Wei King," compiled by the Chinese Emperor Hoang-Ti, at a time which corresponds to 2637 B.C., there are descriptions of a disease which exactly corresponds to what we know as syphilis, and this treatise speaks of it as a very ancient disease, ancient 4,540 years ago.

The Vedas, the Bible of India, is a collection of writings, religious, literary, and scientific, the latter part being called Ayurveda. The beginning of the period of which the Ayurveda treats is lost in the immensity of time, but it is believed to end about 1000 B.C., or 2,900 years ago. It has many passages which treat of certain diseases whose identity with modern syphilis it were folly to deny.

The works of Hippocrates, written either by himself or his pupils, were composed about the middle of the fifth century B.C., for the Father of Medicine practised at Cos in the year 460 B.C. In Hippocrates' works there cannot be found any exact description of syphilis in the strict acceptance of the term, but there are hosts of allusions which cannot refer to anything else.

Galen, the Greek physician who was born at Pergamos A.D. 131, refers many times to lesions which cannot but spell syphilis, and especially does he speak of peculiar pains of the periosteum which were so deep and constant that the patient believed the bones themselves were the seat of the pains, which were undoubtedly syphilitic.

Pliny wrote upon diseases of the Romans which must be diagnosed as tertiary lesions of syphilis. The Bible is full of fairly accurate descriptions of syphilis.

As a result of venereal affection, joint lesions were known by Petrus Maetyr in 1488. The condition was also referred to by Alphonsus Feirus in 1537 and in the seventeenth century by Maiqugie and Fabie.

It is about fifty years ago that Richet ("Sur les Tumeurs Blanches") gave the first clear account of arthritis as a complication of syphilis. Later Oedmanson established the fact that a papillary synovitis with defects in the cartilage of a joint was of syphilitic origin. This fact was substantiated by Fruger, Falkson, Landner, Schüller, and others.

The varieties of congenital arthritis may be grouped under the following classes: (1) Simple synovial (which is most common). (2) Arthritis associated with syphilitic epiphycitis. (3) Gummatous synovitis. (4) Osteitis with synovitis. (5) Deforming arthritis.

The diagnosis of congenital syphilis mostly depends upon the following:

(1) Finding of the Spirochæta pallida.

(2) The parental history. In entertaining the history of patients, we must question the truthfulness, as there is often a great desire to hide early indiscretions, and we must bear in mind that many acquire syphilis innocently. According to

Fig. 1.—Case No. 6.

Buckley, in his private practice 50 per cent. are innocently infected; according to Fournier, 25 per cent.

(3) The skin gives us evidence, either from the scars of eruption, or the peculiar white, waxy color so characteristic of syphilis. In the lower half of the face there exists peculiar linear or streaked scars, or more properly pseudo scars, radiatory from the mouth and lips and extending over the upper lip, chin, and cheek, and give the face an expression of old age.

(4) In the eye we have an interstitial keratitis, the most frequent symptom of congenital syphilis associated with arthritis, between the ages of six and sixteen years. We may have a history of iritis which generally precedes, or is associated with early acute congenital syphilis, between the second and sixteenth months. In a report by E. von Hippel (*Münichener medizinische Wochenschrift*, 1903). out of thirty-two cases of congenital syphilis, the joint affection precedes keratitis. About half of these cases occurred between the sixth and tenth year. The fact that almost always the joint trouble precedes the keratitis is of great importance, inasmuch as by that we are deprived of a reliable sign in making a diagnosis. Edmund Fournier (*Annales de Derm. et Syph.*, 1904, p. 152) and some other French writers lay great stress on the findings in the fundus of the eye as an aid in the diagnosis of hereditary syphilis. Antonelli speaks of vascular changes and alterations of pigment which could only be the stigmata of hereditary syphilis.

(5) In the teeth we have certain notched defects of the inner upper incisors (*Selix Bel Klin. Woch.*, February 24, 1896). I have not used the term "Hutchinson teeth," as authors differ in their description of them.

(6) Labyrinthine, or central deafness, due to lesions of the auditory nerve, is found in children between ten and fifteen years, in congenital syphilis, which is the age of most frequent joint involvement.

(7) Ulcerative destruction of the soft palate should be regarded as syphilitic, and will aid in confirming a diagnosis of syphilitic arthritis.

(8) Enlargement of the spleen is also frequent in congenital syphilis.

(9) Syphilitic epiphysitis is characteristic of congenital syphilis, as has been described by Barlow, Fournier, Parrott, and Taylor. As to its pathology, we find at the juncture of the epiphysis and diaphysis an increased number of proliferating cartilage cells and retarded ossification of already calcified tissue, producing an area of irregular thickening, on section we find a reddish-yellow zone of degenerating cartilage cells running across the epiphysial cartilage. The vascular supply is either arrested or interfered with, and in consequence a low form of inflammation is set

Fig. 2.—Case No. 6.

up, and a layer of necrotic tissue formed. When the destruction of tissue is sufficiently great, it is at this point that separation between the epiphysis and diaphysis takes place.

(10) General lymphadenitis should excite suspicion of syphilis.

(11) Sclerotic atrophy of the testicles occurs in hereditary syphilis.

(12) We can confirm our doubtful diagnosis by a course of antisyphilitic treatment.

There is a class of cases that I wish to call attention to in congenital syphilis, similar to those described by Fournier (83), von Hippel (42), Hutchinson (20), Chilton (11), G. H. Dunlop, and others.

The first case I present then was a history of syphilis in the patient, together with other symptoms which can be accepted as syphilitic.

Case I.—Female, three and one-half years, has had a knee flexed and swollen, with a discharging sinus on the outer aspect of the left knee. The pus contained tubercle bacilli, according to examination previously made at a general hospital, corroborated by the Board of Health. The ankle on the same side was swollen and tender. Knowing the previous history of the parents, the child was placed on antisyphilitic medicine. The ankle

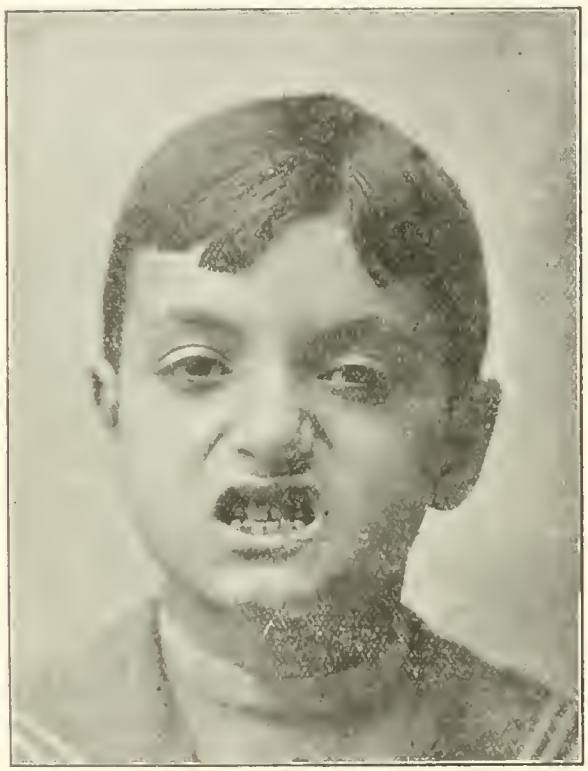

Fig. 3.—Case No. 7.

cleared up and the knee got well after one year, in straight position ankylosed. The mother was confined four and one-half years previously. The care of the first child and of the mother was turned over by me to Dr. S. Twinch. The child died in three weeks of acute syphilis. This is the first case that corroborated an opinion I had entertained for some time previous of tuberculous invasion of a syphilitic joint. It is generally regarded that syphilis and tuberculosis are antagonistic. But in my opinion there is no reason why active tubercle bacilli should not supplant attenuated *Spirachætæ pallidæ*.

Case II.—H. B., female, age five and one-half years. Patient had been operated upon for tuberculous glands, so-called, during my absence on my summer vacation, and on my return in September she was brought to me for what had been called a white swelling of the left knee. The child looked frail, skin white and waxy, had a synovitis of the left knee, slightly painful, with night pain occasionally. Knee slightly flexed, and swollen three-fourths of an inch larger than the right. Being familiar with the syhpilitic history of the father, I treated the patient with mercurials. The synovitis and swelling disappeared in two weeks.

The diagnosis was based on the father's history, the appearance of the child, and the improvement in the arthritis and adenitis under antisyphilitic treatment.

Case III.—Female. A sister of the previous patient was taken with an attack of arthritis in both knees. The family, living in Harlem, called in a physician at night, who diagnosed it rheumatism, and antirheumatic treatment was continued for three days, when the father, suspecting the cause, requested me to call. Under inunctions of 50 per cent. mercurial ointment, with 1-100 grain bichloride of mercury, every four hours internally for three days, the symptoms all disappeared; the joints were painful, the temperature varied between 99° and 102.5°.

Case IV.—S. E., female, age four and one-half years. Patient when presented had a swollen knee, slightly tender, that had been noticed three days previously. On rising, the child complained of tenderness, and the range of motion was limited to about 20°. The general appearance of the child, the loss of nearly all first teeth, the appearance of the eyes, together with profuse nasal discharge, prompted me to add mercurial treatment to the fixation in plaster. On April 14, 1905, I showed the patient at the Eastern Medical Society, when the synovitis of the knee was about well, but on the body was to be seen a papular eruption that had just begun to fade. The brother had been a patient at Bellevue and wore a jacket three years. I am of the opinion that in his case there was a syphilitic focus, which became tuberculous infected.

Case V.—Z., female, ten years old. Patient consulted me regarding a mass of broken-down cervical glands, which were opened and drained. She gave a history of two attacks of rheumatism while a resident of Buffalo. The left knee was swollen, the temperature was 101.5°, pulse 104. The father's syphilitic history caused me to treat the patient with mercurials, and she was salivated in forty-eight hours with 1-10 grain calomel, 3 grains bismuth subgallate, together with mercurial inunctions. The joint symptoms immediately cleared up. The diagnosis was based on the appearance of the skin, teeth, and general lymphadanitis, and the father's infection. Promptly responded to treatment.

Case VI.—Female, aged 14. Patient sent from the St. Elizabeth Home. Left knee flexed and swollen, not very tender, no family history. Had been operated upon for glands in the neck, which showed a long scar. Skin lesion about the nose and appearance of teeth caused me to make a diagnosis of syphilis. The knee was ankylosed with a long plaster splint from ankle to groin, made removable. Manual inunctions were given over knee and internal medication given. Cured in four weeks. Knee is perfect in outline and function. The diagnosis was based on the presence of scars on the face, the teeth, the eyes, and the presence of coryza. Prompt cure on antisyphilitic treatment.

Case VII.—Joe S., male. Came with mother to consult me, as mother wished to avoid an operation which had been advised by another doctor for a supposed tuberculous abscess of right

hip. A large mass extended half way down to the knee, soft, but not fluctuating. From the appearance of teeth, and mother's history, I concluded to try mercurial inunctions and internal mixed treatments. To my surprise the mass disappeared. Patient had worn a splint two years.

Fig. 4.—Case No. 10.

There is no shortening and he is now wearing a convalescing splint.

Case VIII.—Ada R., female, aged 13. Patient had been treated some time for swollen knee. I was consulted in May, 1904. Knee much swollen, red, but had an unusual range of motion for the amount of swelling; it was put in a removable cast for two months. A few weeks later it discharged pus from three openings. The swelling decreased about two inches and a decided thickening could be felt in the end of the femur and synovial membrane. Patient shown at the March meeting, 1905, of the Orthopedic Section; also at the Eastern Medical Society, April 14, 1905. The diagnosis was based on the family history. Treatment has also cured the condition of the knee, and there is little interference with joint function. Patient is still wearing splint.

Case IX.—Charles S., male, aged 6 years. Patient consulted me after the diagnosis of Pott's disease had been made at the Catholic Protectory and confirmed at one of the orthopedic hospitals in this city. Knowing the history of the mother, I placed the child on antisyphilitic treatment. The jacket was worn until last September, in all three years. Normal function of spine; no deformity. There still remains the enlargement of all inguinal and cervical glands.

Case X.—A., aged 10 years. Patient had an attack of fever, temperature 101.6°, with swelling of right knee. I knew the father's history, who was a syphilitic. I salivated the patient in three days by calomel and inunctions. The diagnosis was based on the father's history and the teeth. Patient's knee is now normal.

Case XI.—S., female, aged 22. May, 1896. Contracted syphilis from the father of cases II and III by lip infection. I was called to see her May, 1896, for supposed tonsillitis. The appearance of her throat, together with initial lesion on lip and enlarged cervical glands, made me sure of a diagnosis of syphilis, which so offended the patient that I advised her removal to Roosevelt Hospital. There the initial lesions and the right cervical glands were removed and antisyphilitic treatment was begun. Patient on leaving hospital discontinued treatment, and on May, 1898, she was taken with an attack of arthritis involving both knees and the right ankle. This, under mixed treatment, disappeared in seven days. The patient has had no recurrence of her arthritis, but she has continued with the treatment.

Case XII.—H. G., male. Case of recurring syphilis, involvements of wrist, treated by Dr. Taylor and later by myself. Patient has had relapses. Has history of locomoter ataxia, with frequent gastric crises. The ataxic gait has not increased for three years.

Case XIII.—Patient married, no children. Developed tender spot in spine. Wore jacket several years. Had three serious operations for pus in the abdominal cavity. This was due to necrosis and possible breaking down of the abdominal glands. The deep inguinal and iliac, the retroperitoneal prevertebral glands; as a rule these deep glands are involved in the latter period of syphilis and bear the same relation to visceral syphilis that the superficial ganglia do to the affection on the skin and mucous membrane. No knuckle has appeared. Drainage, mixed treatment, and electricity used. Sinus has closed and patient is able to go about and is well. It is said to be pathognomonic of spine syphilis that angular deformity does not occur, unless we

Fig. 5.—Case No. 14.

have tuberculous invasion. (Froechlich *Presse Médicale*, 1904, No. 46.)

Case XIV.—H. G., male, aged 23 years. Gives a history of acquired syphilis three years ago, at present has gummatous thickening of synovial sac and at the end of the right femur there is a

bony exostosis. Thickening about left ankle. The patient has improved under mixed treatment.

Case XV.—Male. Consulted Dr. Constable, of this city, for swelling on left side of neck. Dr. Constable had a pathologist make an examination of section removed from mass in neck, who made diagnosis of malignant growth; on this, the extirpation of lower jaw was advised. Patient then came under my observation. Had had an undoubted chancre of the lower lip. Under mixed treatment the growth disappeared. Patient did not live in the city and did not keep up treatment. On May 2, 1892, I was called to see the patient, who was in bed with a sore throat; he also had acute synovitis of the left ankle and knee, but they gave scarcely any pain. His mouth was filled with mucous patches. Temperature, 102.2°; pulse irregular. He said that he felt distressed in the region of the pericardium. After careful examination, I made a diagnosis of syphilitic pericarditis and myocarditis; cautioned him to keep quiet. I secured a nurse to take care of him, and prescribed inunctions and calomel. He improved rapidly and felt much better after 48 hours. On the night of the third day, while the nurse and his wife were looking out the window, he got out of bed and lighted the gas. The next day I called about noon and found him much improved in appearance, the condition of his mouth and throat and the synovitis of his knee, but cautioned him again about keeping quiet, as his pulse was still irregular and of poor character. Shortly after I left, the nurse went to the drug store, he suddenly sat up in bed and dropped dead. The mouth and throat had an appearance that is only produced by syphilitic mucous patches.

Case XVI.—Male, aged 43. Was seen by me first January 3, 1893. Had been treated for rheumatism of right knee and cellulitis of the leg. It was clearly syphilitic. He had lost all his teeth from his previous course of mercurial treatment. Although his synovitis cleared up, his ulcer from the broken down gumma did not heal until March 11, 1894. On September 23, 1894, owing to a cold, followed by a severe chill, his left leg and knee swelled and a large area of tissue broke down, extending from the ankle nearly to the knee. Under inunctions and internal medication, the synovitis cleared up in three weeks, but an ulcer as large as my hand remained, the tissue of his leg refused to granulate in. Iodoform and balsam of Peru and other stimulating applications failed to excite new granulation, but instead seemed to destroy tissue. After several consultations with Dr. Edward L. Keyes, to determine a means of encouraging granulation, a zinc vat was made, so that when the patient was in the sitting position, it would reach to the popliteal space. In this the patient placed both legs, and for nine hours a day retained them in water kept at a temperature between 101° and 103° F., by a gas stove. No one but a stoical German could have had the patience to continue this treatment for weeks; after the lapse of ten months continued persistent treatment to July 30, 1895, the ulcer healed, after which it was impossible to induce the patient to keep up medication. On November 15, 1898, I was again called for a synovitis of the right shoulder, with a cellulitis of the arm and shoulder. On the 18th, patient developed cerebral symptoms; on the 20th, Dr. Keyes again saw the case, with me in consultation, and confirmed my diagnosis of syphilitic meningitis. Patient died November 21, 1898.

As to the time of the appearance of congenital syphilis in the syphilitic parents bearing apparently healthy children, Fournier (*Journal de Médecine et de Chirugie Pratiques*) states that of 282 such cases, 251 occurred between the third and twenty-eighth years. In congenital syphilis the most frequent lesions are in the eye, while in the acquired form the most frequent lesions are in the skin.

In acquired syphilitics we may class the lesions as follows:

1. Arthralgia. This is not an arthritis, but pains about the joint.

2. Synovitis. This, with the accompanying pain, tenderness, and swelling, together with a high temperature, gives it the appearance of rheumatism, but there is no acid sweating or cardiac complications. It is described by Fournier, Finger, and Sherren.

3. Gummatous disease may appear first as a simple synovitis, later an irregular thickening of the synovial membrane may be felt, due to gummy deposits. In this form the pain is severe at night and the disease may be regarded as tuberculous.

4. We may have arthritis from extension of disease and thickening of the articular ends of the bones from the cartilage.

5. We may have it by extension of the gummatous process into the joints.

In the presence of *Spirochæta pallida* we have found an aid to the diagnosis of syphilis in the first and second stages that should aid us greatly in future diagnosis.

We are able to differentiate it from tuberculous arthritis, for which it is frequently mistaken, by the absence of pain, by the fact that it is often bilateral in its occurrence, and by the small amount of functional disturbance. When we find other evidence of syphilis, we should always give the patient a course of antisyphilitic treatment.

C. F. Painter, Hutchings, G. H. Dunlop, and others have reported the finding of tuberculous invasions of syphilitic joints. It is after a mixed infection that the joint inflammation fails to yield to mixed treatments.

It will be found that the synovitis, like other syphilitic manifestations, yield promptly to mixed treatment. I have used the bichloride 1-100 grain, with 2 grains of bismuth subgallate, in children; and 1-4 grain proiodide, with reduced iron 1 grain internally, combined with inunctions of 50 per cent. mercurial ointment and 50 per cent. crede ointment over the joint. We should lock up the joint in a plaster splint to rest the inflamed foci during treatment.

If the estimate of the relative frequency of arthritis in hereditary syphilis as given by Fournier, E. Von Hippel, the Hutchinsons, Chilton, G. H. Dunlop, and others is correct, we may ask: Do we have a similar proportion of such cases in New York, and if so, what are they treated as? In articles on rheumatism and arthritis in children they are not even mentioned in the differential diagnosis.

Failure to recognize the syphilitic origin of arthritis exposes the patient to the danger of secondary invasion of pathogenic organisms.

In conclusion I wish to say that if syphilitic arthritis is promptly diagnosed and properly

treated, a complete cure is easily effected, while if left untreated or improperly treated, incurable changes may result, or secondary invasion of other bacteria may occur.

CONSERVATISM IN THE TREATMENT OF SENILE HYPERTROPHY OF THE PROSTATE.*

By JOHN VAN DER POEL, M.D.,

NEW YORK.

In considering the subject of conservatism, or, more correctly speaking, catheterism, in the treatment of senile hypertrophy of the prostate gland, I do not wish to be understood as being too ardent an advocate of the employment of the catheter to the exclusion of radical treatment properly applied, *i.e.* at the right time, but more to lay stress upon the idea that if this side of the question were more fully considered, I think operation would be less frequent, and we would perhaps see fewer of the cases which may be rightly said to be unimproved, still with frequent micturition or still using the catheter, or with incontinence or dribbling from a fistula, or even passing fecal matter through the urethra—probably a worse condition than before operation.

That the improved modern technique in prostatectomy has greatly enhanced the outlook for this class of patients cannot be denied, and to it a large number now in good health undoubtedly owe their lives; but this does not alter the fact that the reverse is sometimes the case, or that the study of the other side of the quesion has not likewise produced good results. Nor can it be denied either that the skill of operators varies as individuals, or that the individual operator varies in his results as he advances in experience, for it is evident that our second half-dozen prostatectomies are done somewhat differently from the first, and the third again somewhat differently from the second.

The great drawback to catheterism is its improper and difficult application. Among the working classes it is very evident that aseptic catheter life is, as a rule, impossible, and even among the well-to-do we readily recognize how difficult it sometimes is to have it properly carried out. Still, when possible, the difficulties at the beginning are usually surmountable, and as Escat says (in a recent report to the French Urological Association), "it is at least a method sufficient to assure patients of a tolerable life, compatible with their age." The bladder, and secondarily the kidneys, gradually become accustomed to its encroachments, often with a steadily diminishing risk of infection, though when badly used it becomes powerless to relieve the patient from the troubles from which he is suffering.

With these patients of the poorer walks of life, where their surrounding conditions make surgical cleanliness impossible (providing the symptoms and findings require it), operation must be considered much earlier than would otherwise be the case, by whichever method or route we deem best, while perhaps the bladder is still clean, when the conditions of course would be most favorable, or, if not clean, after a course of bladder irrigations and urinary antiseptics. But should the patient be of the well-to-do class, or should he be cleanly in his habits and intelligent, catheter life may be possible, and is permissible, but both sides of the question should be presented. He should not only be made thoroughly aware of the chances of infection of both bladder and kidneys, and should be given to understand that the use of the catheter will be continuous (excepting in certain cases), but also the dangers of operation—other factors, kidneys, and general condition, being equal—should be thoroughly explained. And still further, the chances of "failure to benefit the condition" should be gone into, for undoubtedly there are failures, or comparative failures, more, perhaps, than are generally admitted, and if they were always reported as such, considerable information would be gained. I have at present under observation a patient from whom I removed the lateral and median lobes some three years since, all of moderate size, though the median was proportionately much larger than the others. The immediate recovery was rapid, but although there are no more attacks of retention and there is no more residual urine, there are periods of incontinence at night, and micturition, although not so frequent as before, is still ten to eleven times in twenty-four hours. (I do not speak of the causes of these complications, but simply of their existence.)

Again, a patient of eighty-one years, who had had complete retention for ten years, and who had carefully and successfully catheterized himself during this period, whose general condition was excellent for a man of his years, but whose trouble had been aggravated by the formation of calculi, which upon instrumental examination, by cystoscope, and by the *x*-ray plate, proved to be of good size. The question was between removal of the stones, either by litholapaxy (which in his case would have been difficult on account of the enlarged prostate) or by lithotomy and removal of the prostate together with the stones, which latter course I thought indicated, as it was a septic bladder with chronic retention, while the general condition was good. I did a perineal operation. The result was good primarily, his recovery was rapid, and catheter life was discontinued, but, due probably to thinness of the bladder wall immediately behind the prostate where the stones lay, together with his age and poorly resisting tissues, a rectovesical fistula resulted, though at the time of the operation I could discover no injury to the rectal wall. Through this fistula fecal matter passed into the bladder, and from the bladder through the urethra.

Again, in another case, with moderate enlargement combined with calculi, in which prostate and stones were removed at the same time, there are still prolonged attacks of cystitis, with frequent and painful urination, although thorough examination fails to give evidence of any more calculi.

These can scarcely be considered as exceptional cases, and perhaps most operators can cite similar ones; and failures, as we know, are more instructive than are successes.

A class not infrequently operated upon, wrongly so I think, includes those with large, overdistended, atonic bladders, which have lost their power of contraction, a condition best ascertained, though not perfectly so, by observing the force of the stream through the catheter as it falls perpendicularly. These so-called large "silent bladders" do not often recover their tone, and after operation as a rule require catheterization as before. I have at present two patients belonging to this category. One is an excellent surgical risk, sixty-eight years of age, with kidneys which functionate well, with at present practically no obstruction at the neck of the bladder (a Nélaton being used), where the base, however, is depressed and a large pouch exists behind the bar, which is present, and where, although the lateral lobes are reduced to one-half their former size (one

*Read at a meeting of the Alumni Association of the New York Hospital.

side much more than the other) from decongestion due to regular catheterization, he is still unable to void one drop of urine without the aid of the catheter. Should his prostate be removed, or should a Bottini or Chetwood operation be performed, his bladder would still, I think, be unable to contract, he would still either be obliged to use a catheter or would suffer from incontinence, for it is rare that these cases of long standing recover their muscular contractility. The second case—a somewhat similar one—is that of a man who, though he is able partially to empty his bladder, never has less than twenty ounces of residual urine, and when I first examined him, I risked drawing off thirty-seven ounces. His prostate was large, the obstruction was great, and in all probability could have easily been removed, but the contractile power of the bladder was mostly gone, and although he might perhaps have recovered it to a slight degree, he too, I think, would have been left worse off than before, had he survived operation.

Somewhat similar to these, as regards the eventual outlook for muscular power, are the little irritable bladders with chronic cystitis, the small trabeculated and sacculated bladders, with partial retention, the "sclerotic bladders." In these, too, it is very questionable whether prostatectomy or prostatotomy would be of value, as the muscular layer has almost, if not entirely, disappeared, and has been replaced by the bands of connective tissue which we so easily see with the cystoscope.

Another important class contains those in whom we find a moderate enlargement, combined with a slight increase in the frequency of micturition, with a moderate amount of residual urine, one to two ounces, or perhaps more. These patients are in the first stage, or beginning of the second, in which condition they may remain for years, without ever reaching the stage of retention; for, as we know, there are but few old men who are not troubled with some increased frequency at night, and with some little inconvenience in completely emptying the bladder in the morning. With them it is generally agreed that not only is operation contraindicated, but likewise the catheter, for, as Thorndike says, "they can usually be made comfortable for months, and perhaps years, with proper attention to hygiene and urinary antisepsis." But when the obstruction has progressed farther, and the residual urine has increased from four to six ounces, it is evident that other means must be thought of—either catheterism, or operation if the case is not suitable for the catheter.

The old and weak frequently consult us, and often in such condition that they are physically beyond the point where we would care to risk operation (*i.e.* poor surgical risks). When the catheter is properly applied, these patients can frequently, and perhaps in the large majority of cases, be made comfortable, "sufficiently so to assure them of a tolerable life compatible with their age."

It must be admitted, however, that in many cases, catheterism, if persisted in, will undoubtedly lead to a fatal issue, much sooner than if radical operation were performed, *i.e.* in septic and poisoned cases, and yet there are so many types, and so many phases in the different types, that it is impossible to give an absolute rule, but each must be studied by itself, that we may decide when catheterism is permissible and indicated and when it is contraindicated.

As a rule the symptoms as presented to us are so characteristic, that a diagnosis can often be made from the history alone; on the other hand, as we know, there is not an inconsiderable number whose troubles come on very gradually or who, either from apathy or disinclination to treatment, do not seek relief until some severe disturbance in their general condition (the gastrointestinal troubles of the third stage) appear, when our attention may be entirely diverted from the local condition. Although this may not be of frequent occurrence, it occurs, nevertheless, and suggests a more intimate acquaintance with exact symptoms, especially as referable to the three stages, the boundaries of which it is well to bear in mind, and greatly in accordance with which our treatment is directed, for although treatment in general is symptomatic, we seek not only immediate relief, but must look also at the eventful outcome and chances for permanent relief.

The first stage, the prodromal, premonitory, or developmental period, is characterized by the fact that the bladder is still able to empty itself, but the patients complain of frequent desire to urinate (often urgent), with, later, difficult micturition and not infrequently polyuria (most marked during the night), while the power of expulsion may become lessened, with consequent absence of force in the stream, which often even then falls perpendicularly from the meatus. These symptoms are explained by the condition of *hyperemia* which exists in the prostate and submucous tissue.

In all forms the prostatic, periprostatic, vesical, and rectal plexuses are filled with blood, and any increase in this leads to an exacerbation of symptoms and *vice versa;* hence the trouble is apt to be more marked at night, or in those leading a sedentary life, and where constipation is a prominent feature. Tuffier claims that not only are all subjective symptoms referable to it, but in the large majority of the cases also the palpable enlargement per rectum, and this at least seems partly true in that class of cases in which, after systematic catheterization, the volume of the gland is reduced by what the French term "decongestion." "This condition of congestion and edema also explains the irritation, resulting in spasm of the sphincter and retention, when, the longer the retention the greater the congestion and edema, and the tighter the closure of the opening, which, if allowed to continue too long, not infrequently leads to paresis of the bladder from overdistention, which immediately places the patient in the second stage, although when properly cared for the first stage may last for months." (von Fritsch.)

It is thus evident that treatment should be directed toward relief of this congestion, and that our efforts should be directed toward bringing this about. All habits, mode of living, diet, and exposure which tend to cause it should be discontinued, and this alone will not infrequently put the patient in his normal condition.

Internal remedies, with the exception of cathartics to empty the rectum or urinary antiseptics, are probably worse than useless—an occasional sedative perhaps excepted; but of the two antiseptics most in vogue, urotropin and salol, I much prefer the latter (either alone or in combination with the former), with either a clean or an infected bladder, as in both types it usually tends to relieve irritation, often to a very marked extent.

A form of treatment to which I think too little attention has been paid, to be recommended, however, only in the glandular variety of enlargement and more particluarly in the early stages, is massage, or pressure on the prostate, to endeavor to lessen congestion, to empty the follicles which are often still at fault, as the remains of an old prostatitis, and, if not too late, to stimulate muscular con-

traction. In the fibrous forms, however, this is not only of no use, but often adds to the irritation. Again, the passage of a large-sized steel sound, if possible, not only often acts in the same way, but also enlarges the bladder opening itself.

How abdominal massage can lessen the local congestion, excepting by stimulating the general abdominal circulation, or by increasing peristalsis, and so emptying the rectum, it seems difficult to explain, but it is a fact nevertheless that it is of considerable value in lessening painful and frequent micturition.

With the advent of retention, however, the catheter is bound to come into play, perhaps temporarily, perhaps permanently, unless radical treatment is decided upon; and, on account of the dangers and risks involved in its use—infection, false passages, hemorrhages, etc.—and from the fact that the surgeon in consequence must assume considerable responsibility, argument is made in favor of the so-called "prophylactic operation." We know, however, that patients are submitted to the catheter for years and die eventually of some disease having no connection whatever with the genitourinary organs; and, as we have seen, a large number of old men of the first stage never reach the point where they are obliged to use the catheter, but where regulation in their methods of living and hygiene relieves local congestion and places them again in a comfortable condition. Certainly with them a prophylactic prostatectomy would be manifestly improper. But sometimes this is not the case, and following an acute congestion there may be an acute retention. Clean catheterism can place these patients again in the first period, after which it may be abandoned, and they may be left to their ordinary vocations, the wiser for their experience. I do not think it, therefore, justifiable that any operation (prostatectomy or prostatotomy) should be performed at this period, at least, the premonitory, as it would be for the relief of a condition which may never come or for accidents which may never happen.

In acute complete retention, catheterization is often an extremely difficult undertaking, requiring great care, both in the choice of instruments and in their introduction. For the latter, considerable information may be gained, not only by the usual rectal examination, but by exploration of the urethra either with the silk bougie à boule, as von Fritsch recommends, or, better, with the same instrument arranged as a fine instillator (the instillator of Guion), through which a weak solution of cocaine or cocaine and adrenalin can be injected—often with great advantage—into the prostatic portion, to promote the "decongestion" and shrinking of the superficial parts, which often facilitates the passage of the catheter afterward.

Should it be impossible to pass the catheter, our best immediate resource is aspiration, but not too long delayed, while waiting for the occasionally favorable action of hot sitz baths or the impossible action of drugs, for if the distention becomes too severe and too great, partial paralysis of the bladder muscle is apt to occur, which may never again recover its tone.

With the advent of bladder insufficiency and residual urine, the second stage is reached. This may develop slowly, or be the result of an acute retention, but as soon as the insufficiency causes residual urine of from three to four or six ounces, after the milder means have been used and have failed, the catheter is indicated; sometimes we may then be rewarded by a return to the first period, and when not, we can at any rate avoid the third.

Acute retention may occur at any period of the "prostatic age," with or without previous symptoms, or simply as one of a number of recurrent attacks added to a chronic incomplete retention, and when the latter, it must be classed with the chronic cases.

Shall we remove the prostate at this period?

Catheterism, though impossible in a large number of cases, may in others definitely reestablish the urinary function for many years, no matter what the volume of the prostate, and with it, even at advanced age, micturition will be reestablished in a comparatively few weeks, if the retention has not been allowed to exist too long, causing extreme dilatation, with consequent paralysis or partial paralysis of the detrusor muscle. Neither the age of the patient nor size of the prostate indicates whether we are starting with a chronic retention or not, though in this light a small prostate can be regarded as more favorable than a large one.

Impossible catheterism is exceptionally an indication for operation, but if the prostate is infected, (*i.e.* if an abscess has formed), if the previous micturition has been unendurable, with a rebellious cystitis, and these cases are rare, operation must be considered. (von Fritsch.)

Prostatectomy has given good results, as we know, but we take the chances of complications and death, especially so after a partial operation; is it fair to take these chances? I hardly think so; at least, catheterism should be given a chance of doing all that it can before radical intervention is decided upon.

Suprapubic cystotomy has been tried, and with advantage in those cases in which catheterization is difficult or impossible, or on account of the dangers of false passages, hemorrhage, and infection, but if the bladder is clean to begin with, it often becomes infected before the fistula heals, which usually happens when the tension and swelling of the prostate are reduced, and the urine resumes its natural passage. Poncet, whose statistics on this subject are, I think, the largest (though not absolutely conclusive), gives 37 out of 39 aseptic cases as healed, but among 29 patients with acute infection, 16 died, and among 46 with chronic infection, 13 died; while among 34 in which urination through the urethra was not regained, the fistula was permanent. Although other operators show a better mortality percentage, I do not think it a warrantable procedure, except as a preliminary drainage for prostatectomy, either from above or from below, or in very elderly and feeble individuals, or when the bladder is paralyzed, and systematic catheterization is too difficult or is impossible for any reason.

The period of incontinence from continuous distention, the third stage, is the most important and the most dangerous one we have to deal with, with its harmful consequences upon the kidney, with sometimes almost constant strangury, increased at times by enormous polyuria from backward pressure, irritation, and hyperemia of the kidney substance; and when this causes absorption by the blood of toxic substances, with also the well-known picture of intermittent fever, gastrointestinal troubles, and cachexia, which Guion says is due to both a urotoxemia and a urosepsis. Should this not have gone too far, should the changes in the kidneys not be too far advanced, catheterization is often able to place patients back again in the second stage. But with the first few attempts especially, particular care must be observed, as they are old men with lowered vitality, in whom too rough or too prolonged urethral manipulation is liable to be followed by an increase of septic symptoms; while at the same

time the precautionary measure of but partially emptying the bladder, or, better still, of gradually refilling it with a weak silver or boric acid solution, should not be disregarded, for not only is there danger from hemorrhage and shock, but also, should we not be dealing with a septic case, these bladders, when emptied entirely, creating a so-called vacuum, are much more prone to infection than when partially filled, perhaps on account of the thinness of the walls and lessened resistance from inside, permitting an easier entrance of germs.

In uninfected cases, at first at least, the risk of infection should be reduced to its minimum by the least number of catheterizations possible; then after a time the bladder becomes acclimatized, so to speak, and the danger is less, while at the same time, the congestion and edema having become less, the residual urine is not so great and the necessity for frequent interference is less urgent. However, notwithstanding careful and methodical treatment, the enlargement may not decrease, or it may steadily increase, with or without infection, notably in the fibrous or scirrhous form; hence sometimes a chronic incomplete retention will become complete.

In chronic retention the differentiation between infected and uninfected cases is most important.

If the case is aseptic, I think catheterism is as a rule preferable to operation, for although patients are especially vulnerable at this period, we can often get over the crisis without infection; though it is but right, also, that the question of prostatectomy should be considered; and it is just here that the difference of opinion is most marked as to which is the more justifiable course. It must be admitted that the lesions and local troubles due to distention do not contraindicate prostatectomy, and that the operation protects the urinary apparatus from further absorption besides avoiding septic infection, acute pyelonephritis, and acute prostatitis, but whichever way we decide, aseptic catheterism at any rate often places the patients in good condition, either preparatory to operation or not, though we must also remember that we run the danger of infecting a clean bladder, in case we do decide to operate. Age, social condition, vesical contractility, general condition, and state of the kidneys, must necessarily enter largely into our making a decision.

If the retention is incomplete (100 to 300 c.c.), the case is usually less grave, the urinary intoxication is less; and since there is no marked distention of the bladder, there is none of the kidneys, and the chances for either catheterism or operation are better.

If the case is septic, and especially if it has been so for a long time, clean catheterism seems often powerless to eradicate the general and local effects of previous careless treatment or long-standing infection from any source; and although the catheter, and especially the retained catheter for a short time, should and does relieve the symptoms (retention, infection, pain, cystitis, and hematuria) in many cases, there are also many where it fails, and then operation is not only justifiable, but it is our safest and best recourse, providing age, general condition, and kidneys permit. It also cures the retention, pain, and infection, besides the sometimes persistent hematuria, and in this hemorrhagic form, especially when the kidneys are but slightly affected, Albarran claims that the best results are obtained. In acute renal infection, the immediate risks contraindicate an urgent operation, but in general the rule is good that "where conditions of resistance are sufficient, prostatectomy is indicated."

The size of the prostate itself really gives us but little information as to whether we should operate or not, for some patients urinate well when it can be called enormous (although this is exceptional), while others very poorly when it is small; and while a large gland may be considered more favorable for operative success, the small one may mean that we have a poorly contracting bladder.

During both the second and third stages, or, in general, the older a patient becomes the less frequently he has recourse to the surgeon, but the infection may advance step by step, when suddenly some accident occurs, catheter and antiseptics are not well borne, some damage is done, and we are obliged to operate; at the same time, the greater the urotoxemia and urosepsis, the less easy it should be to decide upon or continue catheterism, for in very pronounced cases of this character it may rapidly bring on fatal ending.

A mild grade of inflammation is not of great importance, or, as Tilden Brown says, may be of an advantage, as it renders the bladder less sensitive, "so that the little slips that occur in the technique are not liable to be followed by the more serious results of infection that come to a bladder unaccustomed to rough handling."

Rovsing, in his discussion at the recent International Congress of Surgeons, insisted that catheterization should *always* be given a thorough trial first, that even when hypertrophied the prostate is a useful and important organ, and should not be sacrificed without compelling reasons, while the question as to whether to condemn the patient to catheter life or to remove the necessity for it by operation he thinks should be decided by the condition of the bladder muscle, which, if completely paralyzed, indicates the catheter, but if still functionally sufficient, operation. He is convinced that prostatectomy is done too frequently, and that too little attention is paid to the seriousness of the operation.

Not taking into account those who have an inherent tendency toward conservatism in general, or those who, on the contrary, prefer operating when possible, I think as we advance in our knowledge of this trouble, and are able to weigh results—and not the mortality—of radical treatment (as we are apt to do), compared to the conservative side of the question—it is apparent that the latter is often considerably neglected, and that many cases have been operated upon when results have not justified the means, for it is the condition of the patient after operation which must be looked upon as the result, and not the fact whether he lives or not.

But when the crucial period is present, when it is evident that the milder means are no longer sufficient to maintain the health and comfort of the patient, when operation is demanded, the findings in the case must guide us as to choice in procedures, remembering that it is an operation not to be too lightly urged, nor at the same time put off too long, as the mortality is largely dependent upon the condition of the patient (the state of the kidneys and general condition being the principal guides). Uremia we know is the most frequent cause of death, about equally so after all operations, according to Watson's statistics, but although most important, the condition of the kidneys is the most difficult to fix. Slight renal lesions are not a contraindication to prostatectomy, but (as Albarran says) "they are even benefited by it, and even with very marked lesions, good results have been obtained."

It is an easy matter to quote statistics, to prove that the combined mortality of the different operative procedures has been reduced to 5 or 7 per cent., and we can all show patients who, after prostatec-

tomy, now lead a comfortable life, as compared with a miserable existence before; but those facts do not fully answer the question whether it is so frequently necessary or not; besides, figures could also be quoted to prove the value of conservatism.

It has been said that "the ideal operation would be one which completely removes the obstruction, and at the same time does not kill the patient." To this might be added "or when it does not leave the patient as badly or worse off than before." Excepting by extremists, I think it is now recognized that no one method is best, or applicable in all instances; that when the middle lobe is mostly at fault and is unduly enlarged upward, even though the lateral lobes are well involved, the suprapubic route is the one of choice, and that when the lateral lobes are chiefly involved, they are more easily reached from the perineum; while when we have simply a bar or a contracture at the neck, with the bladder base below the urethral opening, the obstruction is perhaps best relieved with the galvanocautery, either by the Bottini method or better still by what is now known as Chetwood's modification, by means of which the part to be operated upon is under direct control of the finger, and in which the perineal opening gives an opportunity for direct drainage.

To sum up:

1. Catheterism, properly applied and at the right time, renders unnecessary many operations, without which patients would have been as well, if not better off.

2. Modern technique and advance in the knowledge of prostatectomy make operation now justifiable which previously would not have been, with the former statistics and results to guide us.

3. In moderately enlarged prostates, with slightly increased frequency in micturition and a moderate residuum, no local treatment is necessary, excepting it be massage, and then only in the glandular form.

4. In patients of the poorer classes, or where aseptic catheterism is practically impossible, operation must be considered much earlier than where this is not the case.

5. Prophylactic or preventative prostatectomy cannot be recommended, as it may be a useless operation, looking toward an infirmity which may never arise.

6. In the second stage, with a residuum of four ounces or over, after milder means have failed, the catheter is indicated; then sometimes patients will return to the first period, or if not, we can at any rate avoid the third. With large residuum and sclerotic prostate, it may be advisable to operate.

7. In acute retentions we must get all we can from the catheter before intervention, as catheterism, though impossible in a number of cases, can in others definitely reestablish the urinary function for many years, no matter what the state of the prostate.

8. In the third stage, if not too far advanced, catheterism may place the patient in the second stage again. But if impossible or inadvisable for any reason, operate, if kidneys and general condition warrant it.

9. In the large non-contractile so-called "silent bladders," as also in the very small trabeculated and sacculated bladders with chronic cystitis (the sclerotic type), prostatectomy or prostatotomy is not as a rule warranted, as the patients are usually left as badly and sometimes worse off than before.

10. In chronic retentions, if the case is aseptic, catheterism is often preferable, as we can frequently get over the vulnerable period without infection, though at the same time the outlook after prostatectomy (as also its risks and complications) should also be laid before the patient. But if the case is septic, and has been so for some time, clean catheterism seems powerless to eradicate its effects, operation is indicated.

GONOCOCCAL INFECTION IN WOMAN.*

By EGBERT H. GRANDIN, M.D.,
NEW YORK.
GYNECOLOGIST TO THE COLUMBUS HOSPITAL.

Far more than the laity realizes, it is to the credit of medicine that its aim is the prevention of disease. In so far as the family, and this is at the basis of the State, is benefited, just so far the income of the physician is depreciated. An unselfish aim, surely, and yet a most noble one! Look backward, those of you who are able, and accompany the surgeon in his hospital rounds. If he sees not laudable pus he is puzzled; he expects hospital gangrene, and he is not surprised at the development of septicemia or, worse still, pyemia. Wander to the obstetric ward and see the constant elevation of temperature significant of what was termed milk fever. Scan the statistics of those days and you find a mortality rate of 25 to 40 per cent. following the performance of that physiological act—the bringing forth of a child. Diphtheria is a scourge, yellow fever is incurable, measles and scarlet fever are rampant, and the physician of the day we are envisaging must have felt with my revered teacher, Oliver Wendell Holmes, that there were many pursuits full of more certainty as regards result than medicine. The scene shifts to the present, and if the surgeon on his rounds finds pus he questions himself and his assistants. The puerperal mortality has been reduced to within a fraction of 1 per cent. Through the use of antitoxin diphtheria has become almost a benign disease. Resort to segregation limits the spread of scarlet fever and measles. Yellow fever is almost unknown in localities where formerly it was endemic. All these results we owe to our present knowledge of the causal factors of these diseases, and to the stringent application of the old adage, "An ounce of prevention is worth a pound of cure." In view of all accomplished, is it not surprising that a disease which, all things considered, is responsible for more suffering, if not for more deaths, than any of those casually mentioned, should, in these enlightened times, be viewed with apathy and be tolerated in a civilized community? Not so many years ago it was ordered by the Board of Health of this city that tuberculosis should be made a disease returnable even as were measles and scarlet fever. You all remember that this was received rather unfavorably by many in the profession, and yet it must be granted that the wisdom of such decree has been amply borne out by the fruits. There is a disease in this community which bodes greater ill to the family and to the State than even tuberculosis (the white plague), and yet, in public its name is shunned and in executive circles it is even as though it did not exist. This disease is gonorrhea, and it becomes my province to show to-night just what the gonococcus means to the family and therefore to the State. It may be I shall speak emphatically, possibly dogmatically, but if so it is from strong conviction, the result of seeing scores of homes wrecked by this germ, the result of contact with scores of women weeping for the children they could not have—not knowing why, the result of the

*Read before the New York Academy of Medicine, April 5, 1906.

knowledge that fully 60 per cent. of my operative work among women would not exist were it not for this germ.

To the late Emil Noeggerath of this city belongs the credit of first directing the attention of the profession to the destructive effects on the organism of the gonococcus. When his paper on latent gonorrhea was read and published his views were received with skepticism and considered as vagaries. A few years later Neisser differentiated the coccus which bears his name, and to-day, thirty years after Noeggerath, the profession is a unit in accepting his views. It may be maintained that there is no germ of more malevolent nature or harder to kill. It spreads to every organ of the body, affecting in particular mucous surfaces and, like the polar bear, hibernates so to speak, awakening and becoming active after years of slumber. Even the virulent streptococcus is kinder, for if it does not kill, it disappears from the organism. In woman, owing to the peculiar anatomical structure of the uterus, it lies dormant under the mucous membrane to become active under sexual congestion, possibly, or during the puerperium. Once the germ has extended above the internal os I think I may state, without fear of contradiction, it cannot be eradicated and thence it is a simple step through mucous continuity to fallopian tube, to ovary, to pelvic peritoneum. There result endometrial inflammation, salpingitis, oöphoritis, pelvic peritonitis, with their sequelæ—sterility and the operating room.

To bring the matter home to you: It has been estimated that about 75 per cent. of males have had gonorrhea once at least, and fully 30 per cent. carry the latent germ to the nuptial couch. About 45 per cent. of sterile marriages are due to the gonococcus. About 60 per cent. of pelvic inflammatory disease requiring operative interference is due to the gonococcus. Lastly, about 30 per cent. of blindness is traceable to this arch enemy of mankind. These statistics are the mean obtained from the reports made by many observers. Is it a wonder, therefore, that the gonococcus holds rank scarcely second to the tubercle germ? And yet, witness the activity characteristic of the crusade against the latter and the criminal apathy displayed where the former is concerned. The saddest part of the rôle played by the gonococcus is that it affects the innocent—the woman and the child. What is the reason for this apathy?

At the outset, gonorrhea in its true significance is not familiar to the laity. It is looked upon as a simple matter, such as a catarrh of the nose would be. It is the fashion for the young man to boast of the number of times he has had it. The very name is tabooed in public speech. It hides under the term "secret" disease. The physician aids the laity in concealment since he is not compelled to report it to boards of health, as he is such an insignificant affair in comparison as measles. In short, the disease is tolerated only because of ignorance on the part of the laity of its import. Let a vessel bearing cholera anchor off this port, let a few cases of yellow fever or of smallpox develop in this community, and great is the alarm. And yet in this community a fouler, a deadlier, a more insidious disease exists, which rarely kills of itself, but maims the innocent, and the public is indifferent. And how is this disease spread? Your answer is through prostitution largely, and I am in agreement with you, only I wish you to remember that it is *man* the prostitute rather than *woman* the prostitute who spreads it. Spasmodically, well meaning reformers start a crusade against prostitution, with the result that the women are driven from pillar to post or sent to reformatories, while the man is set free to walk at will and to infect other women too often in our very homes after marrying the daughters they swear to protect and proceed to inoculate. The code of morals is different for man and for woman. It should be the same.

Other reformers write letters on race suicide, dwelling only on that phase of the question which relates to methods resorted to for the prevention of conception, in forgetfulness and in ignorance of the fact that the true meaning of race suicide is that woman cannot conceive because she has been inoculated with the gonococcus by man, who is only too ready to point his finger at her and say, as old Adam did, "It is thy fault"! Thus then we, of necessity, reach the conclusion that, if we would annihilate the gonococcus, it must be through the force of education even as this same force has led to the elimination of smallpox or of diphtheria. No parent would tolerate the presence of a man in his family who had either of these diseases, and yet, through ignorance, he is daily allowing his daughter to mate with the gonorrheic. Educate the fathers and mothers, therefore, as to the exact meaning of gonorrhea, and they, in turn, will educate their sons and their daughters. I lay stress on the daughter because she becomes the chief sufferer from inoculation, and it is her right to know that she should protect herself against the gonorrheic as well as against the alcoholic. Further still, interest the employers of labor in the crusade against this coccus, for a large number of victims come from these sources—the factory and the department store, girls who have had no home training and therefore could not be warned at the mother's knee. Further still, let the lesson taught in the home be dwelt upon in the school—that is to say, let the educators appreciate the meaning of gonorrhea to womankind and the race and let the girl as well as the boy be taught. Further still, clergymen of all denominations must be similarly instructed, for often their words carry weight where those of others fail. Thus, in time, public opinion will make itself heard, and never yet did public opinion fail in securing the right. As a result, the so-called professional secret, which prevents the physician from reporting cases of gonorrhea, will be abolished and thus again Boards of Health will be obliged to place gonorrhea in the class where it unquestionably belongs—that of acute infectious diseases.

Not in my day and not in yours shall we witness this consummation which all medical men hope for, but we are not rash in predicting it for the future when we recall how public opinion has backed up the medical man in his dealing with lesser pests. And never let us forget that it is man who must be watched as well as woman. He seeks her, not she him. He is the initial agent of infection. The average man, when he realizes that which the gonococcus means to himself and to the woman he marries, is going to look at the disease in its true light and have himself certified to before he marries. The professional libertine, the man who will not learn and cannot be taught, the law will look after just as soon as public opinion makes itself felt; in any event the fathers and the mothers of the land will demand a certificate of absence of disease before they allow their daughters to be defiled. And yet again, the woman herself will count as a factor. It is not conceivable that, knowing the consequences of mating with a foul man, she herself should not demand the certificate.

Thus hurriedly, I have endeavored to point out

the sociological import of the gonococcus and to trace, in a rough way, the lines along which we may hope to reach its extermination. To some of you these views may seem Utopian, but even so to all of you it must be apparent that along either these or other lines something leading to the protection of womanhood and of maternity must be done. This Academy of Medicine has ever figured in the foreground when questions of public health or policy have been under discussion, and I know that, when the time seems opportune for radical dealing with the question of the gonococcus, so vital to the welfare of the family and of the State, it will not be found wanting in the full weight of its authority in the education of the public.

116 West Seventy-sixth Street.

GIGLI'S OPERATION, WITH REPORT OF A CASE FROM PRIVATE PRACTICE.

By J. A. SCHMITT, M.D.,

NEW YORK.

GYNECOLOGIST TO METROPOLITAN HOSPITAL.

It is no exaggeration to say that Gigli's operation of lateral section for dilating the bony canal of the pelvis represents the most valuable contribution to obstetrical surgery. To judge from many favorable reports, it seems to be gradually supplanting its rival, symphyseotomy, which has never become popular on account of its various anatomical and clinical disadvantages. So far, all reports of pubic section have originated from hospitals, but the importance and value of an operation, especially in obstetrics, are not so much determined by the favorable results obtained in clinics as by the success achieved by the practitioner at the bedside. This is one of the reasons which have induced me to relate briefly the history of a confinement, which was brought to a happy conclusion for mother and child by the performance of pubiotomy.

The case refers to a primipara, twenty-seven years of age, who by her healthy appearance and fine physique did not excite suspicion of any abnormal condition. No history of rickets could be obtained, nor were any signs of this disease present. The distance between the anterior-superior spines measured 27 cm., between the crests 29 cm.; the length of the diagonal conjugate was 10 cm., of the true conjugate 8 cm. The symphisis was thick, high, and steep, and the inner surface of the lateral walls of the small pelvis could be palpated without difficulty. The type was that of a generally contracted pelvis.

Labor began on the evening of Saturday, February 10. Physical examination showed that the cervix was only partly obliterated, but easily passable. The head was at the brim of the pelvis and movable, the occiput being turned to the right side. The large fontanelle could be felt high up, near the median line, and the sagittal suture nearer to the promontory; the left side of the pelvis was not completely filled out. On Monday morning the state of affairs had not changed materially, in spite of regular and strong labor pains. The head was not engaged, though more firmly pressed into the pelvic entrance. The os was now dilated to the size of a quarter. Meanwhile the waters had escaped. In the afternoon, at 3 o'clock, forty hours after labor began, immediately before operation, the condition was as follows: The os, dilated to the size of a silver dollar, was high up and directed toward the hollow of the sacrum; from its anterior circumference the lower segment of the anterior uterine wall was stretched across the pelvic cavity, toward the symphysis, but neither overexpanded nor edematous. The left side of the pelvis was only partly filled out; the head, though more firmly engaged at the pelvic brim, had not materially progressed in its descent. Condition of mother and child was good. The labor pains continued to be extremely strong, and the mother insisted upon the termination of the labor and declared that she would under no circumstances pass through a third night of such excessive suffering. I performed Gigli's modified pubiotomy, after having informed the patient that the operation would be only a preliminary step and that the spontaneous expulsion would be left to nature. Apart from the insufficient expansion of the os, which would have made an immediate delivery impossible, I thought it wise to guard against the reproaches of the mother if she discovered that the child was not yet born.

I made a cross-incision on the right side, corresponding to the location of the occiput, directly down to the pubic spine, lengthening it inward, to admit the index finger of the left hand, with which I tunneled my way along the posterior surface of the body of the pubes, as far down as the lower border of the descending ramus. The second incision was made on the outer surface of the labium majus at about the level of the glans clitoridis. The thumb of the left hand was introduced and pushed forward against the border of the descending ramus. As I had no other instrument on hand, I used a properly curved, flexible uterine sound, which I introduced from above under guidance of the index finger, left *in situ*, and then pushed through under the border of the descending ramus, against the thumb in the lower wound. The tip of the sound now protruded from the lower incision and Gigli's wire saw was tied to it with a silk thread and drawn through the wound canal. The first saw broke;* with the second and stronger one, I succeeded in a very short time in dividing the pubic bone, the separated ends of which now gaped about 2 1-2 cm. The upper wound was sutured, and into the lower a strip of iodoform gauze was inserted. When the patient regained consciousness she again suffered the most intense labor pains. She complained that the pains of the wound had been added by the operation; with every contraction, the pelvis felt as if torn apart, so that she piteously begged me to end her agony. I waited for about two hours and a half; the attempt to press the head into the pelvis was successful during this time, and when the patient was again narcotized, conditions were more favorable for the application of the forceps. The os had dilated to the size of the palm of the hand and the head had descended into the pelvis, though with the sagittal suture in transverse or slightly oblique direction. There could be no doubt that the head began to descend and rotate to the front. The anterior lower segment of the uterus still extended from behind the symphysis toward the center of the pelvic cavity. The forceps had to be applied in the right diagonal diameter; the left blade over the left cheek anteriorly, the right over the occiput posteriorly. After a few tractions the occiput rotated toward the front, and after readjusting the forceps, the occiput was brought under the symphysis and extracted. To accomplish this, extraordinary force had to be employed. The head of the child showed no abnormal hardness, nor were its dimensions above the normal. No signs of configuration of the head and no overlapping of the bones or swelling of the scalp could be discovered. A slight abrasion of the skin and in-

*The principal cause of this disaster of which we read in many reports is the poor quality of wire saws sold by the instrument dealers. To guard against it, a larger size, a previous test, and an abundant supply are to be advised.

tumescence upon the left cheek, due to the left blade of the forceps constituted the sole lesion. Fifteen minutes later the placenta was expressed, and an examination was made of the sexual canal. At the vaginal entrance, that part of the vaginal wall which covered the gap in the pubic bone was torn through, and thus an open communication between the vagina and the pubiotomy canal was established. The cervix was torn on both sides; the anterior lip protruded as a fleshy flap from the vagina, and the depth of the anterior vaginal vault was no more than two inches. Bladder and urethra were intact. The greater part of the laceration was repaired, and only a small opening left for drainage with a strip of iodoform gauze. Around the hip an adhesive plaster dressing was applied.

The patient had an eventful recovery. The puerperium was disturbed by fever, which lasted for two weeks and oscillated between 99.5° and 102°. It was caused by suppuration of the lower part of the pubiotomy wound. The greatest inconvenience the patient experienced was from inability to urinate. She had to be catheterized for four weeks, and despite the strictest antiseptic measures, cystitis developed, from which she is gradually recovering. Through all her miseries, even through her feverish period, her best friend, an excellent appetite, has never failed her. A short time ago she contracted pains in the left leg, but she is thankful that the operated right side is now so strong as to assume the work of the affected side. Her complete restoration to health appears to me beyond doubt. An examination, five weeks after pubiotomy, revealed a perfect involution of the movable uterus, a bilateral laceration occupying about the lower third of the vaginal portion, union of the vaginal tear, and a soft ridge on the anterior and posterior surfaces of the pubic bone, corresponding to the gap of the separated bones. No mobility could be discovered here. The pain had subsided; cystitis is still present, but improving.

I am sorry not to be in the position to give a more cheerful account of this case of lateral section, and hope it will not deter others from performing this blissful operation in suitable instances. Since Gigli's method of operating has been greatly simplified by Doederlein's subcutaneous method, the principal danger of infection of the wound through the lochia appears to be eliminated, or at least greatly diminished. Gigli made a large incision down to the anterior surface of the pubic bone, extending from the pubic spine to the descending ramus; Doederlein makes two small incisions, one over the pubic spine and one outside the labium majus, and has devised a needle with which to carry the wire-saw around the pubic bone. The latest device is a sharp, properly curved needle, which pierces the skin on the outside of the labium majus, is guided around the pubic bone under control of the finger in the vagina, and brought out above and internally to the pubic spine, thus producing puncture of the skin only. This would seem the most ideal plan of performing subcutaneous pubiotomy, if injury to the bladder, which has happened to experienced obstetricians, could be avoided. The risk may be lessened by keeping the point of the needle in feeling contact with the posterior surface of the pubic bone. A rational method, which I recommend after careful study of all propositions referring to this subject and which I would employ, should opportunity offer itself again, is based upon the combination of suprapubic incision with labial puncture. The mode of proceeding is as follows: An incision is made on the side where the occiput is located, internal to the pubic spine and large enough to admit the index finger, which paves the way down to the lower border of the descending ramus, along the posterior surface of the periosteum. The needle is then thrust through the skin on the outside of the labium majus 2.5 cm. distant from the vertex of the pubic arc, and in the direction of the tip of the index finger, which has remained *in situ*. The tip of the needle is carefully pushed forward, so that it comes to occupy a position between the palmar surface of the index finger and the periosteum. So controlled, it is carried around and out of the incision by retracting the index finger and depressing the handle. The final step of the operation is self-evident. The needle, which Mr. Eissner of the Bible House has constructed for me, has an eye, in which a strong silk ligature for tying the wire-saw is threaded. It is in my opinion irrelevant, supposing the mode of procedure to be the same, whether we introduce the needle from above and pierce the labial skin afterward, or pierce the skin first and emerge above. If we follow the former plan, we have to guard against puncturing the vagina by controlling the needle with the finger in the vagina, not to speak of the interference of the projecting abdomen with the movement of the handle. To be absolutely secure in manipulating the needle, some have advocated its insertion from above, between periosteum and bone. This is easily done by an incision a little inside of the pubic spine, followed by nicking and detaching the periosteum from the posterior aspect of the bone with an elevator or rasp. But I do not regard this proposition as commendable, for it deprives us of the only criterion we have of the success of the lateral section, viz., the palpable gap of the separated bones.

Much may be said of the anatomical features which enter into the plan of surgical procedure. According to the investigations of Tandler of Vienna, there can be no doubt that, whatever method we may choose, the crus clitoridis, which is firmly connected by means of the periosteum to the ramus of the pubes, must be sacrificed. The conception to pass the needle between periosteum and lower border of the pubic bone, without injuring the crus, is illusory. Practically, we may ignore this structure, as the bleeding from it is never abundant and can usually be checked by pressure.

Another important question refers to the increase in length of the various pelvic diameters after pubiotomy. From experiments on pelves of female cadavers, the astonishing observation has been made that after lateral section the increase of the true conjugate amounts to 5 to 7 mm. only, and that of the transverse diameter to 8 to 16 mm. These findings can hardly be reconciled with the experience in practice, according to which, after pubiotomy, normal heads have been extracted through a conjugate of 7.5 cm. The lowest limit of pelvic contraction in which pubiotomy is yet admissible is still a mooted question. It must be remembered, however, that in extreme instances of disproportion between head and bony canal, extraordinary force in extracting the child has to be employed. Injuries to the vaginal wall, corresponding to the operated side, are then unavoidable; even the application of a protective elastic band around the hip will be of no avail. That part of the vagina which overspans the gap of the separated bones is most likely to tear, partly from overdistention within and partly from traction without. To prevent such fatalities, some obstetricians repudiate the rapid delivery of the child after pubiotomy and prefer expectant treatment. No fixed rules should be laid down in this respect; they may be more appropriate for hospital treatment, but the re-

lation of the practitioner to his patient differs from that of the physician in clinics. The latter is more independent and unhampered by personal considerations, while the work of the former is often influenced by motives of sympathy. In any event, when conditions are favorable for forceps or version, it would be inhuman not to terminate labor in one narcosis.

There is probably no new addition to obstetrical surgery more apt to revolutionize the various indications for meeting contingencies than pubiotomy. It is indicated in contracted pelves, measuring not less than 7 cm. in the true conjugate. The child must be living and labor terminated in the interest of mother or child. The resources at the disposal of the accoucheur for overcoming the obstacles in moderately contracted pelves have heretofore been the induction of premature labor; version, high forceps, craniotomy, and cesarean section. All these aids may now be supplanted and supplemented by the simplified, subcutaneous pubiotomy, with little risk to the mother and a good prognosis for the child. Instead of inducing premature labor, with its frequent fatal results for the child, we may now confidently wait until full term. The gruesome operation of perforating the head of a living child should be restricted to exceptional cases and replaced by pubiotomy. When the mother declines the destruction of her living child, pubiotomy may be performed in place of cesarean section. In the management of protracted labor from flattened pelvis, our usual means of interference have been high forceps or version. Some accoucheurs reject even these aids in preference to pubiotomy, which, they claim, holds better chances for mother and child. The steps to be taken after pubiotomy, whether expectant or rapid delivery by forceps, or version, with preceding dilatation of the os, furnish still another chapter of this highly interesting subject.

THE OCCURRENCE AND PROGNOSIS OF PNEUMONIA AS STUDIED AT THE LINCOLN HOSPITAL.

By LOUIS FAUGÈRES BISHOP, A.M., M.D.,
NEW YORK.

There is a good deal written nowadays about pneumonia. The vital statistics of a great many cities point to the fact that pneumonia is one of the most fatal of all diseases, not only in proportion to the number of people attacked, but also in the actual number of people who have died from it. This question of mortality from disease as represented by the statistics of various cities and countries is one from which it is not always easy to draw truthful conclusions as to conditions at different times. So much depends upon the prevalent diseases, upon the character and occupation of the population, and upon the names given to diseases when they are reported, that it is really very hard to decide what are the actual changes in the causes of mortality in different countries and different generations. The improved hygienic condition of cities, the improved average living of the people, the improved therapeutics have all made great changes. If persons die of typhoid fever when they are twenty or twenty-five years old they do not die of heart disease or Bright's disease when they are sixty or seventy or eighty years old. So the diminution of death from acute infection, and the absence of epidemics increase the apparent mortality from diseases like Bright's disease or heart disease, which are the results of the gradual deterioration of the body with age. Also in the presence of hard conditions of life such as we find in times of famine and great financial depression when people have hardly enough to eat, and have a very hard time to get along, the diseases which carry people off are more apt to be those to go with a deteriorated state of the system, such as tuberculosis and disorders of the intestinal tract. While in times when people have more to eat and when there is no epidemic abroad people live to good old age, and die of heart disease, Bright's disease, or cancer, which are diseases of advanced age. So I really believe that it is not proved that cancer and heart disease and Bright's disease are any more prevalent than they always were, when we consider that there are more people who are of the age to be subject to these diseases.

Now as to pneumonia. Pneumonia, in a measure, ranks with the degenerative diseases. That is, if people live long enough and become feeble from age, and escape death from epidemic, influenza, dysentery, or any of the infections, it is one of the things that are particularly liable to occur. Nor must we forget that damage to the kidneys and circulation, such as come from high living and overwork, predispose to fatal pneumonia. So I think the same statistical causes which have led to the increased apparent mortality from cancer are active in a measure in pneumonia. Another factor which affects statistics is the fear of tuberculosis. Of late years everyone has been educated to fear tuberculosis, and everyone is afraid of it, and it is more or less getting to be a disgrace to have tuberculosis. Physicians, as a rule, in making out death certificates, when there is the slightest chance of difference of opinion, will naturally make out the one which will be the least shock to their patients. For that reason I believe that pneumonia is often given as the cause of death in cases which are complicated by tuberculosis. So pneumonia again gets an increased percentage and gets the reputation of becoming more and more fatal. The term pneumonia is a very broad one, and covers a large number of conditions of various kinds and various intensity. When we limit the term of pneumonia to acute lobar pneumonia, and when we limit it to patients who are in reasonably good health before the attack, it does not seem to me, as an impartial observer of hospital and private work, that the disease is increasing. I believe we have no more or less pneumonia of this type than we have always had. During the years when epidemic influenza was prevalent of course the number of cases was increased. Another point of interest is the infectiousness of pneumonia. Clinically it does not seem to me that the infectiousness of pneumonia is very marked. We certainly have no experience in the Lincoln Hospital of patients contracting acute lobar pneumonia from other patients in the ward, and we have no experience of nurses or doctors contracting it. The accepted belief now is that a particular germ is the cause of pneumonia, but that has not at all been proved. We always find the lancet-shaped diplococcus present in cases of pneumonia, but whether it is there by accident or whether it is the cause of the disease we do not know; and it is not at all proved that this particular germ, even from a fresh case of pneumonia, is dangerous to other people. So I think that we can dismiss as not clinically important the question of infection in pneumonia.

The prognosis of pneumonia, that is, the decision of what outcome we may expect in particular cases, is dependent upon a number of circumstances, and

we have reason to believe that recently our chances of a true prognosis have been helped by blood examinations. Clinically the prognosis depends, to a great extent, upon the previous life history of the patient; it also depends upon the occasion for the pneumonia. Pneumonias that occur as terminal conditions are necessarily extremely fatal. That is, when people with a chronic condition of feebleness or malnutrition or exhaustion develop pneumonia, the chances are that they develop their pneumonia not because they were infected, but because it was almost the natural outcome of their condition. The same thing is true of people who develop pneumonia when exhausted and debilitated by prolonged indulgence in alcohol. The pneumonia occurring in a debilitated person at the end of a long spree can rightly be classed with that occurring in the old and feeble, the difference of type being in the constitution of the patient and the age. The pneumonia of alcoholics is necessarily a very fatal form, because there is no particular resistance on the part of the system, and because the patient is in no condition to stand the exhausting delirium which almost inevitably follows.

The prognosis in other cases, such as a mild pneumonia affecting one lobe in a previously healthy and robust person, is very good, indeed. These patients get well almost without any treatment. In between these two classes of cases we have a large number in which there is good resistance on the part of the system, and yet in which the disease has developed in an acute active form, and in which there is a considerable involvement of lung tissue. In these cases the prognosis is doubtful, and it is here that very interesting conclusions can be drawn from the examination of the blood. The following two cases are examples:

Case I.—E. G., 50 years of age, was born in the United States. His occupation is a carpenter. He was admitted to hospital ten days ago, complaining of pain referred to the abdomen. No account of his past life or history could be obtained, but he did not seem to be particularly alcoholic, though he acknowledged that he had been drinking somewhat for the past few weeks. On admission he had a temperature a little over 100° and did not develop any particular signs of pneumonia until about the third day, when I detected signs of consolidation in the middle lobe of the right lung. His temperature increased until it reached nearly 105°, his pulse became rapid, at times being over 120, and his respirations were also increased. His pneumonia, beginning as it did in this atypical way, rather gradually, did not run a very typical course. His temperature remained up for four days, and then there was a false crisis, his temperature coming down to normal, but the next day rising again and remaining up several days. His physical signs gradually increased, showing that there had been no improvement in the condition of the lung. Now as to the prognosis in this case: The man did not seem so very sick, and we would naturally judge that he had a fair chance of recovery. Examination of his blood, showed the leucocytes to be only 20,000 with 90 per cent. of polynuclears, both of these points giving a bad prognosis. As high a polynuclear count as 90 per cent. and as low a leucocyte count as 20,000 means that the disease is of a virulent type, and that the resistance on the part of the system is not very great, so his chances suffer in both directions. No efforts were spared in the treatment, however, and the man made a good recovery.

Case II.—S. S., 25 years old, born in Italy; a laborer. The only definite information obtainable as to his previous history was that he suffered severely from malaria in Italy for four years. He, too, on admission did not show any distinctive physical signs, though his temperature was 105°. The next day his temperature fell to normal, but the next evening rose nearly to 107°. The next morning it was down to 100°, and that evening rose to 106°. At this time there appeared signs of consolidation in the right upper lobe of the lung, and from that time on for five days his temperature remained high, but then suddenly fell to normal, where it remained. I should say that he had been treated, since it was realized that he was seriously ill, with large doses of quinine. Examination of the blood showed at first only 41 per cent. of polynuclears and 30 per cent. of large mononuclears, but only 13,000 leucocytes. The 41 per cent. of polynuclears, as compared with the 90 per cent. of the other man, indicated that the pneumonia was not of a virulent type as far as we could tell from the blood; the 13,000 leucocyte count was, however, very low, and, unless I had been disposed to account for this by his previous malaria and by the presence of a large spleen which might have prevented or interfered with the development of the proper leucocytosis, I should have drawn a bad prognosis. The polynuclears increased rapidly, soon attaining 72 per cent., but never reached the percentage noted in the first case. The good prognosis was justified by the result.

In this connection the case of a man who died in the hospital is of interest. His history was as follows: He was 28 years old, had been drinking for a long time, and had developed the pneumonia two days before he came in. The outlook was bad from the beginning, from the clinical point of view, and from the pathological point of view it was bad, because he only had 10,000 leucocytes; that is, he did not show any resistance to the disease, and 91 per cent. of these leucocytes were polynuclears, showing a very severe and malignant infection. So there was the double danger of a severe infection and a very little resistance, and the result justified the conclusion. There was another patient who came to the hospital at the very beginning of his pneumonia, and had a mild attack. He had 30,000 leucocytes, showing a very powerful reaction on the part of the system.

While we must never put clinical pathology ahead of clinical experience and direct observation in making up our prognosis of cases, still we have in the examination of the blood a matter of much importance in helping us to decide as to the danger and probability of the recovery of the patient. And if we cure a patient who has only 20,000 leucocytes and 90 per cent. of polynuclears, it means at least that we have had a pretty hard fight. The low leucocyte count in Case II, the man with a large spleen, suggests that in such a case as this, in which pneumonia is evidently complicated with malaria, we must disregard the count. The leucocytes are not increased in malaria.

54 West Fifty-fifth Street.

"Catheter Cystitis" is, according to Gersuny, often produced in gynecological practice by too deep introduction of the instrument. In this way the vesical mucosa is abraded by the end of the catheter and a *locus minoris resistentiæ*, which favors infection, is formed. He has therefore devised catheters having a collar at a distance of 4, 4.5, or 5 cm. from the intravesical end, which prevents their insertion to an unnecessary depth. The use of these instruments has apparently reduced the number of instances of postoperative cystitis occurring in the author's clinic.—*Centralblatt für Gynäkologie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, May 26, 1906.

THE AMERICAN MEDICAL DIRECTORY.

THE Editor-Secretary of the American Medical Association has published an announcement of a forthcoming directory of the medical practitioners of the country, which is, we understand, a revival of the Standard Medical Directory, purchased by the trustees of the Association about a year ago. Why, if the Association was to get up a directory, it could not do so without giving a bonus to the publishers of a ludicrously incorrect list we cannot understand—but physicians are proverbially poor business men and we shall not stop to speculate on the inwardness of this transaction. The squandering of a few thousand dollars by such a wealthy concern is a matter of comparatively slight importance, albeit suggestive of life insurance methods. The main point is that the issuance of a directory by the American Medical Association is absolutely without excuse (for the long-established Polk's is eminently satisfactory), unless it is to be given free of cost to the members of the Association. But this is not the case, for the circular states that the price of the directory is to be seven dollars, with one dollar thrown off for advance payment.

This is a rank imposition, and is not reconcilable with the assurance of the Secretary-Editor that the publication of the directory is not undertaken as a commercial venture. We make bold to say there are few publishing houses that would not be willing and eager to get up such a work, cram it with advertisements—all strictly ethical, of course, and push its sales with the backing of the Association aided by the large staff of agents and solicitors constantly employed by the *Journal*. They would regard it as a commercial venture presenting peculiarly attractive features.

For many years the Medical Society of the County of New York and the New York County Medical Association published directories of medical practitioners in the States of New York, New Jersey, and Connecticut, which were distributed free to all the members of those societies; and since the amalgamation of the two State societies the Medical Society of the State of New York has taken up the work under the same conditions, the members of the Society receiving the directory without charge. In addition to this the New York Society looks after quacks, keeps a jealous eye on the Legislature of the State to see that it does not pass any bills prejudicial to the interests of legitimate medical practitioners or likely to affect injuriously the health of the community, and protects its members against unjust malpractice suits. The great American Medical Association should do as much or more, but it practically does nothing for its members, two or three or perhaps half a dozen excepted, beyond a free distribution of its transactions. The Association is a great and prosperous mercantile concern, piling up a surplus each year. If the directory venture pans out according to the expectations of its promoters the total income for 1906 will be in the neighborhood of half a million dollars—a tidy sum and full of possibilities for good to those who have the management of it. There are some twenty thousand members who are entitled to a share in this prosperity, and they should insist upon their right to at least a free copy of the directory. The sales of the book to non-members and the receipts from advertisements should pay the cost of production, and even if there is a small deficit the Association will not be bankrupted.

The Editor-Secretary has also gone into the business of publishing medical books—he might as well drag the Association into the making of shoes. We do not know who authorized this venture—perhaps the managers will take us into their confidence at the Boston meeting in June—but, whether authorized or not, if the Association publishes books it should give them without price to its members. If it cannot afford to publish directories and medical text-books without charging its members for them, it should keep out of the business. The American Medical Association is, or rather should be, a mutual benefit society and not a gigantic medical trust so conducted as to put unlimited power in the hands and fat salaries in the pockets of a few of the insiders. Whatever it produces, whether transactions, directories, books, or buttons, should be the property of each and every one of its members. There must be no preferred stock in this successful commercial enterprise, and every shareholder should demand his proportion of the profits. The directory belongs to the members, and it is pure impudence on the part of those who are getting it up to attempt to make its owners pay seven dollars or even seven cents for it.

GYNECOLOGICAL OPERATIONS ON THE INSANE.

THE treatment of the mentally afflicted has undergone marked changes during recent years and the belief no longer holds good that mere isolation in an asylum is all that is required. The necessity of individualizing, of treating these unfortunates as sick people and each according to his or her special needs, has been strongly impressed upon those who are directly interested in the care of the insane. In institutions where such a plan of procedure has been adopted the good results attained have soon compensated for the additional trouble and expense involved. These good results have shown themselves not only in the higher percentages of mental improvement and recovery, but also in the greater contentment and usefulness of those of the more incurable class. Thus the tuberculous patients in

these institutions are now generally treated by the same methods of isolation and "aeration" as are employed elsewhere. A similar spirit of advance can also be noted along other lines, and an attempt is now made to seek out in each patient the various physical diseases and abnormalities and then to remedy them if they are found to affect in any way the general health and comfort of the individual. If the improved physical state which results from such a plan of procedure also exerts a favorable effect on the mental condition of the patient, then the outcome is doubly gratifying. Medical and surgical measures have both been drawn upon to bring about this desideratum.

The assertion has often been made that in women a deranged mental state frequently depends upon pathological conditions of the genital organs. A number of writers who have investigated this subject report, moreover, a large percentage of pelvic abnormalities among insane women, but whether this has any direct etiological relation to their mental condition is immaterial if we take into consideration the great relief which may be obtained from proper treatment of their local condition. The insane patient has moreover an equal right with the mentally compos to be relieved of symptoms which are of sufficient gravity to call for gynecological treatment of the sane woman.

In many of the larger hospitals for the insane, both here and abroad, steps have been taken to afford the inmates necessary surgical treatment. It is the general consensus of opinion that in certain instances mental recovery is also hastened by the relief from physical distress which is experienced after an essential operation has been performed. The patient's physical health has been restored and by this means the moral and therapeutic treatment has met with a more responsive application. Among the institutions in which gynecological surgery has been carried on from a conservative standpoint is the Manhattan State Hospital, on Ward's Island, and in a report on this work which has been carried on by Leroy Broun (*Annals of Gynecology and Pediatry*, March, 1906), it is distinctly stated that no operation has been done on any of these women with a direct view of any possible effect on the mental trouble for which the patient had been admitted to the institution. Fully three-fourths of the patients presented some form of mental disease which is generally considered incurable, but, in accordance with the view above expressed, it was believed that these unfortunates had as much claim for physical relief as those with the more amenable forms of mental disease. Two hundred and forty-two patients, or a little less than 5 per cent. of the total number of women in the hospital during the period covered by the report, received the benefit of gynecological operation, and as a result one hundred and twelve of this number were physically improved to a marked degree. Of the remainder five died from various causes, in three the case proved to be non-operative, and the others were more or less benefited, though not to any marked degree. In no instance was the mental condition of the patient made worse, either directly or indirectly, as the result of the operation. In some cases lives were saved, in others patients who had been bedridden for years or invalids for long periods, were restored to physical health. And the mental improvement in certain instances was observed to be visibly hastened by the favorable change in the patients' general condition.

The results reported by Dr. Broun cannot be regarded in other than a favorable light, and his work in this field is of great value in aiding to bring about a better understanding among the profession on this very important subject. The point of view which he has adopted is a good one and, moreover, a safe one to follow: "Operate to relieve the patient of physical suffering; if as the result of this she is mentally improved, it constitutes a sequel not directly sought, yet welcomed."

GARDEN CITIES.

In the United States, with the possible exception of New York City, there are perhaps no large centers of population so cramped for space, that it is a serious problem how to house the inhabitants with an ample sufficiency of breathing area both indoors and out of doors. In Europe, however, the situation is very different. In the commercial countries, such as Belgium and Germany, the conditions of life in the cities are attracting the attention of sanitarians and philanthropists, and various schemes have been devised with the view of combating the evils of overcrowding. In Great Britain, and in London particularly, the problem presents itself in its most accentuated forms. Some considerable time ago it was suggested that a fairly satisfactory remedy might be provided for town congestion, by the establishment in the country of what are to be known as "garden cities." Such places of habitation, if the views of their advocates are carried out, would be more or less ideal, in fact modern Utopias, in which the worker would be able to rest from his daily toil amid surroundings calculated to invigorate his body and to stimulate his mind.

Recently the Garden City Association of England held a meeting in London in order to consider the overcrowding problem. The Right. Hon. James Bryce dealt with the question of how to check the growth of great cities, and Ryder Haggard pleaded the cause of the agricultural laborer. Mr. Bryce said that unlimited population was rather a curse than a blessing, and that very large cities were undoubtedly a menace in many ways. London was the most conspicuous example, while Southeast Lancashire was practically one town twenty-five miles long by eight wide. The speaker gave as his opinion that when a city grew beyond a population of 200,000 or 300,000, the difficulty of getting into the country was great enough to prevent most people from enjoying its pure air. This was the point at which a city was too large. Mr. Bryce thought that the ideal to aim at was to have new industrial centers or garden cities, with a population of not more than 30,000 to 60,000. The following resolution was moved and passed: "That the housing problem can be solved and the congestion in crowded centers relieved by a concentrated movement of manufacturers, operators, and others to new areas, arrangements being made for securing to the people the increased value which their presence will give to the sites, and the areas being care-

fully planned so as to make adequate provision for the individual and social needs of the people, especially with a view to securing for all time the combined advantages of town and country life."

Mr. Haggard dealt with the continuous depopulation of the agricultural districts, showing that this exodus from the country to the towns was responsible for much of the poverty, with consequent physical and mental degeneration, which was now so obvious a feature of city life in Great Britain.

So far as this country is concerned, the evils of overcrowding in cities, on the whole, have not been as evident as in certain parts of Europe and of Great Britain. But our cities and those of Great Britain are larger than those of any other country. Further, the tendency to flock to the towns is almost as marked here as in Europe, and the majority of aliens settle in towns. In New York, and to a lesser extent in London, the conditions are greatly aggravated by the fact that a very large proportion of the less desirable class of immigrants who come in make their homes in these cities, massing together and frequently existing in indescribably filthy surroundings. If not already, there will be, ere long, room in America for "garden cities."

The Station House Question.

The police station houses of this city have so long been a blot on its escutcheon that it is highly gratifying to have the matter brought so prominently before the public as has been done by the vigorous protests against their unsuitability that have been uttered by Commissioner Bingham. That his strictures cannot be ascribed solely to the desire to increase from a technical standpoint the efficiency of the department which he directs, but are actually justified from a hygienic point of view, is attested by the fact that the Board of Health has condemned thirty-three of these buildings as nuisances inimical to public health. While it is not likely that the Health Department will insist on summarily abolishing these admittedly unsanitary establishments, it is to be hoped that by this expression of official disapproval public attention will be directed to the question with so much insistence that the Board of Estimate will be forced to accord to General Bingham the financial support necessary to carry out his projects of reform. In this connection it would be profitable to consider the suggestion that has already several times been made by those presumably conversant with the conditions, of doing away altogether with that part of the functions of the station house which concerns the detention of prisoners. It has been proposed to have prisons for this purpose attached to each of the City Magistrates' courts, and all persons arrested would be taken directly to one of these. In this way much time and expense in the transportation of prisoners would be saved and the duties of the station house personnel be greatly simplified and lightened. The reconstruction of the quarters intended for the patrolmen could be effected for a tithe of the sum necessary if each police station were to be converted into a model prison in miniature, and undoubtedly the supervision of the prisoners could be much more effectually carried out if the task were to some extent centralized in this way. It has also been urged that more satisfactory medical control of those in need of it could be exercised under such conditions, and that there would be less risk of the occurrence of the errors of judgment that at present lead to disastrous consequences with such painful frequency. The idea seems to present many advantages both from the administrative and from the economic side, while its drawbacks are not apparent; but whether it be considered expedient or not by those with whom the decision rests, it cannot be too strongly emphasized that in one way or another relief from the existing intolerable conditions is imperative and should be secured at all costs.

Some New Indications for the Use of the *X*-Rays.

Since their introduction, less than ten years ago, the *x*-rays have gained for themselves a position in therapeutics which might be described as impregnable. The indications for their use have grown every year until at the present time we find them applied in the most varied conditions. The enthusiasm which accompanied this progress has led to their use in many diseases or diseased conditions, however, which have since been found to be unsuited. The day will come, perhaps, when this therapeutic means will be more restricted in its application than at the present time, but until then we may continue to record novel and enthusiastic suggestions for their employment. Among these indications interest attaches to two which have lately been suggested by Max Kahane in an article appearing in the *Wiener klinisch-therapeutische Wochenschrift*, March 11, 1905. In these the effect of the rays on lymphoid tissue is made use of for therapeutic purposes. The two diseases referred to particularly are appendicitis and tonsillar hypertrophy. Acute inflammation of the appendix and its neighboring tissues is usually referred for treatment to the surgeon because it is quite universally conceded that from the nature of the disease only immediate operative interference can effect a cure. But, on the other hand, there are chronic forms of appendicitis in which there is no indication for interference of this kind, and these Kahane thinks may well be subjected to treatment by the *x*-rays. It is well known that a large amount of lymphoid tissue in the appendix serves as a base for the frequent infection of the latter by a deposit of bacteria, and it is claimed that this danger point may be readily influenced by *x*-rays, especially if this lymphoid tissue has undergone pathological changes. As regards the application of the Roentgen rays in the treatment of tonsillar hypertrophy practically the same conditions hold good, and the use of the rays in this locality is of particular interest because in no one part of the body does the lymphoid tissue come so near to the surface, and therefore nowhere can it be so readily subjected to the direct influence of this therapeutic agent. The author has not put these suggestions to any practical test, reserving this problem for others.

Staining Methods for the Detection of Urinary Casts.

One of the consummations devoutly wished for by the physician who has frequent occasion to examine urinary sediments, is some ready method of staining casts and other urinary deposits in such a way as to render them more easily discernible. The difficulty in distinguishing casts under the microscope lies in the fact that these bodies have an index of refraction so nearly identical with that of the liquid medium in which they float, that their outlines are very faint indeed, and that extremely careful

manipulation of the fine adjustment and such a narrowing of the diaphragm as to exclude the bulk of the rays from the mirror are required in order to render them visible. The processes of staining casts and other elements of the sediment which have hitherto been suggested include the use of a variety of diffusible and soluble dyestuffs, such as methylene blue, picrocarmine, gentian violet, eosin, safranin, Soudan III., Bismarck brown, Lugol's solution, etc. The failure of these dyes to give satisfactory stained preparations of urinary sediments is due to a variety of causes, foremost among which is the impossibility of fixing casts, epithelia, etc., so as to make them susceptible to the action of the staining agents. These dyes stain the liquid medium so that the almost identical indices of refraction of both fluid and sediment remain relatively unchanged.

In view of these difficulties, the method recently presented by Amann in the *Journal Suisse de Chimie et de Pharmacie* for February 10, 1906, is of interest in that it offers at least a partial solution of this problem. Amann conceived the idea that it would be better to leave the elements of the sediment unstained, and to stain the background surrounding these bodies in such a way as to make them stand out clearly under the microscope. For this purpose he used not diffusible and soluble dyes, such as those mentioned above, but pigments in a finely divided state, such as are found in the ordinary water colors sold in collapsible tubes. The color which he recommends for this purpose is Prussian blue, but India ink in liquid form, as used for black-and-white illustrations, may also be employed. A drop of the sediment is placed on a slide, and is immediately mixed with a droplet of the pigment, the mixture being at once covered with a coverslip and examined. The background is made up of particles of the blue or black pigment, while the casts, shreds of mucus, cylindroids, epithelia, etc., stand out well defined. Manipulation of light is rendered easy through the fact that the particles of pigment absorb most of the excess rays, and thus the contours of the casts can be studied to greater advantage.

News of the Week.

San Francisco Medical Relief Committee.—The Association of American Physicians has appointed a committee to secure books and journals for the medical men and the medical libraries of San Francisco. This committee makes an appeal to the physicians of New York in behalf of its purpose. Practically all the San Francisco physicians have lost their books and their instruments, and their medical libraries have been destroyed. The Medical Relief Committee of Manhattan, the Bronx, and Richmond has volunteered to take charge of all books, journals, and instruments which may be contributed. If such contributions are marked "For the San Francisco physicians," and sent directly to the New York Academy of Medicine, 17 West Forty-third Street, they will be forwarded to Dr. Henry Gibbons, president of the San Francisco County Medical Society and Chairman of the local relief committee.

Seaside Park Bill Signed.—Governor Higgins has signed the bill providing for the establishment and maintenance of a seaside park for New York City. For this purpose the Board of Estimate and Apportionment is authorized by a majority vote to appropriate $2,500,000 without the concurrence or approval of any other officer or board of New York City, and the city Comptroller is to issue city bonds to raise the money. Provision is also made to withdraw from the jurisdiction of the Park Department so much of the seaside park as is necessary for a site for the erection of a convalescent hospital or hospitals by any charitable or benevolent society in New York City, this part of the park to be under the jurisdiction of the city Board of Health or the trustees of Bellevue or the Commissioner of Public Charities of the city.

Smoke Ordinance Violators.—Between forty and fifty smoke nuisance cases were disposed of in the Court of Special Sessions on May 16. All but two of the defendants were found guilty, but all were discharged unpunished, sentence being suspended. It remains to be seen what the effect of this attempt at moral suasion will be, but those who are interested in having the ordinance regulating the escape of smoke within the city limits enforced will probably feel that condign punishment of the offenders would have secured a better guarantee of their future good behavior.

Physicians' Defense Company Not an Insurance Company.—In an opinion handed down May 8, the Appellate Court of Illinois holds that the Physicians' Defense Company, of Fort Wayne, Ind., is not an insurance company under the laws of Illinois, as the company does not undertake to indemnify the holder of its agreement against judgment, but only to pay such judgment if necessary. It does not insure the holder against suits for malpractice. It merely makes a defense against them when they are brought and provides legal services for its patrons.

Loving Cup for Dr. Flint.—The class of 1909 of Cornell University on May 18 presented to Dr. Austin Flint a silver loving cup in memory of his retirement from the chair of physiology on account of reaching the age limit.

Medical College for Women to Be Closed.—The Ontario Medical College for Women, founded twenty-three years ago, is to be discontinued. Owing to the admission by Toronto University of women into the same medical course as men, the attendance has been gradually dropping off at the Ontario Medical College, and the managers do not consider it advisable to continue the institution.

Bellevue Hospital Plans.—The latest development in the controversy between the State Board of Charities and the Board of Trustees of Bellevue Hospital regarding the right of the former to supervise the plans for the enlargement of the hospital has been the granting by Supreme Court Justice Fitts, on the application of Deputy Attorney General Pierce, of an order requiring the Bellevue Hospital Board to show cause at a special term to be held in Albany, why a mandamus should not be issued requiring a submission to the State Board of Charities of the plans for the reconstruction of that institution.

St. Joseph's Hospital (Paterson, N. J.) Staff.—In consequence of a disagreement with the directress of the hospital regarding the appointment of new members of the visiting staff, the entire corps of physicians at St. Joseph's Hospital resigned on May 17. The new staff is composed as follows: Dr. Edward F. Denner, Dr. William Neer, Dr. Thomas J. Kane, Dr. Charles Campbell, Dr. James O'Donnell, Dr. Charles H. Scribner, and Dr. J. W. Atkinson.

"Index Medicus."—Mr. William Barnum, chief clerk of the Carnegie Institution of Washington, announces that the issue of the *Index Medicus*

has been unavoidably delayed, owing to the recent printers' strikes in Boston, where the periodical is printed. For this reason, the *Index Medicus* for March, 1906, has not as yet been published, nor has it been possible to complete work on the index to the volume for 1903. Measures are being taken to relieve the situation, however, and it is hoped that the work of publication will soon be resumed on its regular basis.

Ambulance Collision. — An Eastern District Hospital ambulance was struck by a Lorimer street trolley car on May 19, at Noble street and Manhattan avenue, Williamsburg, and the driver and two surgeons were thrown to the street. The surgeons escaped with slight injuries, but the driver was seriously hurt and was taken to St. Catharine's Hospital.

Beer and Athletics. — In commenting on the failure of the German competitors to distinguish themselves in the recent Olympian games at Athens, German writers do not hesitate to ascribe the incapacity of their country's representatives to the use of beer. The present instance is cited as another proof of the deleterious effect of beer drinking on muscular capacity.

Professor Koch to Remain in Africa.—Professor Robert Koch has resigned the presidency of the Berlin Medical Society, to which he was recently elected, because he has found that the researches on tropical diseases on which he is at present engaged in Africa have proved so engrossing that he will not be able to return to Germany for two years or more.

Against Christian Science in England.—In consequence of the feeling against Christian Scientists aroused in England by the death of Major Whyte, which occurred while he was under the care of an alleged healer named Adcock, a member of the House of Commons on May 16 demanded that legislative measures be taken to prevent followers of the cult from carrying on their practices, with a view to protecting the lives of the ignorant and credulous. Home Secretary Gladstone replied that the law regarding the practice of medicine would probably be further elucidated in the course of the trial for manslaughter of the healer mentioned, and that no action could be taken until the trial was concluded.

Chicago Ambulances to Have Physicians.—The ambulances of the police department of Chicago will soon be turned over to the city health department, in accordance with the plans of the Health Commissioner and the Chief of Police. The eight ambulances to be transferred will each be under the charge of a physician.

Hospital Nurses Strike.—On account of the alleged acerbity of tongue of the matron of the Oil City, Pa., Hospital, the eight nurses of that institution left the hospital in a body. It is stated that three ineffectual protests had first been made to the board of directors before the nurses took this step.

A Warning.—We do not by any means oppose the American Medical Association. On the contrary, properly conducted, it has a legitimate field of usefulness that no other association of the profession can fill. It is only as a caution that it should cease to antagonize the honest convictions and rights of a great mass of the loyal members of the profession that we write. Otherwise, the time will come, as with some of the insurance corporations of the day, when searching inquiries will be made, which will threaten the downfall of the now mighty organization.—*Virginia Medical Semi-Monthly.*

Yellow Fever in Cuba.—A case of yellow fever has been reported from Matanzas, the diagnosis being confirmed by autopsy. Several cases occurred in the same neighborhood during February, but energetic precautions were taken, and it was thought that the disease had been stamped out.

Illegal Practitioners Arrested. — The County Medical Society has succeeded in obtaining evidence against four abortionists, and in consequence of the affidavits submitted by the Society's officers warrants for the arrest of the two men and two women in question were issued and carried out.

Obesity a Disease.—At a court in London the question recently came up whether corpulence were a disease or not. A patent medicine company was being prosecuted for selling an obesity cure without the revenue stamps required on all proprietary remedies for any "disease, ailment, or disorder." The magistrate ruled that obesity is a disorder and that the defendants had committed a breach of the law.

Association of American Physicians. — At the annual meeting of this Association, held in Washington May 15 and 16, 1906, the following officers were elected: *President,* Dr. Francis P. Kinnicutt of New York; *Vice-President,* Dr. James Tyson of Philadelphia; *Secretary,* Dr. Henry Hun of Washington; *Recorder,* Dr. Solomon Solis-Cohen of Philadelphia; *Treasurer,* Dr. J. P. Crozier Griffith of Philadelphia; *Councillor,* Dr. L. F. Barker of Baltimore.

Oklahoma Medical Association.—The following officers were elected at the convention of this society held in Oklahoma City on May 9: *President,* Dr. B. F. Fortner of Vinita; *Vice-Presidents,* Drs. M. A. Kelso of Enid, Walter C. Bradford of Shawnee, and Floyd E. Waterford of Holdenville; *Secretary and Treasurer,* Dr. E. O. Barker of Guthrie. The next meeting will be held in Shawnee.

Kansas State Medical Association. — Officers were elected as follows at the fortieth annual meeting of this society, held in Topeka on May 12: *President,* Dr. L. L. Uhls of Osawatomie; *First Vice-President,* Dr. W. F. Sawhill of Concordia; *Second Vice-President,* Dr. P. S. Mitchell of Iola; *Librarian,* S. G. Stewart of Topeka. Dr. G. H. Hoxie of Kansas City was re-elected editor of the State journal.

Utah State Medical Association.—At the closing session of the annual meeting of this society held at Salt Lake City on May 9, the following officers were elected: *President,* Dr. F. Clift of Provo; *Vice-Presidents,* Dr. A. C. Behle of Salt Lake and Dr. E. M. Conway; *Secretary,* Dr. W. S. Ellerbeck of Salt Lake; *Treasurer,* Dr. J. N. Harrison of Salt Lake.

Maine Medical Association. — The fifty-fourth annual meeting of this association will be held in the City Building, Portland, Me., Wednesday, Thursday, and Friday, June 13, 14, and 15, 1906. The president is Dr. Randall D. Bibber, of Bath, and the secretary is Dr. Walter E. Tobie, of Portland.

The American Association of Life Insurance Examining Surgeons.—This society will hold its seventh annual meeting on June 4, 1906, in Boston, Mass., at the Hotel Thorndike. The president of the society is Dr. Henry Wells Dewey, of Taco-

ma, Wash., and the secretary is Dr. John Guy Monihan, of New York.

Connecticut Homeopathic Medical Association.—The fifty-sixth annual meeting of this association was held in Hartford on May 15, and the following officers were elected: *President,* Dr. William Pitt Baldwin, of New Haven; *Vice-President,* Dr. S. Mary Ives, Middletown; *Secretary,* Dr. H. A. Cameron, Waterbury; *Treasurer,* Dr. Ernest J. Walker, New Haven.

Obituary Notes.—Dr. Albert Töpfer of Jersey City died on May 18, at the age of fifty-seven years. He came to this country from Germany thirty-five years ago.

Dr. Fritz Mechtold died at his home in Stapleton, S. I., on May 19. He was born in Germany in 1842 and was graduated from the New York University Medical College in 1881. He had served for some years as a medical inspector in the Health Department.

Dr. James Miller, Jr., Assistant Surgeon U.S.N., died on May 13 at the Midway Islands. Assistant Surgeon Miller was thirty-one years old and had been on duty with a detachment of marines at Midway Islands since November, 1905.

Dr. William A. McDonald of Lynn, Mass., died on May 11, at the age of sixty-two years. He was graduated from the Harvard Medical School in 1872 and had practised in Boston, Springfield, Fall River, and Malden. He had practised in Lynn during the past twenty-five years.

Dr. William M. E. Mellen of Chicopee, Mass., died on May 14 of cerebral hemorrhage, at the age of fifty-eight years. He received his medical diploma from the University of Michigan in 1876 and had practised in Chicopee since 1878. He had held many public offices in Chicopee, including the mayoralty.

Dr. J. M. D. France of St. Joseph, Mo., died on May 9, at the age of sixty-five years. He was graduated from the Georgetown Medical College in 1865 and had practised in St. Joseph since 1869.

Dr. Jacob L. Williams of Boston, Mass., died on May 15, at the age of eighty-two years. He was a graduate of Brown University and received his medical degree from the Harvard Medical School in 1848.

Dr. Carrie M. Hayward died on May 11, at her home in Malden, Mass., after a long illness. She received her medical degree from the University of Michigan in 1898 and had practised in Chicago.

Dr. Eli Allison of Wayne, N. Y., died after a lingering illness on May 18, at the age of seventy years. He was a graduate of the Geneva Medical College in the class of 1861, and had practised in Steuben county ever since. He had been a member of the Steuben County Medical Association for nearly forty-five years and had served as its president.

The Efficiency of Salicylate of Sodium in Inflammatory Eye Disease.—H. Gradle declares that the disease in which salicylate of sodium has proven itself superior to any other therapeutic agent is irido-cyclitis due to traumatism with infection, as well as in sympathetic disease secondary to it. The writer has watched sympathetic inflammation from the day of the start to its termination in three patients, treated by salicylate of sodium. All three recovered with perfect sight. He knows that the first remained well at least five years, the second nearly three years, while the third died with sight intact, nine months later. Even in so small a number of cases in a disease so dangerous to sight invariable recovery is the strongest possible proof of the efficiency of the treatment.—*Illinois Medical Journal.*

Correspondence.

FIFTEENTH INTERNATIONAL MEDICAL CONGRESS.

(From Our Special Correspondent.)

SYMPATHECTOMY—CAUSES OF SPLANCHNOPTOSIS—FEVER AFTER SPLENECTOMY—FOREIGN BODY IN THE ABDOMEN—THE TREATMENT OF HEMORRHOIDS—PERFORATIONS OF THE GASTROINTESTINAL TRACT—TREATMENT OF NEURALGIA—STATUS THYMICUS—RENAL DIAGNOSIS—ANEURYSM OPERATIONS—PRESSURE NARCOSIS—SURGERY OF THE VASCULAR SYSTEM—PROLAPSE OF THE RECTUM—OPTOMETRY—MILITARY BARRACKS—MILITARY FIRST AID TO THE INJURED.

Lisbon, April 27, 1906.

The surgery of the sympathetic system was discussed by two speakers, Jonnesco of Bucharest and De Sousa of Lisbon. The former first reviewed the historical aspects of the subject and then described the results obtained in the course of his own work in this field, which had convinced him of the great value of resection of the sympathetic ganglia. His statistics embraced 159 cases with 314 sympathectomies. In order to derive the full benefit from the operation, for example in exophthalmic goiter, it was necessary to resect not only the cervical chain but also the first thoracic ganglion. Of 25 cases of this disease the greater proportion were cured as was shown by photographs which were exhibited. In glaucoma he had secured 91 cures, and his results were so favorable that the operation had been well received by ophthalmologists. In epilepsy the outcome was less favorable, for out of a series of 100 cases only 12 at the most had been cured. Sympathectomy was to be preferred to resection of the Gasserian ganglion in trigeminal neuralgia owing to the fact that it was less dangerous and accomplished a great deal. Jonnesco cited one case of essential migraine in which the operation effected a cure after all other attempts had remained fruitless. The resection of the pelvic portion of the sympathetic had given excellent results in sciatica, vaginismus, pelvic neuralgia, the pains of tabes, and in a case of nymphomania in a woman 65 years old.

Sousa stated that so far but little knowledge was available concerning the pathology of the sympathetic system. In epilepsy he believed that sympathectomy might accomplish a great deal, but that it was difficult to select the favorable cases beforehand, and that those cases that were refractory to the bromides might be the most suitable for the operation. In exophthalmic goiter strumectomy gave better results but was more dangerous than sympathectomy. In trigeminal neuralgia resection of the Gasserian ganglion, while more certain in its results, should be performed only as a last resort owing to its greater danger. In glaucoma there was not much difference between the results of iridectomy and sympathectomy, and only when the former operation was contraindicated was the latter to be regarded as a substitute. As regards the severity of the operation he said that out of 456 cases that had been reported the mortality was 11, or 2.5 per cent.

In the discussion Rehn of Frankfurt expressed the point of view of the German surgeons in saying that in Germany the thyroid operation was preferred to sympathectomy in Basedow's disease owing to its greater safety and the fact that the results were just as satisfactory. Spontaneous fluctuations in the patient's condition might give rise to error in drawing conclusions from the results of operations. Garré of Breslau, had resected the ganglia in four cases of glaucoma without any results.

Agnes Victor of Boston read a paper on the fundamental causes of splanchnoptosis. The condition was referred to the existence of a developmental defect which was termed abdominal incompetence, and the ontogenetic and philogenetic evolution of the function of the abdominal walls was reviewed in detail.

E. von Herzel of Buda Pest spoke on a hitherto unrecognized cause of fever after extirpation of the spleen. It was well known, he said, that elevations of temperature often occurred after this operation without any apparent reason. This fever was probably caused by the fat necrosis produced as a consequence of injury to the pancreas. In ligating the splenic vessels the tail of the pancreas was likely to be injured, causing the liberation of ferments which caused fat necrosis in the neighborhood and so gave rise to fever. In order to avoid damage to the pancreas the splenic vessels must be ligated close to the latter organ.

Kojuharoff of Sophia described the accidental leaving of a gauze tampon in the abdomen at operation. Nine weeks after a vaginal hysterectomy the patient manifested symptoms of obstruction, and finally passed the foreign body by the rectum. Six months later the patient again suffered from evidences of obstruction, which at a second laparotomy were found to be the result of peritoneal adhesions. A

sinus persisted and death followed a year later from pyemia. The same author in discussing the treatment of hemorrhoids said that no one of the methods in vogue was quite satisfactory. In the course of his experience he had found that the cautery operation was the most useful. In order to prevent hemorrhage he usually passed from one to three sutures through the burned area.

Tillmann of Cologne discussed acute perforation of the gastrointestinal tract and the gall-bladder. He considered that the better results which he had obtained of late were due to greater accuracy in diagnosis and to the simplification of the operation. In perforation of gastric ulcer a sensation of fullness in the region of the stomach was often present, and in perforation of the appendix persistent vomiting was characteristic. In the treatment of such cases the dry cleansing of the abdomen with gauze was preferable to irrigation. All cases of perforation of the appendix which had come to operation during the first 60 hours had been cured. Of 8 instances of perforated gastric ulcer one, which was operated on six hours after the accident, was cured.

Bardenheuer of Cologne presented a new method for the treatment of neuralgia which depended on his theory that neuralgia was due to hyperemia and should be treated by freeing the nerves from their constricting sheaths. The advantage of this method, which never failed, was that the nerve remained entirely uninjured. In the 16 cases of sciatica so far operated on no relapse had occurred in from 6 to 8 years, and in 5 cases of trigeminal neuralgia no relapse had taken place in from 3 to 14 months.

Rehn of Frankfurt, A.M., reported 28 autopsy records and 5 operations which he said demonstrated the effect of pressure of the thymus on the trachea. The affection was not rare, but so far was but little understood. For diagnostic purposes the appearance over the jugulum of a small mass during an attack of dyspnea was of value. Every attack of dyspnea in such a patient indicated surgical intervention, which should be directed toward the gland itself, as tracheotomy was of no use.

Kapsammer of Vienna read a paper on the diagnosis of the surgical diseases of the kidney. He said that cryoscopy of the urine did not give reliable results; and it appeared that even when performed on the blood it was of service only in the hands of very experienced observers. The methylene blue test and the indigo-carmine test were also unsatisfactory in determining renal capacity. The phloridzin method gave unreliable results in regard to the quantity of sugar excreted, since the drug often gave rise to a flood of urine. On this account he was inclined to accept as a criterion the length of time that elapsed before the sugar reaction appeared. If the sugar was not excreted by one kidney until fifteen or more minutes after the injection, functional incapacity of the organ existed. He also pointed out how unreliable the older methods of diagnosis had been by citing autopsy records which showed that at 20,000 autopsies over 700 cases of surgical disease of the kidney were discovered which had not been recognized during life.

The subject of renal diagnosis was further discussed by Cathelin and Albarran, both of Paris, who spoke of the use of the cystoscope and of the functional tests. Kümmel of Hamburg stated that cryoscopy of the blood had never failed him and that he now had records of 1,000 cases.

Garré of Breslau took for his subject suture of the artery in aneurysm operations. He described at some length a case in which an aneurysm of the thigh was successfully treated by incising the sac and restoring the channel of the femoral artery by suture.

Kuhn of Cassel described an apparatus for performing operations on the thorax under pressure narcosis, which could also be used for therapeutic purposes in certain pulmonary conditions.

D'Arcy Power of London reviewed recent advances in the surgery of the vascular system. He paid a tribute to the work done by Crile in the United States and stated that he had been able to follow many of Crile's suggestions with good results. The advances in the ligature of arteries were then passed in review, and Power expressed his preference for silk over catgut and silkworm gut. The treatment of aneurysm was next discussed, and Power explained an apparatus for the wiring of aneurysms with the subsequent passage of electricity, if necessary, which had been invented by N. G. K. Colt, one of his internes. The advances in connection with the surgery of the venous system were considered and Power expressed the opinion that Trendelenburg's method of treating varicose veins was satisfactory in the majority of cases, though it was unsuitable where the veins were very large, numerous, and thin-walled. He called attention to the treatment of varicocele and of hemorrhoids, and concluded his report with an account of the methods in use for the cure of nevi, both vascular and lymphatic. The same author also presented an extensive paper on the symptoms, treatment, and sequelæ of nonmalignant ulcer of the duodenum.

Napalkour of Moscow discussed prolapse of the rectum. He differentiated between prolapse of the mucosa and of the rectum itself. The former, he said, was always the result of catarrhal inflammation, and was best treated by twisting the mucous membrane 180° around its axis. Prolapse of the rectum was really a perineorectal hernia. Its treatment involved the usual principles for the radical cure of hernia, consisting in elevation of the peritoneal sac, in longitudinal folding of the anterior rectal wall, and in shortening and suture of the levator ani muscle.

Mario Montinho of Lisbon presented a chart for optometry which was a modification of that devised by Mithaud. It had the advantage that it was printed in several colors in addition to black and red, so that it made it possible to detect color blindness. This feature was particularly important in examining individuals who intended to enter marine service. Instead of letters of different size colored circles were used, which was an advantage in examining the illiterate. As the circles were of a definite size the acuity of vision could also be determined and the chart could be used for detecting malingerers.

Brissaud of Paris discussed the construction of military barracks from the point of view of the tuberculosis expert. Some of the features spoken of were the suitable location of the buildings so as to protect them against wind, adequate thickness of the walls, and the undesirability of long straight corridors with their inevitable draughts. He said that the parade ground should also be sheltered from the wind, and that when maneuvers were undertaken adequate provision should be made for protection of the men from the elements.

Kern of Berlin read a paper on military first aid to the injured. He said that during an engagement the first aid should be rendered by such representatives of the medical corps as were on the spot, and that for this purpose two-horse ambulances of light construction should be provided for the purpose of supplying material for emergency dressings. These ambulances should be arranged so as to serve for the purpose of distributing supplies and for transporting the wounded. One of the horses should be equipped with a pack saddle and in rough country should be used as a pack horse independently of the ambulance.

Senn of Chicago discussed the treatment of gunshot wounds in military practice. He said that the fate of the wounded depended largely on the thoroughness with which first aid was rendered. This comprised the treatment of shock and hemorrhage, dressing the wound, and immobilization of the injured part. Probing of recent gunshot wounds must be prohibited. Under no circumstances should attempts be made to extract bullets until this could be done in a well-equipped hospital under strictest aseptic precautions and then only in cases in which such operation was clearly indicated, when the bullet could be felt through the intact skin or its exact location had been determined by the employment of the *x*-ray.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENT, ANTI-VACS. AND ANTI-VIVOS.—THE PRESS AND QUACKERY—"CHRISTIAN SCIENCE" AT AN INQUEST—SERUM TREATMENT OF GONORRHEA—HYSTERECTOMY ON A DIABETIC —SCABIES.

LONDON, May 4, 1906.

On Wednesday the House of Commons witnessed another minister pandering to the Anti-Vacs. This time it was the Education Minister. In reply to a question, he said he proposed to insert in the regulations a provision to exempt intending teachers who objected to be vaccinated, leaving local authorities to decide in each case whether they would employ such a teacher. The same discretion is to be extended to pupil teachers entering training colleges. It seems rather mean to throw the responsibility of this repeal by installments on the local authorities. Asked whether such discretion was allowed in any other part of the civilized world, Mr. Birrell said he was not a judge of civilization—and he is the Minister of Education!

The Budget is a disappointment to medical men, as the Chancellor of the Exchequer fritters away a splendid surplus in doles to coal owners, tea dealers, and others who have made large outcries, while the income tax, which falls almost altogether on precarious earnings, is left at the war standard, with a half promise to inquire into its incidence. Whichever party is in, the promises remain unfulfilled.

The antivivisectionists' bills are put down for Monday next.

A fortnight ago I mentioned to you that the new editor of *Punch* had joined the committee for pushing the "Normyl cure" for inebriates. At that time an equally serious surrender to quackery was made by the *Times*. An article headed "The Redemption of the Inebriate," occupying two

columns of leader type and consisting of a gross puff of a drink cure, arranged expressly to appear as an indorsement of it, has given quite a shock to the profession. The article is prefaced by this statement: "These notes have been written by a member of the *Times*' advertising staff after thorough investigation, conducted with the assistance of an independent registered medical practitioner of long experience." Who could have supposed that the *Times* would descend to this level? Such puffs are too common in the cheapest and least respectable periodicals, but for the *Times* to insert them—and that, too, with all the appearances intended to confuse the editorial staff with the advertising department—that is a fall indeed, and bodes ill for the boasted honor of the press.

The entry of *Punch* and the *Times* on the down grade is certainly to be deplored, but it seems we are also threatened with the defection of *Truth*, a paper which has heretofore reveled in the exposure of shams. The *Medical Press and Circular* has lately begun another campaign against journals which admit quack advertisements, and in the fight has challenged *Truth* as to its admission of announcements concerning cures for baldness, wrinkles, and other things palmed on the public by unscrupulous advertisers. The society editor seems to have lost his temper at being challenged by a medical editor, and, neither being accustomed to mincing their words, some lively paragraphs have passed between them.

Yesterday some remarkable evidence with reference to the so-called Christian Scientists was given at the Westminster Coroner's Court. The inquest was concerning the death of Major J. N. Whyte, who met with an accident in the hunting field three years ago, the spine being fractured. He was treated at a cottage hospital, and Sir Victor Horsley was called in and operated successfully. He was brought to London later and attended by Dr. Huxley and Sir Victor. Seven or eight months later he went to Bournemouth and stayed about four months. Then to London a short time and afterward to Osborne, where he came under the influence of the Christian Scientists, subsequently staying in the house of one of these "practitioners." The evidence as to their doings is on the lines of previous cases, but appears so far more shocking than usual. The inquest is adjourned, but part of Sir Victor Horsley's evidence may be given. Called to him again after a long interval, he found him dying and "in a horrible state." It was "the most horrible case he had ever seen." The cause of death was blood poisoning from neglect of bed sores. At the post-mortem the hip had become dislocated by an enormous abscess, which was gangrenous. Asked if it was a case for treatment, Sir Victor said: "Oh, yes, the lives of patients in these cases depend on attention for bed sores. They are the avenue of infection." It was said a powder had been applied, that was only oxide of zinc, with hardly any antiseptic property. Asked if the patient had received proper treatment might he now be alive, Sir Victor replied, "Oh, certainly." The inquiry was then adjourned.

The serum treatment of gonorrheal infection and purpura hemorrhagica was the subject of a paper at the Royal Medico-Chirurgical Society on the 24th ult., by Dr. Soltan Fenwick and Dr. Porter Parkinson. An interesting point brought out was the employment of serum per rectum. Numerous cases had been treated by the authors during the last two years, and all had been cured, and that in a short time, generally only a few days. Pyemic, rheumatic, and acute cases were among those treated by polyvalent antistreptococcus serum injected into the rectum. Similar good results were obtained in two cases of purpura hemorrhagica. One of these two seemed moribund when the serum was resorted to.

Mr. S. Paget remarked on the fact that the serum seemed to give the same results in both acute and chronic gonorrhea.

Mr. Campbell Williams divided gonorrheal rheumatism into three varieties, viz., (*a*) cellulitic, (*b*) arthritic, and (*c*) arthralgic. In the last there seemed to be an effect on both nerves and periosteum, and he attributed the cause to a toxin circulating in the blood and acting on fibrous tissue. In the cellulitic form he thought the serum would probably be more effectual than in the others. The method deserved a more extended trial, and might prove useful even in gonorrheal salpingitis. The cases adduced bore out the view that gonorrhea is due to a mixed infection.

Mr. Mummery said the difficulty of treatment was in the later stages, which seemed less affected by the serum than the earlier. He approved the rectal method. Dr. Parkinson in reply said no preparation of the rectum was required beyond washing it out. Purpura they attributed to toxins or to microorganisms. He thought serum might be useful in gonorrheal ophthalmia.

At a meeting of the Gynecological Society a large myomatous uterus was shown for Prof. J. W. Taylor, who had removed it from a diabetic patient aged forty-six. She had had one child nine years previously and one miscarriage the following year. She complained of menorrhagia. The diabetes had been observed above a year, and abdominal enlargement had gone on rapidly for several months. Urine acid, sp. g. 1038, much sugar, some albumin. The patient had done well, and Prof. Taylor, finding no statistics of hysterectomy in diabetes, reported this case, thinking it might lead others to relate similar ones, in order that the relative dangers might be estimated of noninterference or of removal when the symptoms were so serious as to seem to call for operation.

Mr. Ryall admired Prof. Taylor's courage in dealing with such a large tumor in a patient with diabetes. From a surgical point of view the risks were sepsis and shock. Five or six years ago he did a hysterectomy on a diabetic who was suffering much from pressure symptoms. She died from shock.

Scabies having attracted attention lately in connection with the "ragging" case, I take some notes about it read by Dr. Barendt at the Liverpool Medical Institution. He said that where the primary eruption could not be detected —cuniculi not being recognizable—but the sites of the secondary eruption due to the pruritus were well defined, the patient should be treated for scabies. In women the area of the nipple, in men the genital region, should be carefully examined. Infection was almost always nocturnal and the result of prolonged contact. That handling of bed or body clothes or shaking hands could communicate scabies was not proven. To trace infection the patient should be questioned on his surroundings for the three weeks preceding the onset of the itching. He used B.-naphthol ointment, 9 per cent., made with superfatted soft soap, which neither stained nor had a disagreeable smell, nor aggravated secondary lesions which sulphur always does. Dr. Stopford Taylor remarked that no treatment was satisfactory unless all clothes were boiled or stoved. At Liverpool the sanitary authorities do the stoving free of charge.

OUR VIENNA LETTER.

CENTENNIAL OF V. FEUCHTERSLEBEN—ESOPHAGOSCOPY—TRANSPLEURAL WOUND OF THE LIVER—OSMOTIC CAPACITY OF THE KIDNEY—INCARCERATED HERNIA.

VIENNA, April 14, 1906.

At the annual meeting of the Royal Medical Association, held on the 23d of March, Prof. Neuburger delivered a memorial address on Ernst v. Feuchtersleben, the hundredth anniversary of whose birth falls on April 29 of this year. The speaker portrayed in admirable fashion the development of this eminent physician, poet, art critic, and reformer, and traced the interrelationship of these various fields of activity in his career. Feuchtersleben was born in Vienna as the son of a prominent official, and after having received his education at the Theresa Academy, devoted himself to the study of medicine in spite of the opposition of his family, and was graduated in 1834. Shortly after this, owing to financial disaster to the family, he was obliged to begin practice under circumstances of great hardship, in the course of which he was forced to make use of his literary talent. In the year 1840 he became secretary of the Medical Association; in 1844 he delivered a very popular series of lectures on psychiatry; in 1845 he was made dean of the medical faculty of Vienna; in 1847 vice-director of the medical and surgical departments; in 1848 member of the Academy of Science, and finally, after having declined the portfolio as minister of education, he was made State secretary in the same department; in 1848 he retired. His most important works are "Dietetics of the Soul," which has passed through forty-six editions, and his "Textbook of Medical Psychiatry," the first comprehensive work on psychology and psychiatry, and which has been translated into several languages. His chief claims to medical gratitude lie in his efforts to demonstrate the connection between medicine and its sister sciences, in his pioneer work in the development of psychiatry, and in the fact that he reformed medical instruction in several directions and effected the abolition of the Latin language in medical lectures.

Hajek has described the extraction of a foreign body from the esophagus by means of the esophagoscope. A woman who had swallowed a hook-shaped bone at dinner came to him, saying that the physician who had been called after the bone was swallowed had attempted to push the foreign body into the stomach; since that time she had suffered from both dysphagia and constant pain. The esophagoscopy was easily carried out under cocaine anesthesia, and at a distance of 36 cm. from the teeth one prong of the bone could be brought into the field of view. The other prong was buried in the wall of the esophagus, but removal of the foreign body was easily effected at the first attempt and caused all the symptoms to disappear. This case is another illustration of the inadvisability of using

the bougie when pointed bodies have been swallowed, as in this way injuries of the esophagus, and therefore under some conditions extremely dangerous complications, may easily be produced. If it is necessary to determine the situation of the foreign body this should be done either by means of radiography, or if this is not possible, by the use of v. Hacker's foreign body instrument or with the soft rubber stomach tube, as has been recommended by Stark. Esophagoscopy has already been found extremely useful in removing foreign bodies, and Stark, in his recently published textbook, has been able to report seventy-eight cases, to which may be added eleven others that have just been described by v. Hacker.

Prof. Frisch presented before the Society of Physicians a sixteen-year-old boy on whom he had operated three years previously according to Thiersch's method for complete epispadias with infundibulum. The defect was completely closed, but unfortunately, as so often happens in these cases, the boy had no sphincteric control and had been obliged to make use of a permanent urinal. Owing to the disagreeable odor this entailed the boy was unable to secure employment and was discharged from one position after another. Frisch succeeded in completely relieving the dribbling of urine by the injection of vaseline. This was carried out by plunging the needle through the perineum under control of one finger in the rectum until the point could be felt close to the membranous urethra. Three c.c. of vaseline were then injected on each side. At present the patient has no incontinence, whereas formerly he lost about 30 c.c. of urine per hour while up and about.

Dr. Milko has operated on a case of transpleural injury to the liver. The patient was a shoemaker, thirty-eight years old, who was stabbed in the side with a cobbler's awl. He at once lost consciousness, and severe hemorrhage occurred, so that when he was brought to the hospital half an hour later he was almost exsanguinated. On examination a profusely bleeding wound 6 cm. long was found in the seventh right intercostal space two finger breadths from the sternum. A piece 8 cm. long was resected from each of the seventh, eighth, and ninth ribs, and then the wound in the diaphragm was enlarged with scissors until the convexity of the liver was exposed. The wound in this was deep enough to receive the index finger for all its length. As it appeared impossible to check the hemorrhage in any other way, even firm packing being without effect, Milko decided to attempt suture. Six sutures were introduced, causing prompt cessation of the hemorrhage, and packing was introduced in addition. The packing was removed on the fourth day, and four weeks later the patient was discharged cured.

The osmotic function of the kidneys has been made the subject of extremely tedious but very important calculations by Rohrer, who has been able to ascertain that the osmotic capacity of the kidneys is a calculable quantity. Rohrer gives the total of the capacity as 308.27 mkg., a result that is at variance with that of Dreser-Galeotti, which was only 172.2 mkg. It is, therefore, possible to determine accurately the extent of the osmotic function of the kidney and, although the process is somewhat difficult, we must remember that we know so little of many of the processes going on in the body that we must gladly accept any possibility of obtaining an insight into the changes involved. The same calculation which was used to determine the efficiency of renal osmosis may also be used in all the processes depending on variations of concentration—that is, for all glandular secretions. It is possible that in this way we may in the future be able to express the physiological and pathological function of organs in figures and so make of medicine a science as exact as physics or chemistry.

Dr. Blau has described a successful case of operation for hernial volvulus. The inguinal hernia of a sixty-eight-year-old carpenter had already been incarcerated twice before his admission to the hospital. At the operation a section of ileum 60 cm. long was found which, though strangulated, was still living and covered with omentum. The incarcerated portion of the intestine was much distended, and after division of the incarcerating band it was found that the mesentery of the imprisoned loop was rotated 180° in the hernial ring. On drawing out the proximal portion of gut from the abdomen it was found that it was greatly discolored and infiltrated for a distance of 43 cm., but even this section of intestine recovered its vitality under the influence of hot compresses so that it could be replaced after resection of the omentum.

Swallowed Foreign Bodies may, according to Blair Bell, be rendered harmless in their passage through the intestine by the administration of a quantity of absorbent cotton plucked into small shreds and given in bread and milk. The foreign body becomes enveloped in the shreds of cotton so that any sharp angles are covered over and injury to the intestine is avoided.—*Medical Press and Circular.*

Progress of Medical Science.

Boston Medical and Surgical Journal, May 17, 1906.

A Biographic Clinic on Tchaikovsky.—G. M. Gould gives copious extracts from the writings of this eminent composer, which according to the author illustrate the inhibiting effect of overattempted but impossible ocular function. In other words, Tchaikovsky suffered from eyestrain.

The Treatment of Organic Heart Disease by the Pneumatic Cabinet.—According to C. E. Quimby, the mechanics of the circulation are illustrated by the following propositions: (1) The circulation depends upon an alternation of differential blood pressures, and its amount is determined solely by the difference, not by the absolute amount of such pressures. (2) The integrity of the vascular mechanism and, hence, duration of life, depend directly upon the maintenance of the absolute amount of blood pressure below a fixed limit; or below an established ratio to heart power. (3) Every cardiac lesion causes an immediate and progressive increase of blood pressure, either absolute or relative, and such increased pressure is the essential cause of death. Therefore (4), the ideal treatment of organic heart disease is to maintain the circulation under low blood pressure; or to hold any inevitable increase of pressure within the limits of possible compensation. The author then describes the cabinet method of treatment. He declares that lowered atmospheric pressure is the equivalent of a differential pressure in favor of the pulmonary circulation, and then makes the application of this principle to the various common valvular lesions. He does not claim that the cabinet will cure those organic heart lesions commonly regarded as incurable, but an experience of fourteen years has firmly convinced him that it affords more immediate, extensive, and lasting relief than any other known measure.

New York Medical Journal, May 12, 1906.

Constitutional Low Arterial Tension and Its Relation to the Life of the Individual.—L. F. Bishop calls attention to the fact that there are certain individuals in whom the blood pressure is constitutionally low, who often have a gouty ancestry and are found in families who seem to have more than their share of high arterial tension. The patients have a very feeble pulse over long periods of time, and yet show none of the ordinary symptoms of circulatory disease. Such conditions must not be confounded with the low tension due to impaired cardiac power, or that resulting from exhaustion of the circulation from an unusual demand for pressure, as in Bright's disease. The patients present certain peculiarities. They thrive best under the stimulation of excitement, and require for their well being an unusual amount of activity and exercise. They are often able to endure without injury an amount of prolonged excitement, or even dissipation (excepting the use of alcohol), that in a person with a tendency to high arterial tension would be most harmful. These patients require active exercise. Many of them find that cold bathing does not agree with them, but that a very hot bath of short duration acts as a very powerful stimulant. While the ordinary symptoms of circulatory deficiency are absent, still there is sometimes so great a lack of peripheral circulation that cold feet and hands are a source of annoyance. Other patients with this condition suffer from occasional fainting attacks, and are inconvenienced in general by the slow response of the demand for an extra blood supply in any particular region of the body. Hence the erectile tissues respond slowly to the usual stimuli. Some of these persons gradually acquire a normal tension, and in many of them the conditions becomes less marked toward middle life.

Clinical Manifestations of the Toxemia of Pregnancy.—J. C. Edgar concludes an elaborate article in this issue. He says that as he sees eclampsia he is compelled to recognize at least two varieties, first, an eclampsia of nephritic origin or of renal insufficiency, and second, an eclampsia which is the natural consequence of a neglected toxemia of the kind peculiar to pregnancy, and which he ascribes to faulty liver action. He believes that these two types can be clearly differentiated. A faulty nitrogen partition may exist in both, but is especially marked in the eclampsia following the toxemia peculiar to pregnancy, and the same points of differentiation exist here as in the preeclamptic toxemia of nephritic origin and that due to the toxemia state peculiar to pregnancy. One general aim of the paper has been to determine from urinary analyses some definite conclusions to guide the general

practitioner in the diagnosis of pregnancy toxemia, but the author is not yet prepared to formulate definite statements along this line. The expression "imperfect metabolism" expresses as well as any the limit of our present knowledge.

Journal of the American Medical Association, May 19, 1906.

Fatigue.—F. S. Lee reviews the known facts and the theories regarding the phenomena of fatigue; showing that although physiologists are generally in agreement as to the facts of muscle fatigue so far as demonstrated, and it is pretty certain that the peripheral nerve fibers are themselves exceedingly resistant, the question of the susceptibility of the nerve centers to fatigue is still considerably in dispute. In view of the recent results of Sherrington, Joteyko, Story, and others, Lee is inclined to think that the muscular system tires before the nerve centers, and that the latter are, like the peripheral nerves, resistant to fatigue. They also throw a certain measure of doubt, he says, on all supposed proofs of central fatigue. A physiological explanation of the facts of mental fatigue is not possible, he says, in the present state of research. We cannot deny the fact of fatigue of psychic centers, but we can only speak with caution as to its being of central or peripheral origin. As yet we know too little in regard to the chemical changes attending fatigue. Lee's own experiments make it seem probable that a loss of carbohydrate has considerable part in the production of muscular fatigue, and he has also experimented with three metabolic products generally recognized as fatigue substances, sarcolactic acid, mono-potassium phosphate, and carbon dioxide, and finds that these exercise a toxic depressant action, especially on the muscular system, and that the sensation of fatigue is in large part the psychic manifestation of this depression. Other like fatigue substances will probably be discovered, and Weichardt's alleged discovery of a special fatigue toxin and antitoxin is mentioned in this connection as requiring confirmation. Little is known as to the production of fatigue substances in the central nervous system. The action of these substances, however, is not confined to the tissues in which they arise; excessive activity of one tissue can cause fatigue of others, and there are probably few physiological functions that are not affected unfavorably by the prolonged and excessive activity of the muscular and nervous systems. The facts of acid intoxication are noticed as analogous to fatigue phenomena, so far as the latter are due to toxic substances. In conclusion, Lee mentions as noteworthy the lack of serious endeavor, except by the nostrum vendors, to provide specific antidotes for fatigue, considering its importance in our daily life. Alcohol, which in small amount seems to have a favorable action, is followed by unfavorable after-effects and cannot be classed as a valuable antidote, and the same is true of other substances of similar physiological properties. A true antidote must recognize the causes. Both scientific and unscientific experience have shown the real value of sugar as a partial restorer of working power, and alkali, such as sodium bicarbonate, may not be without some value. These, however, are only in part efficacious, and only rest and sleep can be thoroughly relied upon.

Serum Prognosis of Tuberculous Pleurisies.—P. Courmont has investigated the agglutination reactions of blood serum and of the pleural serosity in tuberculous pleurisies. He finds that the prognosis of tuberculous pleurisy with effusion is favorable, according to the intensity of the agglutinating power of the pleural liquid, and grows worse with the diminution or absence of this reaction, which increases as recovery progresses and diminishes in fatal cases as death approaches. His conclusions are given, in substance, as follows: (1) The mortality is about 25 per cent. in cases with agglutinating power of the pleural effusion, and about 75 per cent. in those in which this is absent. (2) In patients with agglutinating effusion the ratio of recoveries is large in proportion as the agglutinating power is high. (3) One can see the agglutinating power increase as the case progresses toward recovery, and *vice versa*. (4) These facts support what has been held concerning typhoid fever, viz., that the agglutinating reaction is a reaction of defense, or at least goes parallel with the reaction of resistance of the organism. It is in general in inverse proportion to the gravity of the disease and in direct proportion with the intensity of the resistance. (5) The study of the agglutination in tuberculous pleurisies leads to important prognostic conclusions.

Treatment of Tetanus by Magnesium Sulphate Injections.—S. Logan reports two cases of tetanus treated, according to the method suggested by Dr. S. J. Meltzer in the MEDICAL RECORD of December 16, 1905, with injection of sulphate of magnesium into the spinal canal. Though neither patient recovered, in one of the cases the convulsive phenomena were strikingly reduced. All that Dr. Meltzer claims for the method is that it will prevent exhaustion and allow the system to work off the poison. In the other case the magnesium solution seemed to have little effect, which was attributed to insufficient dosage. Logan calls attention to the following points: (1) The evident sedative effect of the drug on the motor tracts of the cord, and he thinks that possibly if this had been kept up more persistently in the first case the outcome might have been different. (2) The interference with respiration, which was the only annoying feature of the treatment. This was relieved, however, in the first case, and the respiratory function was the last to fail. (3) The complete relaxation, which is out of the ordinary course of events in tetanus. He thinks it possible that we are likely to overestimate the convulsive features of the disease, and not to consider sufficiently the importance of neutralizing the toxins. The treatment is only a palliative one, but, as such, he believes it deserves a further trial.

The Leucocyte Formula in Pertussis.—F. S. Churchill has studied the lymphocyte increase in whooping-cough and reviews its literature. In 36 cases, leucocytosis existed in all but one. Differential counts showed a lymphocytosis in 30, and in 15 out of 16 patients examined in the catarrhal stage. The significance of a high percentage of lymphocytes is of course greater as the child advances in years. His conclusions are as follows: "(1) A general leucocytosis, is present in almost all cases of whooping-cough. (2) A lymphocytsosis, *i.e.* an increase in the number of lymphocytes, is found in about 85 per cent. of cases at some time during the course of the disease. (3) A lymphocytosis is found even more constantly during the early or catarrhal stage, over 90 per cent. showing the phenomenon at this time. (4) A lymphocytosis is found usually in those conditions difficult to distinguish from whooping-cough. (5) The presence of a lymphocytosis in a child with a hard, persistent cough is a factor of great diagnostic value. It is also of prophylactic importance, inasmuch as it can be utilized to prevent the spread of the disease by leading to the prompt isolation of the patient. (6) The child's age must be taken into account in estimating the importance of the lymphocyte percentage."

Improved Method of Suturing in Appendicitis.—J. E. Summers describes his method of operation in appendicitis, with especial reference to the manner of inserting the sutures. The wound is sutured from peritoneum to skin, inclusive, by a one-string continuous stitch. Commencing at the inner angle, the peritoneum is closed by a simple continuous or buttonhole stitch. When the outer angle is reached, the needle (a full-curved, round one, spear pointed) is passed from below upward through the transversalis and internal oblique muscles, the needle emerging one inch outside of and above the outer angle of the separation in these muscles. This manipulation pulls the closed and puckered wound in the peritoneum above and somewhat outside of the line of the cleft in the muscles. These muscles are closed from without inward by a few deep (including all muscle) continuous stitches. If the deep continuous stitch through the muscles has sufficed, the needle is passed from the inner angle of this closure superficially through the internal oblique muscle downward and brought out at the lower angle of the wound in the fascia of the external oblique muscle. This fascia is then closed, either by a simple continuous stitch from below upward, or else the fascia may be made to overlap, and in this way give firmer support. Summers, however, thinks overlapping of the fascia unnecessary. He closes the skin with either a compound buttonhole stitch or a subcuticular stitch. The whole procedure from the commencement of the operation to the closure of the wound takes from eight to twenty minutes, according to the difficulties found within the abdomen and the thickness of the abdominal wall. After fixing on this technique as the most appropriate for the purpose, he selected 61 cases as suitable, and except five patients who were detained several days because of complications independent of the operation, as bronchitis, diarrhea, etc., all were discharged on the sixth or seventh day following operation, many being at home, perhaps, from fifty to one hundred and fifty or more miles a day, one week from the day they left home. In cases of several farmers, he has known of their being at work on the farm on the seventh day.

The Lancet, May 5, 1906.

Fatalities Which Have Occurred Under Ethyl Chloride.—T. D. Luke has gathered the records of twenty-two fatal cases, which he summarizes. Nevertheless, he considers it far safer than chloroform for short op-

erations. His personal experience embraces over 2,000 administrations in all classes of patients, and he has never seen a single fatality. In two instances there was a temporary arrest of respiration, with considerable cyanosis and widely dilated pupils. He notes that dangerous symptoms, when occurring, come on with a rapidity not exceeded by the onset of dangerous symptoms in chloroform cases. Of the twenty-two cases referred to, eight occurred during dental operations. He figures out the mortality rate as about one to 8,000 administrations. He notes that the same conditions seem to obtain as with chloroform, in that the accidents have occurred in nonalcoholics, without constitutional dyscrasia, who have died from a sudden and unpreventable syncope. He would discourage the promiscuous and irresponsible use of all this class of anesthetics.

Primary Caries of the Mastoid Process as a Cause of Mastoid Abscess in Young Children.—L. F. Gamgee presents the following conclusions: (1) In young children a form of mastoid abscess not uncommonly occurs (in 10 out of 61 cases) in which there is no history of otorrhea and in which the membrana tympani appears to be normal. (2) In these cases the abscess is of slow and painless formation, the patient's temperature not being raised, and the ear not being displaced. (3) In these cases the abscess is due to primary caries of the mastoid, the patch of caries occurring somewhere along the line of the mastosquamosal suture, this being in a young child the softest and most vascular portion of the bone. (4) If the patch of caries forms in the upper part of the mastosquamosal line, and if perforation of the bone occurs, the dura mater of the middle cranial fossa is exposed and the mastoid antrum is not opened up. (5) If the patch of caries occurs in the middle or lower part of the mastosquamosal line, the antrum is quickly opened up and then the caries spreads rapidly through the mastoid. When the patch of caries is found to be situated in the upper part of the mastosquamosal line and the rest of the mastoid is healthy, then it can be taken that the abscess was caused by a primary caries of the mastoid. When, however, the patch of caries is found to be situated in the middle or lower part of the mastosquamosal line—*i.e.* in that part which runs along the posterior boundary of the supra-meatal triangle—it must remain uncertain whether the abscess is due to primary caries of the mastoid or to tuberculous inflammation of the middle ear. But, reasoning by analogy, it seems at all events probable that mastoid abscesses of this class have a common origin —viz., in caries of the mastoid process; that the patch of caries occurs nearly always along the line of the mastosquamosal suture, and that whether the mastoid antrum is opened up or not depends upon the exact position in the line of the suture at which the caries occurs.

Obscure Cerebral Manifestations of Tuberculosis.—J. Fortune records three cases of tuberculosis in which the cerebral symptoms overshadowed those referable to lesions in other organs. In one patient delusions of a melancholic nature were prominent, though a cavity developed in one lung and the autopsy showed in addition enlarged adrenals, these structures being studded with colloidal cysts and thick, careous pus deposits. The author discusses the relation of the lung and adrenal lesions in their etiological aspects. In the second patient there was confusion, semi-stupor, and a history of epileptic attacks. Caseous nodules were found in the lungs and bronchial glands. A curious condition was found in the brain. On running the hand over the cortex hard patches were felt where the pia mater was firmly attached. The cortex was firm and tough, and fibrous in feeling. These scar-like nodules were less than pea-sized and in the cerebrum of each side, but not in the frontal lobes, six such spots being on the right side and four on the left. In addition, in the cortex of the right occipital lobe a cyst with tough walls and containing caseous granules was found. The cyst was a quarter of an inch in diameter. None of these cortical nodules was encapsulated or easy to separate from the surrounding gray matter. In both lateral ventricles the ependyma was granular and small calcareous nodules of the size of a hempseed were found. In the left lobe of the cerebellum the white matter was firm and difficult to tear, and the gray matter was almost non-existent. The white matter was contracted and gritty on section. In a third case of delirious mania, a cavity was found in the lung. On the basis that a toxemia is the cause of this form of insanity, one must presume that mixed infection had occurred. Many are the causes assigned to this disease, quite as many, in fact, as to all diseases not known to be due to a specific organism, and pulmonary tuberculosis is in this array.

British Medical Journal, May 5, 1906.

Treatment of Human Trypanosomiasis.—J. L. Todd refers to the use of a meta-arsenic anilin compound, for the administration of which he gives the following directions: Make a 20 per cent. solution of this compound in distilled water, or, preferably, saline solution. Inject it subcutaneously in the doses indicated below. The solution should be warmed to almost blood heat just before use. In this way the pain at the site of injection, which occasionally follows the use of the drug, is obviated. Give in this manner for four to six days 0.6 c.c.; then raise the dose to 0.8 c.c. for four to six days; then again raise the amount given to 1 c.c. per day. Continue to give this dose until signs of intoxication commence to appear. When this happens reduce it, as in the ordinary administration of arsenic, until the limit of the patient's tolerance is reached, and keep the dose at that point.

Serum Therapy by the Mouth.—D. M. Paton has used sera by the mouth for several years and claims remarkable results. Their action as thus employed is neither antitoxic nor antibacterial, but is best explained by the theory of increased tissue resistance. In other words, along with antitoxic and antibacterial resistance to infection, or alone when those other elements are absent, there is produced an increased resistance in the tissues to the pathogenic action upon them of the organisms present; that this produces what may be called a sterile soil without harmfully affecting the organisms themselves. This is present in active immunity, and can be transferred to the patient as passive immunity by the oral use of the serum in regular doses. Concerning the diphtheria antitoxin, Paton notes that there is in this disease a paralyzing agent acting mainly on the involuntary muscular system, and to resist that muscular depressant there is developed a muscle recuperative element in the serum, available by its oral use. There is also a proteolytic agent causing the production of digestive action and leading to the formation of albumoses and other products of digestion, and to meet this there is produced in the serum an antiproteolytic power also available by oral use of the serum. In diphtheria the concurrent use of the serum by the mouth in doses of 1 drachm with the hypodermic injection materially assists the recuperative powers of the patient, and leads to a rapid and complete recovery when given in time.

The Diffusion of Red Blood Corpuscles Through Solid Nutrient Agar.—A series of experiments is detailed by H. C. Ross, the technique of which must be consulted by those interested. He finds that if in a tube containing the sloped agar a drop of blood is placed on the surface of the slope, coagulation will occur in the usual way, and the drop will remain clearly defined, showing bright red against the yellow tinge of the medium. Provided the surface of the agar has not been injured by the platinum loop or other instrument used for inoculating the tube, the blood will remain on the surface, and will not soak in at ordinary temperatures, no matter how long the tube is kept. When the blood has coagulated the tube may be inverted or placed in any position without the blood running, as the clot adheres to the smooth surface of the agar. He believes that the diffusion is a purely mechanical one, and it has been suggested that it is probably a colloid absorption. The phenomenon is not confined to human blood. No suggestions are advanced as to its possible significance.

The Bacteriology of a Common Cold.—The experiments of C. H. Benham lead him to attach value to the claims of Cantley, who has isolated from these cases a diphtheroid bacillus (*B. coryzæ segmentosus*). The author's general conclusions are as follows: (1) Both diphtheroid and Pfeiffer bacilli (*B. catarrhalis*) were present in his cases, but the latter was found in so small numbers as to be negligible. (2) Other organisms were present in about the same proportion as in normal noses and throats. (3) The diphtheroid organism present conformed to the description given by Cantley of the bacillus discovered by him in seven out of eight cases of common cold (and confirmed by Gordon and Prosser White). (4) The diphtheroid bacillus gave reactions in carbohydrate media which differentiated it from diphtheria on the one hand and *B. xerosis* and the Hofman organism on the other. (5) The question of the exact symptoms, if any, caused by the diphtheroid bacillus and the *Micrococcus catarrhalis* respectively cannot be regarded as settled. In view of the fact that

nasal discharge was not a prominent symptom in the author's cases, it seems likely that the diphtheroid bacilli are rather a cause of a painful sore throat, with headache, malaise, muscular pains, irritable cough, and scanty viscid expectoration. Whether they cause a coryza—a cold in the head—is open to question, especially in view of the presence of the *M. catarrhalis* in nearly half the cases. (6) It seems, therefore, best to give a name such as the *B. septus*, which does not assume a knowledge of the pathological significance of the organism. (7) Its occurrence in as many as 95 per cent. of cases nevertheless makes it almost certain that it is of importance in the etiology of a common cold.

Berliner klinische Wochenschrift, April 30, 1906.

Causes of Coated Tongue.—Rollin says that while the older clinicians were accustomed to say that the mucous membrane of the tongue mirrored the conditions existing in the stomach, modern teaching has discredited this view. He maintains, however, that there is a good deal of truth in the former opinion, and that it is incorrect to assume that no immediate connection can exist between gastric disorders and the state of the tongue. Observations on the fasting stomach contents in cases of hyperacidity and of subacidity show that while in the former condition a great deal of lingual epithelium is present, in the latter affection the reverse is true. In hyperacidity the tongue is nearly always clean, whereas in subacidity it is proverbially coated. The difference in its condition in the two disorders is therefore due simply to the more active casting off of the cells which takes place in hyperacidity, and this the author thinks may be explained by the better nourishment of the organ, dependent on the high hemoglobin content of the blood which usually accompanies hyperacidity. In diminished acidity, however, anemia nearly always exists, and this reacts on the tongue by inducing a state of local malnutrition attended by diminished exfoliation of the epithelium.

Severe Anemias Without Regeneration of the Bone Marrow.—Hirschfeld discusses a type of anemia which is different from the ordinary secondary anemias and from pernicious anemia. He considers that as several other cases of this type have already been described and he now adds two more to the number, that this third variety of anemia should be recognized in addition to the normoblastic and the megaloblastic forms. In general, the blood picture during life resembles that of a secondary anemia of great severity, and the course is an acute or subacute one, always terminating fatally. The bone marrow is very much altered, however, and consists only of a thin fluid of a faint red color, containing very few cells. In consequence of the inadequacy of this organ, no nucleated red cells appear in the circulation. The author believes that the causation of such severe lesions of the bone marrow depends on some poisonous principle which has a special affinity for the structure in question. The diagnosis of these paralytic or asthenic anemias is often extremely difficult and may even be impossible during life.

Münchener medizinische Wochenschrift, May 1, 1906.

Sugar Determinations by Means of a Modification of Trommer's Test.—Simrock speaks highly of a reagent for detecting sugar in urine, known as Heins' solution and having the following composition: copper sulphate 2.0, water and glycerine each 15.0, 5 per cent. potassium hydrate solution 150.0. The advantages of the solution are that it is ready mixed and is permanent. Ten to fifteen drops of the suspected urine are added to a much larger bulk of the reagent in a test-tube, and the mixture is boiled. The same precautions in regard to factitious drug reactions that are necessary in using Fehling's, Trommer's, or Nylander's reactions must be applied to this reagent also. Uric acid, creatinin, glycuronic acid, and chloroform, if present in considerable quantities, may simulate the presence of sugar. Albumin and bile pigment are without effect. A rough quantitative estimate may be formed by noting the length of time that elapses before the characteristic precipitate appears in the fluid on heating, and also from the amount of precipitated copper which appears at the bottom of the test-tube on cooling. The author criticises the very common practice of adding a little chloroform to urine to preserve it, and says that glycerine forms a satisfactory substitute which does not interfere with any of the usual tests.

Staining the Spirochaeta Pallida.—Berger says that he has found that this organism may be stained effectually and promptly by combining solutions containing azur with saturated or moderately dilute solutions of numerous other dyes. Probably the excess of azur acts as a mordant in facilitating the imbibition of the stain in question. Undiluted carbol fuchsin solution, carbol gentian violet solution, or Löffler's methylene blue may be used in this way. The following mode of procedure is suggested: The specimen is air dried and is then placed in absolute alcohol for from five to ten minutes. It is dried and about five drops of Löffler's methylene blue, for example, is dropped on the specimen. Half a minute later three drops of azur ii solution are added, and half a minute after this six drops of Giemsa's solution are added to the mixture, and the whole is allowed to stand for two minutes longer. The preparation is then washed with water and mounted in the usual way. It is important not to remove the stains with blotting paper or to wash them off with water during the process; each fresh solution is to be added to the fluid already on the slide, allowing free mingling to take place. The author also attaches importance to the preliminary alcohol fixation, which he says contributes greatly to securing clear pictures.

Anesthetic Drugs in the Treatment of Inflammatory Processes.—Rosenbach states that he is in sympathy with the statements recently made by Spiess, to the effect that inflammatory processes may be very beneficially influenced by the action of local anesthetics. The author goes somewhat further than Spiess, however, for he maintains that not only painful stimuli must be prevented from leaving the affected area, but also impulses of any sort must be checked at their inception. This is to be effected by alterations modifying the local irritability of the tissues, and for this purpose Rosenbach has found morphine of the greatest utility. For superficial lesions of slight extent, he believes that the application of local anesthetics, as recommended by Spiess may be sufficient, but for more extensive processes and for those that are too deeply seated to be reached from the surface, he considers that morphine is necessary. He also mentions the desirability of excluding from this form of treatment cases in which the inflammatory reaction is apparently beneficial, but he does not state very clearly how such a distinction is to be made.

Deutsche medizinische Wochenschrift, May 3, 1906.

Partial Congestion and Pressure Treatment in Inflammation.—Heermann states that he has obtained excellent results in the treatment of phlegmons, cellulitis, furuncles, erysipelas, lymphangitis, sinovitis, etc., by the application of local pressure. This is to be carried out in such a way as to prevent the dissemination of the infectious process through the blood or lymph stream, and is effected by fastening, centrally to the injured part, some solid object, such as a tightly rolled bandage, a padded piece of wood, etc., firmly in position by means of a strap or bandage. In the after-treatment of inflammatory processes in which incision has been necessary and the acute stage is over, the author has found that healing is promoted in a similar way by applying firm pressure over the affected area. The method may also be used to secure the closure of obstinate sinuses and abscess cavities. Heermann suggests that the good effects produced in this way must depend on grounds similar to those underlying Bier's method of treatment by hyperemia.

Exploratory Drilling for Diagnostic Purposes.—Plesch says that excepting the now but little used procedure of harpooning, there is no method available for obtaining bits of tissue for medical examination from the living patient without subjecting him to a more or less considerable surgical operation. He has devised for this purpose two hollow drills, one for the soft parts and one for bone, which he says can be used with satisfaction for this purpose. The instruments are of very small caliber, 1.5 to 2 mm., and the one for bone is provided with serrations at its extremity. It is operated by anesthetizing the superficial parts and then drilling through the tissues by means of any convenient method for rotating the instrument. If bone marrow is desired for inspection, the drill must be drawn out and the cylinder of bone removed from its interior, after which the drill is again passed through the hole in the bone and is pushed into the marrow. When only the soft parts are to be examined, the drill, which for this purpose is of still smaller diameter and has a sharpened edge, may be rotated simply by hand. The author believes that the bone drill will be found of especial value in the diagnosis of mastoid disease and in studying lesions of the bone marrow. The drill for the soft parts is applicable under any conditions in which it is desired to secure bits of tissue for examination.

The Prophylaxis of Gastric Hemorrhage.—Boas says that although the means for detecting occult blood in

the stools have been greatly improved, they are still far from perfect. The chief difficulty lies in the inability to distinguish between blood of human and that of animal origin in any clinically applicable manner. Nevertheless, the importance of watching the feces for evidences of gastric bleeding must be insisted on, and it is in this direction that the most can be done for the patients. Cases of chronic gastric ulcer should not be dismissed from treatment until repeated examination of the stools has shown that these are free from blood. Furthermore, those who have already suffered from the disease or who are subject to bleeding from the gastrointestinal tract owing to other causes, should be subjected to frequent stool examinations for the purpose of obtaining timely warning of an impending hemorrhage. For the treatment of occult bleeding rest in bed is the principal consideration, except in cases of carcinoma of the stomach or intestine. The milk cure is considered the most reliable general plan of treatment. In case the bleeding does not stop in the first three days, he also recommends the repeated use of rectal injections containing 10 to 20 per cent. of calcium chloride. The advisability of persisting in any particular dietary régime is also to be determined by watching the stools for occult hemorrhage during several days after any change has been made.

American Journal of the Medical Sciences, March, 1906.

Rhythmic Lateral Displacement of the Heart as a Sign of Unilateral Pleuritic Exudate.—Charles Lyman Greene gives the following conclusions: A rhythmic lateral movement of the heart occurs in unilateral liquid pleural effusions. Such movement is most marked in medium-sized effusions. The heart approaches the affected side in inspiration and moves outward in expiration. The extent of the movement is variable, but often amounts to two inches. It may be measured by fluoroscopic examination, auscultatory percussion, or in the case of right-sided effusions by simple deep percussion of the free cardiac border, or in some instances by mere inspection of the apex beat. Deep breathing, and especially forced expiration, are essential to the success of the maneuver, and to obtain this morphine must sometimes be administered. Marked rhythmic lateral movement has not been found in pneumonia, tuberculous infiltrations of the lung, malignant disease of the pleura or lung, or in subdiaphragmatic abscess.

Orthostatic Albuminuria, a Clinical Study of a Case, with Special Experiments, Showing the Cause of the Variations in Amount of Albumin.—Orville A. Kennedy reports this interesting case. For the first two or more years the orthostatic albuminuria presented an exceptional clinical picture. The quantity of albumin was often very large; the quantity and density of urine were normal. There were numerous cylindroids, no tube casts, and no constitutional disturbance. After an interval of more than twelve years the symptom group was found to be changed. The quantity of urine was decreased while the density was increased. Tube casts were present, but cylindroids were absent. There was no edema, and neither circulatory nor constitutional disturbance. The indication of these unusual groups of symptoms is that the albuminuria began and continued for more than two years without the existence of renal inflammation or organic lesions. The long-continued irritation, however, finally resulted in a nephritis. The peculiar build of the patient suggesting a loosely built tissue structure, his anemic condition, and his nervous temperament are etiological factors. Careful experiments showed that the amount of albumin varied directly as the amount of fatigue felt by the patient.

The Function of the Left Prefrontal Lobe.—Charles Phelps believes that it is no longer possible to avoid the positive conclusion that control of the mental faculties resides in the left to the exclusion of the right prefrontal lobe. The results of his investigations to determine in what part of the prefrontal region, if in any, the psychical centers are specialized, he presents in the following syllogistic form: Mental decadence always attends conjoint lesion of both prefrontal regions; mental decadence always attends lesion of the left prefrontal region alone; mental decadence never attends lesion of the right prefrontal region alone. In all of the cases of left prefrontal lesion cited, excepting seven, death resulted at an early period. In the cases of recent occurrence an early fatal termination, the characteristic frontal lesion has been found to be laceration, although it is not conceivable that the destruction of tissue is the cause of death. Neither is it certain that laceration determines the characteristic mental disorder. It seems probable that it is rather an indication of the amount of general disturbance of cerebral nutrition or of a more limited local disturbance. To one death is due, and to the other an abnormal state of the psychical centers. The writer contends that grave specific and immediate mental disturbances are due exclusively to lesions of the left (pre) frontal lobe.

Aspiration in Acute Articular Rheumatism.—F. J. B. Cordeiro, in reviewing his cases, says that the number is too few to draw any general conclusions. The fact is noted, however, that in these cases an aspirated joint has never been reattacked during the same or a subsequent illness. An aspirated joint practically recovers immediately, while in the case of an operated joint weeks are required for the wounds to heal. In one of the writer's cases a number of bodies which seemed to be zoöglear masses were seen and were crowded with extremely minute round bodies, micrococci or spores. These did not stain readily.

On "Double Ego," with Report of an Unusual Case.—Alfred Gordon gives the history of a patient who is absolutely convinced that he is composed of two beings, number one and number two. The latter is always for "the bad part of life." He feels that number two is not a material being; he feels its presence, but he does not hear or see it. He thinks also that besides these two there is a third element, the function of the brain, which controls the actions of both. The fundamental pathological feature is a disturbed consciousness. There are periods of amnesia together with genuine attacks of petit mal. Their existence makes it probable that epilepsy is the actual disease. The writer calls the condition epileptic psychosis. The patient's hallucinations constitute "an epilepsy of the sensory centers." He has had spells of fighting with number two, which were always preceded by provocations on the part of this ego in the form of an internal voice. The onset of the spells was sudden. Appropriate anti-epileptic treatment ameliorated the condition for some time. The writer emphasizes the fact that this case is probably unique as an example of the coexistence of two egos at the same time.

Late Results of the Treatment of Inoperable Sarcoma by the Mixed Toxins of Erysipelas and Bacillus Prodigiosus.—William B. Coley learned early in his investigations that it is extremely difficult to produce erysipelas at will, and that the curative properties of erysipelas are derived, at least in a measure, from the toxic principles of the streptococcus. There is danger, too, in the use of artificially produced erysipelas. The destructive effects of the erysipelas toxins are greatly increased by the prodigiosus toxins. The results of this treatment vary greatly with the preparations used. In certain cases the toxins introduced into the blood serum so increase its resisting or destructive properties that it more than counterbalances the proliferating energy of the tumor cells. These cases often end in permanent cures. But in the majority of cases the action of the toxins is never equal to the task and life is eventually destroyed. The writer thinks that results justify the routine use of the toxins after all primary operations for carcinoma as well as for sarcoma. He also believes that in nearly all cases of sarcoma of the extremities it is justifiable to give the toxins a trial before resorting to operation. In twenty-six personal cases the patients were alive and well from three to thirteen years after treatment. All of these cases were beyond operation and were considered absolutely hopeless and beyond treatment by any hitherto known method.

The Rationale of the Roentgen Ray.—James W. Hunter, Jr., declares that the *x*-ray must not be considered as a "cure all," but in its own proper sphere it is very potent. It is hardly probable that it will ever succeed the usual surgical methods in the treatment of malignant disease. But the combination of the two, removal and exposures to the ray, should greatly increase the percentage of cures. The *x*-ray should be given the preference in small growths, for it leaves excellent scars, and is attended by perhaps fewer recurrences than are surgical procedures. It may prolong life in the late stages of malignant disease, or in recurrences after the removal of the breast. In the writer's opinion there is no drug or therapeutical agent whose employment is more thoroughly rational.

Serotherapy of Typhoid Fever.—Raoul Brunon gives some very interesting results of his experiments with the anti-typhoid serum of Chantemesse. The mortality of typhoid fever was estimated at 17 per cent. when the patients were treated by baths. It fell to 3 per cent. under the treatment by serum and baths. All of the patients treated in the first week recovered. Those that died did not receive the injections until the fifteenth, sixteenth, and thirty-eighth days. After the injection there was a short period of reaction, followed by a period of defervescence.—*La Province Médicale.*

Book Reviews.

Personal Hygiene, Designed for Undergraduates. By Alfred A. Woodhull, A.M., M.D., LL.D. (Princeton), Brigadier-General, U. S. Army, Retired; lately Colonel, Medical Department, U. S. Army. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1906.

This excellent little book contains the substance of a course of lectures delivered to the students of Princeton University during several years past. The work may best be described in brief by giving the titles of the various chapters, as follows: (1) The Skeleton; (2) The Muscular System; (3) The Lungs and Respiration; (4) The Heart and the Circulation; (5) The Nervous System; (6) The Contents of the Abdomen; (7) Digestion and the Care of the Digestive Apparatus; (8) The Development and Care of the Body; (9) Physical Culture Exercises; (10) Fatigue; (11) The Elimination of Waste and the Care of the Skin; (12) Catching Cold, Swimming, Bathing; (13) Clothing; (14) Food; (15) Tobacco; (16) Alcohol. The lectures are addressed to lads, many of whom are still in the developing period, physically as well as mentally, and some of the recommendations, therefore, do not apply to the fully grown man. But, even so, with few exceptions the counsel of the author, with the possible exception of his disapproval of tobacco, and in less degree of that of alcohol, is applicable to mankind in general. To young men, especially to students in preparatory schools and colleges, the book can be unqualifiedly recommended, and we should be glad to see it in the possession of every college student throughout the land. The author has, however, missed one opportunity which is regrettable. The book contains little or nothing on sex questions. This, we believe, is a serious omission. Many, if not most, of the sexual ills which afflict mankind arise, we are convinced, through ignorance of their serious consequences, and it is especially in such a course of lectures on hygiene to young men that the opportunity is presented for a sober and serious presentation of the manliness of purity. The author states in his preface that one lecture, on the Avoidable Diseases, has been omitted. If this lecture was the one on sexual diseases, we think its omission was a mistake, and we hope that, in the next edition—the book deserves to run through many editions—a chapter on this most important subject will be added.

Manuale delle Malattie dell' Occhio, ad uso degli Studenti e dei Medici Practici. Dr. Carlo Enrico May, già Capo di Clinica e Professore di Oftalmologia nei Collegio dei Medici e Chirurghi di New York. Traduzione Italiana sulla quarta Edizione Americana, con note ed aggiunte del Dr. Edmondo Trombetta, Docente di Oftalmologia nella R. Università di Torino. Torino: Unione Tipografico-Editrice, 1906.

The Italian translation of Dr. May's well-known and deservedly popular manual of ophthalmology reproduces most faithfully every detail of the original, both as to text and as to illustrations. In addition, the Italian version contains a number of excellently selected editorial notes by Dr. Trombetta of Turin, the translator. These additions include some useful bibliographic indices, in which, to be sure, Italian literature is not neglected. There are also throughout the book note on treatment, as practised in the Italian clinics by the translator personally, or by his colleagues, and as all such additions appear bracketed, the Italian version offers an interesting opportunity for comparing our own with the Italian therapeutic experiences.

The addition of May's book to the steadily growing list of American medical textbooks translated into Italian cannot but prove gratifying to Italian students, and is a mark of appreciation of the constant advances in the teaching of ophthalmology in America. The work has also been translated into German and French.

Chemistry of the Albumens. Ten Lectures Delivered in the Michaelmas Term, 1904, in the Physiological Department of University College, London. By S. B. Schryver, D.Sc. (Lond.), Ph.D. (Leipzig); Lecturer in Physiological Chemistry to University College, London. Philadelphia: P. Blakiston's Son & Co., 1906.

The structure of the albumens is a problem in which considerable advance has taken place in the last few years. These advances have made possible a better understanding of the chemical dynamics of the proteid molecule in the normal animal body, and although this particular phase of the subject is still in its infancy, the paths already laid out promise to lead into regions that a few years ago we scarcely dared to think of invading. In the first part of these lectures the structure of the albumen molecule is considered from the viewpoint of the chemist, and the methods that have been employed in investigating this subject are demonstrated. The general properties and the reactions of the albumens are first discussed, then comes a consideration of the "degradation products" of the albumens, the protamines and histones, the nucleic acids and the glycoproteids. Lectures follow on the chemistry of hemoglobin and its congeners, on the intermediary degradation products of the albumens, and on Fisher's researches on the synthesis of the polypeptids. The second part, including the last lectures, is devoted to the study of the biochemical action of the albumen molecule, including the consideration of the history of the subject, beginning with the hypothesis of Pflueger (1875), and ending with that of Verworn (1903). It is now nearly two years since the lectures were delivered, and in this space of time a great deal of work has been done in the chemistry and biochemistry of albumen; yet Schryver's monograph remains as a milestone recording the progress of our knowledge of albumen up to the time of writing.

Handbook for Attendants on the Insane, with an appendix giving the Regulations for the Training and Examination of Candidates for the Certificate of Proficiency in Nursing of the Medico-Psychological Association of Great Britain and Ireland. Fourth Edition. Reprinted, with Revised Regulations. Published by the authority of the Medico-Psychological Asociation. Chicago: W. T. Keener & Co.

This is a more or less authoritative handbook for nurses and attendants on the insane. It emphasizes the practical part of their duties, and gives valuable guidance in the numerous questions that will frequently arise in the daily life of such attendants and nurses. Enough theoretical matter is introduced to render intelligible the more practical instructions which form the bulk of the book. There can be no doubt of the worth of the volume; and it should prove as popular in this country as it has in Great Britain.

Intracranial Tumors Among the Insane. A Study of Twenty-nine Intracranial Tumors in Sixteen Hundred and Forty-two Autopsies in Cases of Mental Disease. By I. W. Blackburn, M.D., Pathologist to the Government Hospital for the Insane, Washington, D. C. Illustrated by thirty plates and sixty-five microscopical drawings. Washington: Government Printing Office, 1903.

This volume will be welcomed as a contribution to the anatomical basis of insanity, and, as the title indicates, includes a detailed study of twenty-nine intracranial tumors found in 1,642 autopsies performed in a hospital for the insane. Seventeen of the cases studied belonged to the spindle-celled endothelial sarcomata. Five of the tumors were gliomata; one a typical sarcoma of the brain; one a gliosarcoma, three adenomatas of the hypophysis, one a tuberculoma of the brain, and one on aneurysm of the right middle cerebral artery. The plates and drawings show the topography of the tumors, as well as their finer microscopical structure.

Recent Advances in Physiology and Bio-Chemistry. Edited by Leonard Hill, M.B., F.R.S. Contributors: Benjamin Moore, M.A., D.Sc.; Leonard Hill, M.B., F.R.S.; J. J. R. MacLeod, M.B.; M. S. Pembrey, M.A., M.D.; A. P. Beddard, M.A., M.D., With diagrams. New York: Longmans, Green & Co.; London: Edward Arnold, 1906.

Progress in the more philosophical branches of medical lore has been so extensive of late and has led into so many scientific byways, as the number of those who make it their life work to study the theoretical aspects of medicine has increased, that to the ordinary physician much of the recent work is more or less unattainable. The editor of the present contribution has sought to remedy this state of affairs by assembling in one volume the very large amount of material relating to medical biology which represents the present state of knowledge but which is so widely scattered through the periodical literature as to be readily available only to specialists. It suffices to make only a few selections from the list of twenty section headings to indicate the interest of the subjects discussed: "Energy transformations in living matter; chemical transformations in living matter and its products; theories as to mode of action of catalysts and enzymes; the atmosphere; the effect on life of lessening the barometric pressure; the influence of increased atmospheric pressure; the metabolism of uric acid and the other purin bodies; the formation of urea; the secretion of urine," etc. These are all subjects of practical as well as of academic interest, which it behooves the medical man to be well read in; but to discuss critically the treatment of any one of them by Dr. Hill and his collaborators would require far more space than is available in a necessarily brief notice. The reviewer must therefore content himself with calling attention to the nature of the work, its practical importance, the excellent sense of proportion exercised by the editor in his allotments of subjects and space, and the skill that has been used in infusing a sense of continuity into what is necessarily a piece of patchwork. The perusal of these essays would be of advantage to any medical reader.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held April 5, 1906.

DR. CHARLES L. DANA IN THE CHAIR.

This meeting was held under the auspices of the Section on Obstetrics and Gynecology.

Election of Vice-President.—Dr. WENDEL C. PHILLIPS was elected to this office to fill the unexpired term of the late Dr. George R. Fowler.

Sociological Aspects of Gonococcal Infection in Women.—Dr. EGBERT H. GRANDIN read this paper. (See page 831.)

Medical Aspects of Gonococcal Infection in Women.—Dr. JOS. TABER JOHNSON of Washington, D. C., presented this paper. He stated that this was one of the most important, if not the most important, question before the medical profession of our country and of the world to-day. The reasons why this subject ought to engage the attention of all good men and good women, notwithstanding the strange silence of the sanitary societies upon the prevalence, destructiveness, and demoralizing effects of this widespread infection, were that gonococcal infection was more general throughout the world than any other infection except measles, not less than 90 per cent. of the men in larger cities having had gonorrhea; this infection was the cause of at least 50 per cent. of the female, and much of the male, sterility which was incurable at present; that from 20 to 50 per cent. of the blindness of children, whose eyes were infected during delivery, was due to the gonococcus; that gonorrhea was as potent a cause of abortion as syphilis; and that if an infected woman did succeed in giving birth to one child, the uterus was in such a receptive state that infection speedily crippled both this organ and the adnexa so as to destroy forever that woman's conceptional capacity; the germ of Neisser was then one of the most potent causes of the reduction of natality. Many gynecologists stated that more than one-half of their abdominal sections were required on account of this infection. The consensus of opinion was that two-thirds of all the cases of infection of men came from public prostitutes and the remaining one-third from clandestine prostitutes. Forty thousand of these women died annually and 30 per cent. of this number lost their lives every year as the direct result of gonorrhea. It was now believed that gonorrheal infection was one of the most frequent causes of ectopic pregnancy. A great battle in which a thousand soldiers were killed or wounded, an epidemic of cholera or yellow fever, the wreck of an ocean liner, a mine explosion, the numbers dying from the "great white plague" aroused the sympathies of the public, but philanthropists, sanitarians, and legislators gave no heed to the warnings of the greater social perils which were caused by the "great black plague." As the chief danger to the woman lay in the ascending gonococcal infection, every consideration demanded the most energetic treatment of the acute attack before the vaginal or cervical disease could spread upward. Our only certainty lay in the complete destruction of all the gonococci below the internal os. If any were left they were able to reinfect the mucous membranes for a very indefinite length of time. We should never pronounce a woman cured so long as the microscope could show the possibility of extension of infection to the pelvic organs, or of communication of the disease to anyone else. Every gonorrheal woman should be treated with the possibility always present in our minds that she might become one of the 80 per cent. dead from gonorrheal pelvic disease. The disappearance of gross symptoms was not evidence of cure. The more we knew of the latent powers for evil of the gonococcus, the more we should strive to prevent this germ from hiding in any of the folds or crypts of the mucous membranes ready to spring into a renewed virulence under favorable circumstances. Pregnancy might occur through an infected vagina and cervix and the latent gonococci spring into activity during the parturient process, infecting the conjunctiva of the child and, in breech deliveries, causing vulvovaginitis. Exclusive medical treatment of gonococcal infection in women consisted in preventing the spread of the disease above the internal os. The chief points during the first week were rest in bed, milk and bland diet, perfect cleanliness, and the drinking of large quantities of water. The bowels should be frequently opened with saline purgatives. Upon the subsidence of the acute symptoms the mucous membrane of the cervical canal should be destroyed with nitrate of silver, carbolic acid, the actual cautery, formalin, or the sharp curette, followed by a strong solution of mercuric bichloride. The vaginal portion of the cervix should be painted over with one of these strong germicides, the vagina should be thoroughly irrigated with a strong solution of permanganate of potassium, or ichthyol and glycerin, and then be packed with iodoform gauze. This treatment should be repeated so long as the microscope demonstrated gonococci in the secretions and discharges. The use of nitrate of silver or Churchill's tincture of iodine might be required to destroy vaginal germs, followed up by copious and frequent vaginal astringent and antiseptic douches. In urethral infection copious urination should be induced. There should be gentle instillations of some similar germicide. The glands of Skene and the ducts leading to them were famous hiding places for latent gonococci, and nothing but their complete destruction could prevent recurrent attacks. If germicidal instillations were not curative the ducts should be slit open and curetted and the glands dissected out or otherwise destroyed. Recurring abscesses of the Bartholian glands were usually of gonorrheal origin.

The Surgical Treatment of Gonorrhea in Women.—Dr. J. WESLEY BOVEE of Washington read this paper. After recounting the anatomical structures of women that were usually invaded by the gonococcus he considered briefly gonorrheal ureteritis and nephritis. There was no doubt in his mind but that this form of invasion was quite common. In many cases of pus tubes the microscope failed to reveal the presence of the gonococcus, but we were content to rely upon our knowledge of tissue changes brought about by this germ and the clinical history of the case. About the only form of ureteral involvement by the gonococcus that required operation was stricture. This might be an indication for ureterotomy or ureteral resection. Of course the treatment of pyonephrosis was nephrotomy with a possible nephrectomy. Gonorrhea probably involved the uterus and its appendages much more frequently than was supposed. In chronic gonorrhea spontaneous recovery could not be expected, nor could we hope for non-surgical cure. In acute gonorrhea the best treatment was non-operative. In some cases the accumulation of pus in the *cul-de-sac* of Douglas might occur so rapidly that operation during the acute stage of the disease was imperative. Whenever pus escaped from the tubes into the peritoneal cavity there was indication for evacuation. In the endometrium the disease should be treated by the sharp curette, followed by tincture of iodine carefully applied in full strength on cotton. Even this treatment in a few cases might not eradicate the disease. That the tubes were involved in 43 per cent. and the endometrium in 54 per cent. of the cases of chronic gonorrhea demonstrated the tendency of such extension without operation. In those cases in which the appendages had been removed and in which such symptoms as metrorrhagia, profuse leucorrhea, and pelvic pain indicated activity of the Neisser coccus in the uterus such treatment of the in-

terior of the uterus as had been mentioned was strongly indicated. He had preferred vaginal hysterectomy as being surer in its results, and as being but little more dangerous. With the employment of agents for obliteration of the cavity one could not feel confident of success. Conservation of the appendages was, in the large majority of cases, followed by sterility, uterine hemorrhages, menorrhagia, pelvic pain, and recurrence of infection. If pregnancy followed it was liable to end in abortion, and evidence of a markedly sharp puerperal infection. If the husband had latent gonorrhea we might expect reinfection of the tubes and ovaries at any time. And, again, acute exacerbations frequently recurred so long as gonorrheal tubes and ovaries, or even the intrauterine form remained. All were agreed that some form of surgical interference was necessary. The vaginal route should be chosen in the majority of cases, but if the vagina was very narrow he preferred the abdominal route to increase working space. The abdominal route offered greater facilities for the operator, but for the patient the vaginal route was preferable. Allowing the cervix to remain, left a better vaginal roof than we could expect in vaginal hysterectomy, but should it be degenerated or deeply lacerated, or should the patient have an hereditary history of carcinoma, it had better be removed. In all these vaginal operations for gonorrheal tubes and ovaries *cul de-sac* drainage was advantageous. For large exudations gauze was preferable. The advisability of removing the ovaries with the tubes depended upon their pathological condition and the age of the patient. If they were in good condition and not firmly adherent, then neither the nature of the infection nor the degree of it in the Fallopian tubes should be regarded as indications for extirpation of the ovaries. If the woman was past the age of forty years they should be removed. As to whether one tube should be left when the other was sacrificed he thought that if the endometrium was evidently involved, the other tube, though apparently healthy, should be removed. He thought the uterus should be removed with the tubes, in view of the probability of the affection lurking in the uterine muscle. He concluded that: (1) Earnest effort should be made to cure acute gonorrhea in women before it had entered the uterus; (2) except when there was an accumulation of a large amount of pus in the *cul-de-sac,* non-surgical treatment was best in acute gonorrheal tubal involvement; (3) in chronic gonorrheal pyosalpinx, ablation of the tubes was the best treatment; (4) the vaginal route, with few exceptions, was preferable to the abdominal route for this work; (5) the ovaries were not to be sacrificed unless they were hopelessly involved, or the patient was more than forty years of age; (6) both tubes should always be removed; (7) the body of the uterus might be retained if not adherent or considerably involved; (8) *cul-de-sac* drainage was applicable to both vaginal and abdominal ablations.

Dr. Prince A. Morrow said that his remarks would be devoted to the question of prophylaxis, more especially from the point of view of the social dangers of the disease. The most valuable contribution to our knowledge of gonococcal infection in women had been given by the gynecologists. Gynecology had entirely transformed our conception of gonorrhea, in respect to the character and some of its dangers to women, and had largely magnified our knowledge of its social significance. The intelligent prophylaxis of any infectious disease must be based upon the sources of contagion and its mode of communication. The distinctive peculiarity of venereal infection was that it was communicated through the voluntary acts of individuals and in married life husbands were the purveyors of the infection. While there was no criminal intent, such actions had all the consequences of crime. These crimes against virtuous wives were not confined to the lower and depraved classes of society. They were committed by men of the best social position, men of conscience and character, of intelligence in ordinary matters, but with a fearful ignorance of everything relating to venereal infection. Men exposed themselves in ignorance of the serious nature and real significance of venereal infection; then infected others in ignorance of the prolonged contagious character of this infection, and of the fact that it might be infectious after apparent cure, in ignorance of the fact that the dangers of infection were accentuated by all the conditions of marriage, and especially the procreation of children. The remedy was general enlightenment of the public in regard to the dangers of venereal infection, both individual and social, and the laws of its contagion. Men should be made to know that the absolute indispensable condition of entering marriage was freedom from any contagious sexual disease. Enlightenment of the individual was not alone sufficient, as experience showed that many conscienceless men, fully informed of the dangers of marrying with an uncured venereal disease, nevertheless from material or other considerations took the risk and exposed their wives to infection with every assurance that the consequences would be covered up and concealed, that professional ethics would protect them from exposure. The medical secret related only to the individual; it did not extend to the people collectively. If the general public were enlightened as to the frequency and significance of these social crimes, if the knowledge possessed by the medical profession was given to the people, an aroused public sentiment and an awakened public conscience would no longer tolerate them. Publicity, the fear of exposure, would prove a stronger deterrent, a more powerful corrective, than any laws which could be placed upon the statute books.

Dr. William M. Polk, speaking for the gynecologists, said that it was well to remind the profession that this campaign of education had been going on vigorously for a long time, but, unfortunately, they could not produce such an impression upon the people as the genito-urinary surgeons could who stood at the outposts of danger. The consideration of this question among men was without difficulty; but in the case of the virtuous and good woman it was a subject difficult to approach. Although the physician might give her a warning, she, in her loyalty to the man, would hardly raise the issue upon the nuptial night. With regard to the treatment he said that if this enemy was as formidable as stated, why could not one administer an anesthetic at once in the acute infection, lay open the cervix as far as the internal os, if necessary, and make direct application of such strong substances to every part of that mucous membrane as to reduce to the minimum the possibility of offering a refuge for the rehabilitated gonococcus. So far as the treatment of the interior of the uterus itself was concerned, the radical measures advocated for the treatment of the cervix could not be applied. Something could, however, be gained by the application of formalin. He thought the Fallopian tube should be considered as a part of the peritoneal excavation itself; therefore the process should be limited as much as possible by giving free vent to the secretions. There was a tendency for the secretions to accumulate in the *cul-de-sac* of Douglas, and it was very important in cases of acute gonorrheal infections involving these parts to institute drainage through the *cul-de-sac.* Early incision in the most dependent part and drainage were to be emphasized.

Dr. J. Riddle Goffe remarked that gonorrhea was said to be the most frequent, and the most distressing of all the pelvic infections of women. The responsibility for the spread of gonorrhea should be placed where it belonged. Oliver Wendel Holmes said that every man who attended a confinement that was followed by puerperal infection was himself responsi-

ble; Dr. Goffe said that it was a long time before Holmes' view was accepted, and it was not until this responsibility was placed upon the physician that the condition was met in the proper light and reform came. Responsibility was not taken until knowledge was given as to how this condition should be met. And this applied to the subject under discussion. He said the laity should be told, "You are responsible," but the laity should first be instructed as to the true nature of the infection. With knowlede came responsibility, and there could be no responsibility without knowledge.

Dr. A. Jacobi said this disease was not infrequent in babies. Often the eyes became infected in the vagina as the child was born. Credé's method was said to protect the eyes, but many missed that protection, and many inmates of blind asylums were so because of gonorrheal infection of the eyes. He had seen many cases of general infection resulting from a gonorrheal conjunctivitis. He recently had seen a general pyemia result from gonorrhea of the eyelids. In babies were also seen salpingitis, öophoritis, peritonitis, etc., from gonorrheal infection, but these cases in little girls were not so dangerous as in the adult, although they were more tenacious because of the wrinkled condition of the mucous membrane lining the uterus. Up to the sixth, eighth, or ninth year the infected uterus would never get well, because anything getting between these folds of the mucous membrane would never get out.

Dr. George H. Balleray emphasized the importance of beginning the treatment of these cases in the early stages, and said that very often these cases were not diagnosed by the family physician; these women were usually told they had simply the "whites." If seen early and properly diagnosed there was little difficulty in getting the disease under control before it spread to the uterus and adnexa. He believed every woman with this disease should be placed in bed and douched with bichloride solution, 1-2,000 every six hours, followed by a large douche at a temperature of 112° or 114° F. The bowels should be regulated and diuretics given. He could not indorse the treatment recommended by Dr. Bovée in subacute cases; here he thought it justifiable to dilate the cervix and irrigate the uterus. But he was opposed to the use of the curette, the devil's own invention. If the appendages were hopelessly diseased they could be removed. In some cases hysterectomy must be resorted to.

Dr. Robert A. Murray said that it had been claimed that 90 per cent. of men had gonorrhea, a statement he doubted; but if this statement was true the large proportion of gonorrheas must be cured, and thoroughly so, or the world would be depopulated. He said it was the duty not of the gynecologist or urologist, but of the general practitioner to treat these cases as they came to him. The moral and religious aspect of the question rested in the prevention of gonorrhea, and every man with gonorrhea should be informed that he had a discase which would infect him as severely as smallpox, and which would infect his wife and cause, in the majority of instances, her ruination.

Dr. Arnold Sturmdorf emphasized the great importance of radical and thorough treatment of the disease in its early stages, especially in women. These were not cases for office treatment; the women should be placed in bed and the attending surgeon should have all the paraphernalia of a well-equipped surgical service if he would be successful.

Dr. Jos. Taber Johnson closed the discussion. He said he was particularly interested in what Dr. Jacobi had said regarding gonorrheal infection of the mucous membrane of the uterus in young girls. He recalled to mind a visit to Tait a few years ago and the statement made by him that most of the cases occurring in gynecologigal practice were due to lack of development of the uterus, such as displacements, inflammations, endometritis, corporeal leucorrhea, etc. The reasons for the occurrence of gonorrheal vulvovaginitis in young girls, appearing in both dispensary and hospital practice, had never before been explained as it had this evening. The disease was never recovered from when it affected the mucous membrane of the uterus in young girls, and probably in the majority of the cases this was due to a lack of development of the uterus.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 22, 1906.

Dr. Arnold Sturmdorf in the Chair.

Appendix Removed from a Pregnant Woman Without Interrupting the Pregnancy.—Dr. Abram Brothers presented this specimen, which he had removed from a patient, married one and a half years, and pregnant three and a half months. Four days previously she had been seized with severe abdominal pains, which gradually showed a tendency towards localization on the right side. There was no vomiting, but the bowels were constipated. The temperature was about 102° F. and pulse 120. The peritoneal cavity was opened and an enlarged pregnant uterus seen and protected with gauze pads, being hardly disturbed during manipulation. A cystic half of the right ovary was exsected. The appendix was found directed upwards and inwards with injected blood-vessels, recent adhesions being found at its base and adjacent portions of the cecum. The appendix was removed in the usual manner by exsection and cauterization of the stump. The abdominal wound was closed without drainage. The specimen showed a catarrhal appendix with three fecal concretions. The patient made an uneventful recovery.

LeFort's Operation for Vaginal Hernia, Following Vaginal Hysterectomy.—Dr. Brothers presented this specimen, removed from a woman 60 years old, who had had her uterus removed by vaginal hysterectomy two years previous for the cure of a complete prolapsus. She underwent two subsequent operations for the cure of a vaginal hernia. She was in a very wretched state and gladly accepted the proposition of obliterating the entire vaginal canal if necessary. A window-shaped area was denuded on the anterior and posterior surfaces of the vagina, after reducing the hernia after the method devised by LeFort. The operation, which is fully described in Pozzi's work, proved to be quite successful and simple in its performance.

Uterus and Vagina Removed en Masse by Vaginal Hysterectomy for the Cure of Prolapsus Uteri (Edebohl's Operation).—Dr. Brothers presented this specimen. The patient was about 50 years of age, very emaciated, and was operated upon after the method proposed by Edebohls. The main purpose of the operation was to obliterate the vaginal canal so that a condition of vaginal hernia could not occur. The anterior vaginal wall was so intimately adherent to the bladder that it had to be completely separated by the scissors, and made the operation quite difficult. The rectum and bladder escaped injury and the removal of the uterus presented no technical difficulties. After the stumps of the broad ligaments were brought together and the peritoneal cavity shut off above, circular sutures were passed from above downwards so that a column of raw tissue extended upwards from the vulvar orifice to the stump of the broad ligaments. The patient showed no reaction until the eighth day, since which time she had been suffering from a low grade of pneumonia. Her general appearance seemed to indicate an ultimate recovery.

Perforation of Intestine Due to a Fishbone.—Dr. Brothers presented this specimen. The patient was a woman, 60 years old, whom he had apparently cured of a tuberculous peritonitis by incision and drainage over two

years previous. A sinus leaking during the six months following left her with a ventral hernia. One week previous to admission a bulging was noticed at the site of the cicatrix, which increased in size and caused severe pain on coughing or breathing deeply. Percussion was flat and the tumor felt hard. The temperature was 102° F. and pulse 120. The case was very unpromising and the preliminary preparation of the abdomen was done without anesthesia. With considerable difficulty the intestines were separated from the anterior abdominal wall and each other until a large cavity containing about eight ounces of a straw-colored liquid was perforated with the finger. This was the "bulging tumor" from which she suffered. While separating the adhesions an ulcer of the intestine presented on a coil attached posteriorly and in the region of the lower angle of the wound. While trying to get this coil of intestine up to the level of the wound he noticed a sharp point projecting from the center of the ulcer. This was seized with forceps and drawn out; it was a fish-bone which measured nearly one and a half inches in length. Isolating the coil of small intestine with gauze pads, as it could not be brought out of the abdominal wound, he proceeded to pass a circular, tobacco-pouch suture about the margin of the ulcer. Depressing and inverting the ulcer the suture was drawn together and tied. To reinforce this suture a few extra Lembert sutures were passed in a second tier. These buried completely the first sutures. After passing a cigarette drain through the lower angle of the wound down to the site of the intestinal perforation the ventral hernia was treated in the usual manner. For two days after the operation the temperature ranged between 102° and 103° F. and the patient's mind wandered. Bilious vomiting kept up and nothing was retained on the stomach. Cathartics and enemata were interdicted, but strychnine and eserine salicylate were given hypodermically. After 48 hours the patient had an involuntary movement and on the ninth day was regarded as being out of danger.

Dr. Grace Peckham Murray said she was interested in the Porro operation, and that it had been performed many times at the New York Infirmary with great satisfaction. At the same time she believed it to be a pity that we should lose sight of the fact that a less extensive operation than the Edebohl's operation was to be preferred.

Hysteroepilepsy.—Dr. George H. Balleray presented the ovaries that he had removed from a patient, 36 years old, two weeks ago, for the relief of hysteroepilepsy. She had had five children, the last two years ago. There were no neurotic symptoms. With menstruation established after the birth of her last child she had epileptic attacks. She was admitted to the hospital and the ovaries were removed. What the result would be he did not know. The specimen and report of the case were presented in order to get the views of the members of the section.

A second specimen presented was removed from a woman, 37 years old, who had had five children, the last five years ago. She was admitted to the hospital with the supposition that she had an abortion. Her temperature was high and she passed membranes. A mass on the right side proved to be a pus tube. No improvement resulted until an abdominal section was performed and the tube removed; it contained a considerable amount of pus and the ovary was cystic. On the left side there was a small and rudimentary tube which was lost in the broad ligament. The round ligament was one-quarter or one-fifth the size of the one on the right side.

Dr. A. Brothers said that he had had one experience. He had removed an ovary as large as the one shown from a young girl for hysteroepilepsy. Six or seven years later the attacks returned and, therefore, he had lost confidence in this procedure as one for curing this variety of epilepsy. It cured only the diseased ovary.

Dr. J. Riddle Goffe said he was surprised that this subject had again been brought up for discussion, believing that it had been investigated thoroughly years ago. Dr. Goffe had ceased to do this work on such cases for years, and did not believe that the operation was at all justifiable.

Dr. Arnold Sturmdorf said that the members should discriminate between the cases of true epilepsy and true toxemia. A number of reports had been published in which there had been a cure of the tonic and clonic convulsions.

Hysterectomy.—Dr. Balleray presented a uterus he had removed from a patient ten days ago. She was 44 years old and her last child was born five years ago. She had suffered for a year and a half from metrorrhagia, it of late being quite excessive, and she came to the hospital for its relief. The pathologist thought she had an adenocarcinoma, although Dr. Balleray did not think it was at all malignant. In the hospital she improved. The cervix, which was enormously enlarged when she entered the hospital, diminished in size. The appendages were not diseased. From the clinical history given the disease was not a malignant one, yet it resisted treatment, and hysterectomy was performed. He said he had seen cases that resisted all treatment by curettage, packing, etc., and in which nothing did good except hysterectomy.

Specimen of Tumor.—Dr. Balleray presented a tumor removed from a young woman, 29 years old. The interesting point was its rapid growth. It seemed to be closely adherent to the body of the uterus and was apparently pedunculated with a short pedicle.

Gonorrheal Pyosalpinx.—Dr. Balleray presented this specimen. The patient had a gonorrheal pyosalpinx and the cervix looked unhealthy. He started in to do a vaginal hysterectomy, but finished the operation by abdominal section.

Specimens of pus tube and ovary removed from a woman with gonorrheal pyosalpinx were also presented. A diagnosis of appendicitis had been made, as is often done in these cases. After the appendages were removed a large mass was noted about the level of the anteriorsuperior spine. It was found to be a cyst of the right ovary, the size of the uterus; it was very soft and friable and ruptured. It was rotten. The contents resembled a dermoid except that there was no hair and the tumor seemed to have started behind the peritoneum.

Salpingitis as a Cause of Ectopic Gestation.—Dr. Samuel W. Bandler considered the cause of sterility and extrauterine pregnancy as existing in salpingitis; the ciliated epithelium was destroyed and the egg arrested in the tube. He related cases to prove his contention. Specimens were also shown and proved that four out of eight cases had an inflammatory etiology for the ectopic condition.

Uterine Hemorrhages of the Menopause.—Dr. Grace Peckham Murray read this paper. She said that it was generally accepted that the menopause began with the cessation of menstruation or marked menstrual irregularities, and ended with the termination of the varied disturbances incident to this period. Her observations had led her to believe that in New York women the cessation of menstruation was much later than forty-five years. As to frequency of hemorrhage at this period recent writers averred that it was not as common as was formerly supposed. Up to the time that Dr. Duff wrote his paper containing the report of the examination of 482 healthy women and found among them only 39 who gave any history of menorrhagia of any importance, the medical profession as a whole were apt to regard hemorrhage as a natural accompaniment of the menopause. The important questions were whether an increased flow at the time of the menopause was physiological, and whether a hemorrhage, either that of menorrhagia or metrorrhagia, was merely functional and not pathological. Dr. Murray said that she had studied the question for twenty years and hoped at a future time to furnish tabulated statements that would bear her out in the following conclusions: She believed that the normal change of life was established without an increased loss of blood, that the flow was less during the second decade of menstruation than during the first; less during the third

than during the second, and that the flow decreased slowly at the period of cessation. The flow became less, and less time was occupied; it also became thinner and decomposed more readily. In some cases cessation of the menses occurred without any intervals occurring between the regular times, but more often intervals of one, two, and then three months occurred, the usual type being that the times were lengthened by a month or more. In her experience she had yet to see a case in which there did not exist some reason for an increased flow at this time. A wide range of conditions existed which would cause an abnormal loss of blood at this time. Troubles other than local were said to bring about hemorrhages at the time of the climateric, such as congestion of the liver, cardiac, renal, and splenic affections, and the dyscrasias, such as anemia, purpura hemorrhagica, hemophilia. A hemorrhage might also have a nervous origin. Cases of premature menopause occasioned by grief or shock had occurred in her experience. Cases in which a constant loss of blood took place had been found in some instances to be due to hemorrhoids, caruncles, or the bleeding of erosions from a completely prolapsed uterus. Uterine hemorrhages were produced often at this time from causes which obtained throughout the menstrual life of woman, but were more likely to occur as a woman became advanced in years and her sexual organs had been more exposed to disease from her mode of life, her marital relations, and her frequent pregnancies resulting in births and miscarriages. This was the great reason why an excessive loss of blood had come to be regarded as concomitant with the menopause. Such inflammatory conditions as cervicitis, endometritis, and metritis came under this category, and the hyperplasis, which resulted from long-continued inflammations. The benign growths, polypi, fungoid endometritis, fibroids, especially the intramural variety, were not infrequently found. Fibroid infiltration, a condition rarely noted and which gave rise to intractable bleeding, might often be the cause of hemorrhage. As was well known, hemorrhage was often a symptom of carcinoma, and on this account an immediate examination in cases of hemorrhage at the time of the menopause should be made. Another group of cases was composed of those who had vascular disturbances due to interference with the circulation of the uterus or changes in the blood-vessels themselves. A diligent study of the histology, normal and pathological, of the uterus and its appendages at the time of the menopause was urgent upon us to bring about a better understanding of the problems which the climacteric presented, not only of hemorrhages and other vascular changes, including the vasomotor symptoms, but of those which related to the nervous system as well.

Dr. J. Riddle Goffe agreed with Dr. Murray, that extreme hemorrhages occurring at the menopause were pathological. Time and time again had he curetted women for recurring hemorrhages without relief; often the pathologist had reported adenocarcinoma after examination of the scrapings. These cases all should be followed to the end and not be permitted to go away without some effort at relieving them, even though it might be necessary to do a hysterectomy.

Dr. A. Brothers said that the subject of irregular bleedings at the menopause was strikingly brought to them and stated that the frequency of these bleedings had been greatly overestimated. The treatment would, of course, depend upon the pathological conditions presented. There were forms of irregular bleedings, as illustrated by Dr. Balleray's specimens, and he believed the treatment advertised all over Europe should be alluded to, the use of superheated steam, but only when malignant disease had been excluded. cluded.

Dr. S. Marx said that the sum and substance of the question resolved itself into what one considered excessive bleeding at the menopause, and he personally believed that excessive bleeding should be regarded as a pathological condition. He emphasized the importance of treating the patient as a woman, but not as a woman at the menopause. If she should be the victim of a slowly growing carcinoma, or anything else, that had continued for a period of years, treat it and not especially the woman at the menopause. With regard to Dr. Brothers' remarks he said he would prefer the clinical evidences, plus the macroscopical examination, rather than the microscopical evidence alone.

Dr. Bandler said that in some instances the microscopical examination showed nothing. Sometimes there was a fibrosis and, in some cases, nothing but a hysterectomy would result in benefit. He personally obtained the best results from a combination of ergotin, hydrastin, and stypticin; they acted to produce a normal contraction of the uterus.

Dr. George H. Balleray believed that excessive hemorrhage at the menopause was pathological and believed, too, that the family physician was very prone to believe that every case at a certain age in which there was a loss of blood meant "change of life."

Dr. Murray closed the discussion. The main feature she wished to present in her paper was that excessive hemorrhage at the menopause was pathological, and not physiological.

Gigli's Operation (Pubiotomy) in Private Practice, with Report of a Case.—Dr. John Adam Schmitt read this paper. (See page 833.)

Dr. S. Marx did not believe the case reported by Dr. Schmitt was one of generally contracted pelvis, but simply a flat pelvis, the rachitic point being excluded by the history. Pubiotomy or symphyseotomy could never be made an elective operation, and, in this case, the tentative application of the forceps to the head above the brim might possibly have delivered the child through an unsectioned pelvis. He would attempt neither of these measures without first trying others. One or two tentative tractions upon the head of the child would inform us whether something could be accomplished or not. Pubic section would never, in his opinion, become elective, and other operations must anticipate it.

Dr. George L. Broadhead said that he had discarded symphyseotomy and pubiotomy long ago in favor of cesarean section.

Dr. William S. Stone did not believe that pubiotomy should have been done in the case reported by Dr. Schmitt.

Dr. Herman L. Collyer said that he believed he performed the first symphyseotomy in a tenement or private house on record, and his own experience would make him forego doing anything in the line of a pubiotomy or symphyseotomy outside of a hospital because of the dangers of sepsis. The operation should by no means be undertaken by the general practitioner.

Dr. Schmitt said that those who attempted such operations and failed were naturally prejudiced against it. Judging from reports received from hospitals, pubiotomy was the operation of the future. Pubiotomy was a simple operation in suitable cases.

Vaginal Cesarean Section.—Dr. J. Riddle Goffe gave in brief the indications for the operation of vaginal cesarean section, its history and its results. This operation should not be confused with a simple section of the cervix. The incision went not merely through the cervix, but into the real body of the uterus, and the child was removed through that incision. This method did not enter into competition at all with the abdominal cesarean section. The abdominal cesarean section was performed because of some obstruction in the bony canal; the vaginal cesarean section, because of obstruction in the soft parts. The technique of the vaginal cesarean section was simple and consisted in a transverse incision in front of the uterus across the vagina, a dissection of the bladder from the cervix and anterior wall of the uterus up to the fornix and peritoneum. The cervix was then grasped by the forceps and an incision made from the external os up to the point where the peritoneum was attached, its length varying from four to six inches. The bladder could be lifted up by a retractor, and the work was not blind work at all. If

necessary a posterior incision was made up to the attachment of the peritoneum posteriorly, care being taken at all times not to enter the peritoneal cavity. After the uterus was opened it was a simple matter to apply the forceps or possibly introduce the hand and turn and deliver the child. The general indications for the vaginal cesarean section was some obstruction in the soft parts, in the cervix or lower segment of the uterus, and the most striking indication was puerperal eclampsia. This was the most rapid method of emptying the uterus, requiring not more than six to ten minutes. Another striking indication was an undilatable cervix. If the child was dead and the cervix undilatable after labor pains had existed for a long time, it was indicated. Dr. Goffe also considered carcinoma of the cervix, myoma, rigidity of the cervix, premature detachment of placenta, etc. In cases of intrauterine hemorrhage life could be saved by a prompt vaginal cesarean section. Also vomiting of pregnancy in some cases was an indication for this operation. Again, there were certain conditions of the mother that indicated this operation, such as organic heart disease, where it was believed the woman could not go through labor. Again in edema of the lungs or certain affections of the kidneys, this operation was indicated when it became necessary to empty the uterus promptly. There were certain indications for the vaginal cesarean section when the interest of the child was to be considered. For instance, when the mother's death was imminent, this operation should be done before the death of the mother. Vaginal cesarean section had been resorted to for all these indications by various operators in various parts of the world, and it was done more often in Germany than elsewhere. Dr. Goffe reported one case, a woman who was six months pregnant, with a dead fetus, who was in labor for seven days before the case came to his knowledge. He performed vaginal cesarean section, a very simple matter in this instance, turning and delivering the fetus by the foot. Catgut was used in sewing up the incisions. This operation had come into sharp competition with the heavy dilators. Among the advantages of the operation were comparative freedom from sepsis, the peritoneal cavity not opened, rapidity of work, the ease with which it was performed, and its real simplicity, no nervous strain or shock attending it. The results of this operation were entirely successful. It had met the expectation, and all who had used this method were enthusiastic about it.

Dr. S. Marx said he had done the operation three times and knew its value. He thought that Dr. Goffe went too far when he stated that this particular operation was advisable after the patient had been six days in labor in the case reported by him. In this case the cervix would have been drawn up, and a better operation, he believed, would have been the introduction of the hand or bougie. The Bossi dilator he condemned most emphatically and in unmeasured terms.

Dr. Herman L. Collyer said that the object of the operation appeared to be to prevent inevitable lacerations, which were likely to occur in the broad ligaments, which would be followed by severe hemorrhage, often fatal. Therefore the cervix should be slit posteriorly to prevent this. This he believed to be the real object of the operation.

Dr. A. Brothers said he had used the Bossi dilator in eclampsia and had dilated manually as well. There were cases in which the hand could not dilate. Section of the uterus he believed had a place in gynecology, not only at full term, or at the sixth month, but even much earlier.

Dr. Goffe, in answer to Dr. Marx's criticism, said that, in the case reported the cervix had not dilated, and had not taken a part in the development of the uterus, etc., but was a solid cervix. Regarding the statement about the hand as a dilator, and not the heavier instruments, such as Bossi's, he answered that if the hand sufficed, not so much place in literature and discussions would be given to dila-

Dr. Philander A. Harris, of Paterson, also discussed Dr. Goffe's remarks.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 19, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	383	193
Diphtheria	370	54
Measles	1252	37
Scarlet Fever	305	28
Smallpox	.....	.....
Varicella	83	.....
Typhoid Fever	15	4
Whooping Cough	37	5
Cerebrospinal Meningitis	31	32
Malarial Fever	.....	.....
Totals	2,476	353

The Sterilization of Flexible Catheters.—Adrian recommends the following procedure: The instruments are subjected to the vapors arising from a 1 or 2 per cent. formalin solution at a temperature of 60 to 75° C. An exposure of three minutes suffices to insure destruction of all germs, the instruments are not damaged, and the amount of formalin adhering to them is so slight that it is not necessary to rinse them off in sterile water.—*Centralblatt für die gesammte Therapie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending May 19, 1906:

SMALLPOX—UNITED STATES.

		Cases.	Deaths.
Florida, General	Apr. 28–May 5.	10	..
Illinois, Chicago	May 5–12	1	..
Indiana, Terre Haute	May 5–12	1	..
Kentucky, Covington	May 5–12	1	..
Maryland, Baltimore	May 5–12	1	..
Crisfield	May 7	1	..
Minnesota, General	Apr. 23–May 7	18	..
New Hampshire, Portsmouth	May 10	1	..

MEDICINE AND LAW IN RELATION TO THE ALCOHOL, VENEREAL DISEASE, AND TUBERCULOSIS PROBLEMS.*

BY S. A. KNOPF, M.D.,

NEW YORK.

IN view of the vastness of the subject that I have chosen to speak on, it will be possible to touch only on some of the vital points at issue, and perhaps throw out a few suggestions as to how to attack these problems. My main purpose in presenting such themes before this distinguished gathering of jurists, sociologists, and physicians is to arouse a discussion so that we may hear the opinions of the men who are authorities on one of these subjects. To get their advice will be of great value, not to speak of the inspiration we are sure to receive.

In consideration of the urgency of the case and the vital issues at stake which demand a solution of these problems, we shall all have to put our shoulders to the wheel, and it would seem that the members of this society are preeminently fitted to take the initiative.

I am not going to burden this paper with many historical data or statistical figures; I intend to mention only a few points concerning the probable origin of these problems and to speak of the relative frequency of the diseases under consideration. There is a passage in Ricord's "History of Syphilis" which traces the origin of alcoholism and illegitimate intercourse back to the time of Abraham and Lot. The fifteenth chapter of Leviticus evidently proves that the great Jewish lawgiver, Moses, had in view the prevention and cure of diseases liable to follow sexual intercourse. A regulation referring to this was promulgated about 2400 Anno Mundi. For the first authentic and scientific description of tuberculosis we are indebted to Hippocrates, who lived from 406 to 377 B. C. He very characteristically speaks of consumption as the disease most difficult to treat and which proves fatal to the greatest number.

I do not need to say anything to an audience of this type about the frequency of alcoholism, the thousands of cases afflicted with acquired or inherited syphilis, or the prevalence of tuberculosis in all countries we like to call civilized. The more seemingly civilized a country is the more terribly afflicted is it with all three of these diseases.

From the following table of statistics published by the Department of Commerce and Labor in Washington, it will be seen that we are sixth in the list of alcoholic consumers.

COUNTRIES.	POPULATION.	PER CAPITA CONSUMPTION
United Kingdom	42,373,000	4.99
France	38,666,000	10.21
Germany	58,843,000	5.53
Italy	33,189,000	6.61
Russia	134,272,000	1.39
Belgium	6,985,000	7.33
Sweden	5,032,000	3.05
United States	80,372,000	3.23

*Read by invitation before the Society of Medical Jurisprudence at its regular meeting, March 12, 1906, held at the New York Academy of Medicine.

Do not think me unpatriotic if I say that we should come much nearer the head if every source of alcohol consumption had been considered in these figures. I have it on good authority [1] that there is more alcohol sold in this country in the shape of patent medicine than is actually dispensed in whiskey over the bar.

If you doubt the accuracy of this statement, permit me to refer you to the list of analyses by my late friend, Dr. Abbot of Boston, published in his report on food and drug inspection for the year ending September 13, 1902; the publications of Mr. Bok in the *Ladies' Home Journal;* of Mr. Ashbel P. Grinnell, in the *Medico-Legal Journal;* of Mr. S. H. Adams, in *Collier's Weekly;* and an article in the *Journal of the American Medical Association*, October 22, 1904. Dr. Abbot's list shows that sixty-seven analyzed patent medicines, some of them advertised as entirely harmless, or as a cure for inebriety, contain from 6 to 44 per cent. of alcohol.

According to the estimate of my venerable friend, Prof. A. Jacobi of this city, "The American people do not spend less than $200,000,000 annually for patent medicines"; surely we must ascribe a large amount of alcoholism to this origin.

From the very nature of venereal disease accurate figures are not obtainable except from the Army and Navy statistics, where men are subjected to regular medical examination. In Munson's[2] work on military hygiene the following table is given:

In Germany, among	every	1,000	soldiers	27.9	are	affected.
In Russia,	"	"	"	36.0	"	"
In Japan,	"	"	"	36.0	"	"
In France,	"	"	"	40.9	"	"
In Holland,	"	"	"	48.1	"	"
In Austria-Hungary	"	"	"	61.0	"	"
In the United States	"	"	"	73.7	"	"
In Great Britain (home statistics)	"	"	"	173.8	"	"
In Great Britain (Indian statistics)	"	"	"	522.3	"	"

Estimates of the frequency of venereal disease among the civil population have been made by Fournier of Paris, Weiss of New York, Kober of Washington, Neisser of Breslau, and Parks of London. According to these authorities, one-seventh of the population of Paris is syphilitic, 12 per cent. of that of Berlin, 15 per cent. of that of New York. Parks, in speaking for England, says: "It is a question whether a large number of the young men of the upper and middle classes do not suffer in youth from some form of venereal disease. In the lower classes it is perhaps equally common."

Neisser holds that, possibly with the exception of measles, gonorrhea is the most widespread of all diseases. How very prevalent tuberculosis is is

well known to most of you, and I will not detain you with detailed statistics, but simply state that each year the world yields up 1,095,000, each day 3,000, each minute two of its people, as a sacrifice to this plague. Of the 80,000,000 individuals now peopling the United States, more than 10,000,000 must inevitably die of this disease if the present ratio is kept up. According to some statisticians every seventh, and according to others every sixth death is due to tuberculosis.

What are the consequences of alcoholism, of the injudicious, excessive use or abuse of alcoholic beverages? Leaving aside the physical suffering which the intemperate individual brings upon himself and which comes most frequently under the observation of the physician, I ask you to address your inquiries concerning the social, the mental, and moral results of alcoholism to the directors of reformatories, prisons, sanatoria, and insane asylums. They will all tell you that the majority of the inmates of these institutions are there as the direct or indirect results of alcoholism.

Insanity is on the increase, particularly in our state. According to the annual report of the Commissioner of Lunacy for New York, there was in 1892 one insane person out of every 337. Now there is one in every 299. The commissioner considers the condition grave. There are 27,406 insane in the public and private institutions of the state and 6,000 insane are maintained in their own homes. It cost the state $4,593,477 to care for the insane last year.

Not all the crime committed during an attack of alcoholic mania or as a consequence of chronic indulgence in alcohol is punished in our prisons or recorded by our statisticians. Ask our judges of police and divorce courts, our settlement workers and friendly visitors for the most frequent cause of social misery, domestic dramas, privation and want, and they will all tell you that drunkenness is most frequently at the bottom of it all. What is the economic loss to a community arising from the over-indulgence in alcohol? Did drunkenness not exist we could do with half of our police force and police courts. Our prisons, reformatories, asylums, and alms houses would be depopulated instead of being overcrowded. In many homes where now there is misery, suffering, want, and discord, there would be happiness and plenty if temperance could take the place of intemperance. Instead of many children which now bear the stigma of degeneracy as evidence of parental alcoholism there would be strong and healthy children not hampered for life. Permit me to mention here that in sanatoria for tuberculous children, where careful statistics are taken of the parentage of the little patients, it has been shown that of the largest number one or both parents were addicted to the use of alcohol.

Alcoholism often paves the way and leads to sexual over-indulgence and illegitimate relations. The anamnesis of a case of contracted syphilis or gonorrhea in a young man will only too often reveal the fact that the sexual act was preceded by excessive alcoholic indulgence. Syphilis and gonorrhea, although less visible on the surface, are nevertheless productive of an infinite amount of physical, mental, and moral suffering. In view of the extreme contagiousness of these diseases and, in the case of syphilis, of the possibility of direct hereditary transmission and in view also of the strong desire of nearly every individual who has contracted a venereal disease to keep his affliction a secret, I am not quite certain whether this disease is not the greatest and most frequent evil of the three great diseases of the masses. The amount of misery produced by venereal disease must certainly be appalling. The consequences of a not or insufficiently treated venereal disease are two well known to need to be mentioned here.

The master work of my friend, Dr. L. Duncan Bulkley,[3] on Syphilis Insontium, will tell you of the misery that results to the innocent through inherited or acquired infection. The suffering entailed on the trusting wife who becomes infected with the gonococcus germ and whose very life is often endangered thereby is graphically described by all the modern authors of works on gynecology. The works of Fournier, Lazare, Keyes,[4] Morrow,[5] Weiss,[6] and others will enlighten the student on the many other phases of syphilitic and gonorrheal affections which I have not time even to mention here. The economic loss and social misery in our own as in other countries is of the greatest concern to the physician, statesman, jurist, and sociologist.

Dr. S. M. Burnett of Georgetown University believes that 15,000 of the 50,000 blind persons in the United States lost their sight from gonorrheal infection, involving a cost to the commonwealth of seven and one-half millions annually.

Concerning the sterility following gonorrheal infection, Dr. Kober[7] says: "The destructive effects of gonorrhea on the procreative functions have been very properly emphasized in connection with the 'race suicide problem' and are certainly startling when we are told that 50 per cent. of all involuntary childless marriages are due to this cause. From what has been said thus far on the subject of venereal disease you will agree with me when I say that the loss to a country which must result from the expense of caring for the blind whose condition is due to gonorrheal infection; the idiotic, degenerate, or pauper due to a syphilitic parentage or direct syphilitic acquisition; and from supporting the acute and chronically afflicted during the time he is incapable of work is well nigh incalculable.

Tuberculosis, the last of the problems under consideration, is a chronic, infectious, communicable, preventable, and curable disease. These words in themselves are explanatory of the nature of this malady. I have spoken of the physical and mental suffering of the alcoholic and that of the individual afflicted with venereal disease, and the misery they cause to those living with them. I wish I could be spared the task of relating to you what this preventable and curable disease, consumption, entails upon thousands and thousands of our fellow-citizens. It is the more painful in that it causes the greatest suffering among the poor. The prognosis of pulmonary tuberculosis often depends just as much and even more on the pocketbook of the patient as on all other factors. There is no more painful duty to be performed by the physician than to tell the poor man or the one in moderate circumstances that to cure him of his tuberculosis his work must be abandoned for at least a year, and that, in addition to this, he must have as good, if not better food, and better care than he ever has had before. The most frequent sufferers from tuberculosis of all are those living in our tenement homes with lack of air and light and often with scarcely the barest necessities in regard to food and clothing.

The greatest chance of cure for the patient of little or moderate means will be found in the sanatorium, where, when received in time, he has 80 per cent. of chances of being cured and lastingly so; and no particular climate is essential for the cure of these invalids. Experience has shown that our own home

climates are admirably adapted to the cure of our consumptives, and our own little seacoast sanatorium at Sea Breeze has surpassed all expectations in the cure of scrofulous and tuberculous children. But our sanatoria for consumptive adults and tuberculous children are few. A number of efforts to establish them in our state have been dwarfed by the inhuman Goodsell-Bedell law which was enacted during Governor Odell's term of office. This law is a disgrace to our statute book and the sooner it is repealed the better. I charge its promoters with having created a veritable epidemic of phthisiophobia. Thanks to this law, it is virtually impossible to establish a sanatorium anywhere in the state of New York. That such an official phthisiophobia must be invariably followed by outbreaks of private phthisiophobia is evident. Careful and conscientious consumptives who are no more of a menace to their fellow men than a well person have been treated like outcasts. Well equipped and well conducted sanatoria in which one is safer from contracting tuberculosis than in a Pullman or street car have been designated as plague spots. Thanks to such follies, thanks to the indifference of statesmen and philanthropists and often also to city fathers, thousands of our fellow-citizens must die, not because their disease is incurable, but because there is no place to cure it.

Concerning the economic loss that comes to a community because it fails to treat its consumptives at the right time and in the right place, I could give you figures that run into the billions, but I will confine myself to our own city and will give you the figures of our own Health Commissioner, Dr. Darlington. In a recent publication on the cost of tuberculosis in New York City, he says: "Estimating the value of a single life at $1,500—not necessarily a high estimate—and taking only those lives between 16 and 45 years, the loss of life in this city alone from tuberculosis amounts up to the startling sum of $23,000,000 annually."

How can medicine and law combine to combat these three great medico social diseases whose causes and social symptoms I have only been able to point out to you in a very meagre way, but the gravity of which I hope I have succeeded in impressing upon your minds?

What may we do to combat alcoholism? I would suggest that, as far as practical, laws be enacted to prevent habitual drunkards from marrying. The laws making it a felony to sell liquor to a minor, or to administer strongly alcoholic beverages or strong liquors to a child without a physician's prescription should be strictly enforced. There should be a law which would make it obligatory to have a label placed on every bottle of patent medicine stating the exact analysis of its contents, with such ingredients as alcohol, opium, or other poisons in large type.

The pure food bill now before the House of Representatives, which contains an important patent medicine section, I hope will pass and become a law. May I here incidentally remind you that this bill will probably be voted on ere long, and I beg all of you, physicians, sociologists, and philanthropists, to write to your respective congressman, requesting him to support the bill as it stands, warning him that the attempt to render inoperative or ineffective the patent medicine provision is merely an effort to perpetuate dangerous fraud.

The section referred to in the pure food bill provides that (1) a proprietary medicine shall be regarded as misbranded (hence illegal) unless it be labeled with the amount or percentage of alcohol, of opium, of cocaine, and of any other poison contained therein; (2) that a proprietary medicine shall be regarded as misbranded if it bear a label misstating the nature of the medicine or any of its ingredients. To take a concrete case: A consumptive "cure" containing alcohol and opium must have the fact that it contains these substances printed plainly on the label, and it must not be called a *cure*, for that claim is a misstatement and fraudulent.

Mothers should be taught the nefarious influence of soothing syrups and other sleeping medicines upon children. I hold the highly nervous state of our children, which is produced by too much mental work at school and at home, and not enough sleep nor outdoor life, largely responsible for the readiness of our young people to acquire the alcohol habit. A still greater cause of the nervous wrecks among our rising generation, particularly among the working population, is child labor. This fearful disgrace to our nation is responsible for much of the intemperance of our young people, whose wrecked nervous systems cannot resist the temptation to drink. According to Mrs. Florence Kelly, Secretary of the National Consumers' League, well known for her work in this cause, there are not less than two million children earning their living in factory and shop in the United States. Child labor, not only in factories, but also that kind of labor imposed upon children by thoughtless or cruel parents in their homes, should be done away with by the enforcement of rigid child labor laws. To prevent our school children from becoming nervous wrecks because they work too much and play too little and do not sleep enough, our school boards and pedagogues should make new curricula tending to educate the childrens' minds without detriment to their physical development and well being.

Rational temperance should be taught in schools and these temperance lessons should be adapted to the age and understanding of the pupil. In college life the drinking of alcoholic beverages should be discouraged.

What suggestion have I to offer to prevent alcoholism among adults who are free and independent American citizens? I believe in the Gothenburger system, which consists in the manufacture and sale of alcohol by the government and giving the dispenser of alcohol a salary so that no benefit accrue to him no matter how much alcohol he sells, but I fear this system is not practicable in our country. Perhaps even a law limiting the manufacture of alcoholic beverages is not yet feasible, but I believe it is possible to limit the number of licenses of saloons. However, it is my firm conviction that through the building of model tenement houses, the creation of more parks and play grounds and healthful places of amusement, open Sundays and weekdays, where the laborer can partake of non-alcoholic drinks and enjoy the society of his friends, will do more to do away with alcoholism than dragoonic laws.

I have deep sympathy for the laborer who, after a hard day's work, before returning to the dark, dreary, cheerless tenement home for which he has often to pay an exorbitant rent, stops at the brightly lighted saloon and takes a drink. He meets there the friend which he cannot receive at home and cannot meet at the clubhouse, for he is not a member of any club. Add to the above suggested places of amusement a smoking room in all public libraries, a number of hot coffee stands in winter and plenty of fountains with pure, cool drinking water in summer, and you will have another feature to discourage alcoholism. There is one lack in our American city which I am convinced leads many a man into a saloon to take a drink which he would not do did not the calls of nature make a demand on him

to go somewhere. I do not believe there are, outside of the parks, here in New York more than a dozen public urinals. Paris, which is certainly a beautiful city, has many thousands. With a little esthetic taste they can be hidden away behind shrubbery or neat screens. I venture to say that the installation of a few hundred of such places would add to the comfort of many and would certainly reduce the amount of liquor sold. It is for our city fathers to look after this matter. However, in our eagerness to attack these various problems in our city, let us not forget our fellow-citizens in the country, the farmers, their wives, children, and help, particularly of the poorer classes. The humdrum existence of many farmers' families is often responsible for alcoholism and consequent insanity, or insanity independent of alcoholism. We delight in taking the mothers and children of the poor in our large cities on excursions into the country. Whoever thinks of taking the wives and children of the poor farmers to the city to show them the marvels of modern city life and the great inventions of our times? I am sure these poor country women and children would enjoy an excursion to the city as much as our tenement dwellers enjoy an excursion to the country.

This offers a new field for practical philanthropy destined to become a factor to aid in the solution of all the three problems under consideration. I am convinced that it will be necessary to stem the tide of emigration from village to city and reverse this tendency as far as is in our power. Statesmen should protect the interests of the farmer so that farming should have more attractions to the rising generation than it has had during the last few decades. Philanthropists should aid the statesmen by endowing institutions for instruction in scientific and profitable agriculture, and also by providing healthful amusements; good libraries, and other educational institutions in country districts, thus making living in the country more interesting and attractive to the young people.

The greatest source of intemperance in this country I believe is to be found in our habit of treating. The habit of going with a number of friends to a saloon and then alternately treating the crowd has ruined many a young man and made of him a moral and physical wreck. The young man starting out in life should take with him the moral training which will enable him to be a gentleman, and be considered a polite gentleman, though he absolutely refuses ever to enter a liquor saloon in order to treat or be treated to drink.

I believe, however, that in a city of such a cosmopolitan character as ours it is wise to open saloons on Sundays certain hours after church service. At present there is a bill pending at Albany called the Tully-Wainwright Local Option Bill, which is intended to do away with the present Sunday laws. The bill provides that in any "residence district" of 300 or more voters in any city, or 100 voters in any town, the residents may petition to have the sale of liquor stopped for a period of two years. No less an authority than the Right Rev. Vicar General Lavelle of St. Patrick's Cathedral, who is well acquainted with the needs of the masses, has written a letter to Senator Tully advocating the passage of the measure but indicating clearly that he would also like to have the present law amended so that in certain districts the sale of beers would be permitted during part of each Sunday. In his letter to Senator Tully commending the bill, Mgr. Lavelle said in regard to this: "Respectable people of small means should have an opportunity on Sundays to get proper beverages for their dinners in their homes. The same is true of those who go to the beaches and other resorts for recreation. I am aware that many people object to this permission on the ground that it would be only an opening wedge for universal and harmful indulgence. But this objection loses all its weight when we realize that we are getting a law that can be enforced to the very letter, one which the people themselves will be anxious to see properly executed as the officials whose duty it is to carry out its provisions." I believe that having the saloons open for a few hours on Sundays would cause less drunkenness instead of more.

From the little I know of club life, rather less alcohol is used by the members on Sundays, certainly never more, and why? Simply because there is no restriction placed upon the consumption of liquors. I have already said that the saloon is the poor man's club. Let us give him the same rights as are accorded to the member of the fashionable club. The tendency to lay in a supply for Sunday or to fill up on Saturday to last over Sunday, to get it on the sly or through side door or family entrances or with the aid of an indigestible Raines law sandwich, does not lessen but rather increases the consumption of alcohol. Forbidden fruits seem to taste sweeter. Only by means of these increased receipts is it possible for the saloon-keeper to pay high enough tribute to the powers that be to be able to carry on his trade unmolested even on Sundays. The laws of this Empire State relating to closing saloons and places of amusement on Sundays are absurd. I have seen some strange, not to say profane, things at a New York place of amusement which had advertised its performance as a "Sacred Concert." The fact that so many of our so-called Sunday-closing laws are so ridiculous makes it a relatively light matter for the conscience of some to break the law by bribe-giving or bribe-taking. Temperance societies and societies whose members have pledged themselves to drink only with meals should certainly be encouraged. There exists in Germany *ein Aerztlicher Abstinenz-Verein*, and we have here in America a total abstinence society composed of physicians. It is for my esteemed friends of the legal society to form such a society now if they feel so disposed. To the best of my knowledge there exists as yet no society of total abstainers among lawyers.

What are we to do with the chronic drunkards arrested and rearrested—those, for example, who spend half of the year in our alcoholic wards in Bellevue or in the workhouse? In some European countries the habitual drunkard is disfranchised and afterward put under guardianship. I do not know whether such radical measures would be feasible in a republic. I believe, in the end, it would be better for the individual and the country if we would establish special sanatoria for the treatment of alcoholism where the well-to-do should pay and the poor should be received gratuitously. We have people's sanatoria for consumptives, we have large asylums for the insane, why not try to cure those afflicted with alcoholism, which is as much a disease as any other affliction? To cure him at the right time and in the right place when there is still hope of making out of the drunkard a useful member of society, is certainly better and more economic than to wait until he commits a crime or is sent to the insane asylum, or hospital, or almshouse as incurable.

Our lawmakers should not only see to it that such institutions should be established by states and cities, but should also enact laws whereby the fraudulent institutions claiming to cure alcoholism by myste-

rious and often dangerous methods should be wiped out of existence.

You are all familiar with the fearful results which come to the unfortunate individual who imbibes beverages containing wood alcohol. Blindness and the most severe nervous and mental disturbances are often the result. No law can be too severe which is intended to stop the sale and dispensing of wood alcohol for internal uses.

Before leaving this subject, may I say one more word on a cause of alcoholism which I believe is little known as such and for which only our methods of education the future wives and mothers can be held responsible. I claim that bad cooking and the injudicious selection of foods induce the desire for alcoholic stimulation. Let us have more cooking schools and make plain and good cooking a part of the curriculum of all girls' schools. Let such cooking lessons be based on economic, hygienic, sanitary, and physiological principles. It is more important to know how to cook a good, substantial, and nutritious meal, composed of soup, meat, and vegetables, than to know how to make fancy cakes and jellies.

How may we combat the second disease on our program? I begin again by suggesting a law making it prohibitory for people suffering from syphilis or gonorrheal diseases in any of the infectious stages to contract marriage.

I believe in making these diseases reportable to the Board of Health with such restrictions as assure the unfortunate sufferer protection against publicity. The only condition I would insist upon is that the reporting physician should receive a leaflet of instruction issued by the Board of Health, explaining to the patient, to whom it should be handed, the disease and the precautions he should take to prevent infection.* I believe, furthermore, in educating the people at large by lectures and pamphlets, and in instructing school children and adolescents concerning the nature of these diseases. The teaching in schools and colleges might be done by the school physicians and the lessons adapted to the age and understanding of the pupils.

The subject of licensing prostitution I approach with diffidence. Our greatest syphilographers do not agree on it. There are as many opposed to it as in favor of it, and both sides have statistics supporting their arguments. Here in America, in addition to the difference of opinion among medical authorities on the subject, there is a strong popular prejudice against laws regulating prostitution. What, then, can we do to minimize the dangers arising from this social evil? Besides the educational campaign already suggested, there should be liberal provision for the treatment of venereal diseases in special dispensaries with evening classes, and, above all, special hospitals. I would prefer to have different hospitals for each sex, and the unfortunate prostitute should receive the same kind and considerate treatment which is extended to the paying male patient, whether she pays or not. I insist upon this point, for I have witnessed in some European hospitals the most inconsiderate and unkind treatment of these unfortunate women, so that I did not wonder that some of them vowed, when once discharged, never to pass the portals of a hospital again.

And now a word as to how it may be possible to strike at the root of this evil by preventing the woman from becoming a prostitute and the young man from becoming affected by illegitimate intercourse. Let us as physicians, jurists, and sociologists, acknowledge that at the bottom of it all is our present social fabric. Prostitution gets its recruits, to no small extent, from the unfortunate girl who has loved, not wisely, but too well. Her own sister will stamp her as an outcast and her child as a bastard. A little more humanity, a little more sisterly love, a little more compassion, is needed here. Let woman be more womanly toward her sister who may have fallen, but nine times out of ten through no fault of her own. A helping hand stretched out to the unfortunate child mother will often prevent her from becoming a prostitute.

A few more homes where the unfortunate girl who has become a prospective mother may be received several months before her confinement and kindly cared for till all is over, a few more homes where the unfortunate woman of the street may be received and another chance be given her, and prostitution is bound to diminish.

The underpaid factory or shop girl is another frequent recruit for prostitution, often by reason of necessity for her daily wants, and sometimes by her desire for finery. Let all philanthropists among the manufacturers and large store keepers, while still at the head of their enterprises, remember this. It is a greater philanthropy to pay the girls in their employ living wages so that the temptation to go wrong will be removed, than to leave millions in their last will and testament to cathedrals, hospitals, and similar charities.

Better wages for our young men and more model tenement houses, with reasonable rents, will encourage many young men to enter the matrimonial state and rear a family. It must be obvious to all of us that early and happy marriages are the best means to combat prostitution and venereal disease. I think it is absolutely wrong for fear of indelicacy to keep the masses in ignorance concerning these vital matters.

I doubt the wisdom of our lawmakers, city fathers, and reformers in perpetually hounding the unfortunate prostitute. These women are driven away from one part of the city only to turn up in another, and, instead of confining the evil to one section, it is spread all over. I have the strongest doubts that the social evil as such can be suppressed in a city like New York by no matter how strict a police regulation. On the other hand, to limit the evil to some portion of our city, a district which could be properly controlled by an efficient police, would stop the concomitant thievery and robbery and greatly diminish that still greater crime of having men live on the shame of women. Remove by sensible and just laws the necessity of bribe-giving, and the bribe-giver will cease to exist. I do not like this perpetual cry of some against a corrupt police, an inefficient judiciary, etc., etc.

Let us make laws that can be enforced. Remove the ridiculous character of some of the laws, and you will find the vast majority of our policemen true guardians of the peace and willing to perform their duty, and our judiciary you will find as spotless as any.

It is for you lawyers and lawmakers, members of this Society, if you are in accord with these views, to take the initiative in this direction. I believe I can guarantee you the hearty support of the medical profession in this matter. My faith in mankind and womankind and in the progress of humanity at large is too great not to believe in the possibility of ultimate victory over the social evil. It will not be

*The German Society for Combating Venereal Disease has just issued two most excellent circulars for such purpose.

by harsh suppression, but by an intelligent, humane repression, by improving the social condition of woman and the masses in general, by tolerance instead of prosecution, by evolution instead of revolution.

Permit me before taking up my last subject, tuberculosis, to suggest a way to educate the masses as to the prevention of alcoholism and venereal diseases. Let some philanthropic person, or, better yet, the Government, offer a prize for the best popular essays, one on how to prevent alcoholism, and one on how to combat venereal diseases as afflictions of the masses. Let the prize jury be composed of medical, legal, and sociological authorities. The essay should be divided into several sections, adapted to children, to the adolescent, to man, and to woman. The best and most suitable essays submitted should be printed and distributed by the Government, free or at cost.

The tuberculosis problem, which has attracted the attention of the crowned heads of Europe and the President of our own, of the French, the Swiss, and even the South American republics, has become of late most intense. Local, national, and international associations for the study of tuberculosis exist nearly everywhere. There exists an international bureau, and international congresses are held every few years. The next one is to be held in our own country in 1908. It would thus seem that much was being done; but let me assure you, there is more to do. As in the two preceding diseases, marriage between tuberculous and healthy, unless in exceptionally well arrested cases, should be discouraged. As to the procreation of tuberculous children I have strong convictions, but I know that there are many men and women, inside and outside the medical profession, who differ with me. However this may be, I am willing to take the responsibility before the law and my God for each time I have taught a tuberculous husband and wife not to procreate a race predisposed to tuberculosis; and, with all due respect to the opinion of others, as a physician with, I may modestly claim, a somewhat larger experience among the poor and poorest of the poor, the middle classes, and also among the well to do, and as a student of sociology as well as of preventive medicine, I am not for quantity but for quality. Education along this and other lines teaching the measures to prevent tuberculosis should be still more encouraged.

Our Health Boards should be upheld by the law in their efforts to diminish the source of infection arising from carelessly deposited sputum, which, when tuberculous, is a frequent source of infection. In our railroad stations and in public places it does not suffice to put prohibitory signs. Such places should also be provided with a number of well-kept spittoons. Placing signs over these receptacles reading "Spit Here," instead of placing the "Don't Spit" signs elsewhere, will materially diminish this sort of infection. Laws protecting us against the dangers of tuberculous food substances should be rigorously enforced. Sweeping the streets in a dry state should be counted a crime against our fellow men, and the laws should be enacted accordingly. Appropriations to enable the Street Commissioner to give us clean streets and the Health Commissioner to give us clean air should be forthcoming. Filthy streets and a smoky atmosphere are disease producing and particularly productive of diseases of the respiratory tract, such as tuberculosis, pneumonia, grippe, etc.

Our fellow practitioners in law and medicine of the gentler sex will, I know, be willing to help the cause by a sensible dress reform, particularly by wearing the short rainy-day skirt, for their own comfort as well as for an example to others. They will thus lessen the real danger there is in wearing trailing skirts in the street, which so often do the scavenger's dirty work. In schools and colleges, factories, and workshops, offices, department stores, and Government concerns the simple precautions to prevent the spread of tuberculosis and to assure sanitation and proper ventilation should be practised and taught. Since I am addressing judges and lawyers, I ask you to make your influence felt in rendering sanitary our prisons and reformatories in insisting that tuberculous inmates are isolated and treated. I also beg of you not to consent to the discharge of a prisoner because he is dying of tuberculosis unless you are absolutely sure that he will be well cared for and not become a new source of infection and a burden to the community.

The medical profession should do its utmost to diagnose and recognize the early cases of tuberculosis, and city and State governments should enable the medical profession to send the poor and deserving cases to sanatoria where they have the best possible chance of being cured.

The Goodsell-Bedell law should be repealed and a sufficient number of sanatoria should be built for consumptive adults and for scrofulous and tuberculous children. The unscrupulous quack advertising "sure consumptive cures" should be prosecuted to the full extent of the law. It should be widely published that there is no secret remedy and as yet no specific for the cure of consumption, that our best means to this end are fresh air, good food, pure water, and careful medical supervision.

What I have said regarding child labor, too much school work, poverty, want, and unsanitary homes as predisposing factors to alcoholism, I can only repeat when speaking of tuberculosis. But in addition I may say that the belief of the masses that alcohol is a good preventive for tuberculosis, or a good remedy in consumption, is erroneous. On the contrary, alcohol is responsible for more tuberculosis than any other one cause.

I have presented to you in a very fragmentary way the causes and social symptoms of three of our most widely spread diseases of the masses. I have ventured a few suggestions to remedy the evils, but my hope lies in the inspiration we will receive from the galaxy of distinguished men who have honored this Society and me by their willingness to discuss my modest paper.

May the words of wisdom to which we will now listen help us in solving these great problems for the honor of our Society, the glory of our nation, and the welfare of mankind.

THE NEED OF PUBLICITY IN VENEREAL PROPHYLAXIS.*

By DENSLOW LEWIS, M.D.,

CHICAGO, ILL.

CHAIRMAN OF THE SECTION ON HYGIENE AND SANITARY SCIENCE OF THE AMERICAN MEDICAL ASSOCIATION.

The venereal diseases exist and have always existed. They cause among adults the greatest morbidity and much suffering and distress of mind. They occur also in children and may be acquired innocently, that is to say, without sexual intercourse. Often the young wife, whose husband is ignorant of the possibilities of infection, is made an invalid for life or becomes a candidate for the operating table. This great venereal plague, which is omnipresent, counts its thousands of victims. It blights many an unborn child, and is often the cause of blindness in the newborn. It is a destroyer of health and happiness; it tends to sterility. With the hope of children annihilated, the foundation of the family becomes insecure and the way is open for marital infelicity and divorce. Beyond question the venereal diseases are a potent element in adding to the misery of mankind, and as a disturber of our social relations they certainly play a leading rôle.

How important therefore is a recognition of this great curse of humanity; how necessary that all should know of the imminent danger that lies in wait for every man, woman, and child. How essential then a factor in our education should be the inculcation of adequate knowledge regarding the possibility of venereal infection, and how imperative should be an extension of the truth in reference to this devastating scourge of our civilization. And yet it is only a year ago that any concerted effort in this country was put forth looking towards a rational prophylaxis of these diseases. It is only since February, 1905, since the organization of the American Society of Sanitary and Moral Prophylaxis, by Dr. Prince A. Morrow of New York and other eminent practitioners, that any systematic attempt has ever been made to limit the spread of these loathsome diseases by a common-sense education of the public in the understanding of the danger that threatens everybody.

Prior to that time, as I know from personal experience, the way of the would-be exponent of the truth was not a path of roses. Even his most sincere efforts were condemned,[1] and every attempt to secure a hearing was often considered an outrage. The medical profession would not listen. The subject was too obnoxious and the whole matter was apparently so loathsome that even the mention of it was intolerable and most reprehensible. If by any possibility a man ventured to say an earnest word in protest, professional opinion would exert itself, as exemplified by Howard Kelly's criticism of a paper I presented by invitation in 1899 at the Columbus meeting of the American Medical Association, when Dr. Kelly said: "The discussion is attended with filth and we besmirch ourselves by discussing it in public." As further evidence of the hesitancy of the profession to take up this matter before the public, I recall the experience some fourteen years ago of Dr. Ferd. C. Valentine of New York before the American Medical Association. One member remarked that this is a Christian country and our association is a Christian association and that no such vile thing as venereal diseases should ever be allowed to come before the Christian American Medical Association.[2] Two years ago, however, Dr. Valentine appeared by invitation before the Conference of State and Provincial Boards of Health of North America at its nineteenth annual meeting, held in Washington, D. C., and discussed freely matters in reference to the segregation of prostitutes, the methods of examination for venereal diseases and the means of educating the public in a knowledge of the danger that confronts the young and the ignorant. It was apparently considered a bold thing to do, for the secretary, Dr. Gardner T. Swarts of Providence, R. I., said, regarding this attempt at a rational education along preventive lines: "Such a movement is a sensational and questionable one with many." The effort of Dr. Valentine made a profound impression. His recommendations were very generally concurred in; he was tendered a vote of thanks, and, at the suggestion of the president, Dr. J. N. Hurty of Indianapolis, he consented to forward his paper to the *Journal of the American Medical Association* for publication. His remarks on that occasion are noteworthy. They show why honest men persist; they demonstrate the motive that actuates the true humanitarian. He said: "Titles, as we grow older, lose their glitter; the degrees we have received grow tarnished. One grows ambitious for a higher honor—that of doing good."

So the first great obstacle to a rational understanding of the subject is surmounted. It is now admitted that we must seek the truth; it is recognized that we must diffuse the knowledge we already possess; it is realized our endeavor must be earnest and our study of the subject comprehensive. The first step has been taken; the value of publicity is acknowledged.

In considering the truth regarding the venereal diseases, we must acknowledge first of all the dominating influence of the sexual instinct. Why should we not? It means the perpetuation of the species. It is the most important function of which any man or woman is capable. Did it not exist, the human race would come to an end in one generation. It is a pure and noble function, and we must not only recognize its existence, but also admit the facts regarding its manifestation and the very serious results that follow its misapplication or perversion. Standing next in importance to the instinct which demands self-preservation, this imperious force in every man and woman differs in degree, but, always a potential element, requires satisfaction and demands recognition. We may say what we please, we may find fault as we will, this fact remains: The sexual instinct is the basis of every earnest endeavor, every poetical aspiration, every noble purpose. Without this instinct there would be no home, no civilization, no government. Did not the desire exist for sexual intercourse, the corporal manifestation of this great instinct, love were a farce and the home, the basic principle of all civilization and morality, were an impossibility. We admit then the existence of this great factor in life, and we are glad to admit it. We realize the necessity and the advisability of having this dominant force in our nature sensitize and vivify all our actions, because it means the present happiness of humanity and the future existence of the human race.[3]

With this admission of the importance of this function—the greatest of which we are capable—should come also a realization of the necessity of accurate knowledge regarding all incidents in its manifestation. If it is the ruling function of our existence, does it not follow that thoughtful consideration of it is a most serious duty of every earnest student, and that knowledge regarding its every de-

*Presented to the fifty-sixth annual meeting of the Illinois State Medical Society, held in Springfield, May 15-17, 1906.

tail is a matter of exceptional interest and most serious inquiry? This is a fact, always acknowledged in theory but now for the first time recognized in practice. We admit the existence of this function. We know its forceful influence on our lives. We acknowledge its supremacy. We deal with it and do not ignore it or deny its existence. This is the second step necessary to a rational consideration of venereal prophylaxis.

My individual views regarding methods of instruction along these lines have been often expressed.[4] The subjects of masturbation, rape, criminal abortion, infanticide, and divorce are concerned in a consistent effort of an educational character in reference to the venereal diseases. With the approach of adolescence comes a realization of the awakening of the sexual instinct. The boy wonders what this new sensation may mean. His school fellows are ready with fanciful explanation and oftentimes, but little urging it needed to induce the indulgence in masturbation or the premature exercise of the newly developed function—the necessity of such action, as indicated by his schoolmates, being in accord with his own inclination. The boy knows of no danger. No one has told him. Why should he not do as the other boys are doing? When seminal emissions occur he is told, and he often believes, that the performance of the sexual act is imperative to conserve health and prevent imbecility. If there is impropriety, wrongdoing, or danger, why has he not been warned? He has been told about brushing his teeth and taking a bath; he knows he must learn his lessons and conduct himself with decorum at the table. Let us now understand our duty and tell him the truth about the sexual instinct and the need of controlling it. Let us pacify and dispel his fears and teach the dignity of virility. Let us inculcate principles of honor toward the young girl and let us explain regarding the danger of venereal infection.

With the girl the need of actual knowledge is of even greater importance. One mistake on her part, if discovered, blasts her reputation for life. Indiscretion in the boy is ruin for the girl. She is never forgiven. Moreover, in addition to the danger of masturbation, unnatural practices, and venereal infection, is the danger of conception, which usually means criminal abortion or infanticide, and too often a life of prostitution. In my own personal experience, I have known of hundreds of cases where ignorance has been responsible for the ruin of the young girl. Many a worthy family of high social position mourns to-day the loss of a loved one who might have been the wife of an honest man, had she been told regarding the possibilities. There are men and women in exclusive society who have wealth, reputation, and honor, and yet their lives are embittered by the knowledge, which they hide from the world, that a daughter, through lack of instruction and warning, is now an outcast.

In the case of a working girl the danger is much greater, and with her the withholding of knowledge becomes, in my opinion, criminal and heartless. Her position in the working world is less remunerative than man's, and the strenuousness of competition in business is often enhanced by the importunity of employers, customers, and other male acquaintances. A little sympathy and a few extra dollars often induce her, in her ignorance, to be compliant. How unjust is our civilization and how farcical is our pretended Christianity, if we do not go to the assistance of every young girl whose necessities force her to contend against this danger which may mean seduction, disgrace, crime, or venereal infection.

I want the young people throughout our country to know the truth. They must know hygiene and physiology—the physiology of the whole body. They must know how the sexual instinct manifests itself, how it can be controlled until such time as marriage permits its indulgence in the furtherance of its legitimate object. They must know regarding reproduction, and the girl especially should realize how her indiscretion may result in conception or venereal infection. Our only hope for the coming generation is in knowledge. If we are sincere in our humanitarian endeavors, let us cast aside all thought of false modesty and maudlin sentimentality, and let us warn the young against the dangers that confront them by a consistent exposition of the truth. Herein is the only possibility of effective prophylaxis.

Permit me an additional word regarding the Society of Sanitary and Moral Prophylaxis. I am the first Illinois member, and for that reason I now impose on your courtesy and bespeak your active interest in the work of the society as others are doing in the different State medical societies throughout the country. In Dr. Morrow's presidential address he says: "A free discussion is, of course, an essential preliminary to any well-considered action, especially when such action proposes to deal with what is confessedly the most difficult of all the problems of social hygiene."[5] In speaking of the proposed work of the new society, he says: "It should be a campaign of education, a crusade against ignorance." In justification of such action, he adds: "There exists in all classes of the public the densest ignorance as to the dangers of these diseases and their modes of communication, direct and indirect." Referring to the need of knowledge of the sexual act, he remarks: "Young men should be taught that the reproductive function is given for a higher purpose than mere sensual gratification, that it is susceptible of control, discipline, and proper direction;" and in protest against the false modesty that so long has interfered with the inculcation of a knowledge of the truth, he continues: "The chief obstacle to the dissemination of this prophylactic enlightenment inheres in the very name and nature of the diseases themselves, or, rather, in the atavistic impregnation of the public with the idea that knowledge of the reproductive system and its diseases is shameful and even demoralizing, that such knowledge is not proper or fitting for the young." He says, further, and most truthfully, as we are all forced to acknowledge: "The entire system of our educational machinery is organized upon a basis of silence and secrecy in regard to the reproductive function which, from a biologic point of view, is the most important function of the body. It would appear that the aim of parents and instructors is to give the young, when launched into the world, a brevet of ignorance of all matters pertaining to sex and sexual hygiene."

I take pleasure in quoting these statements, for they coincide with the views which I have so often expressed during the past seven years. Publicity is indeed the first essential; knowledge of the truth is, in effect, the greatest safeguard. Bulkley and Margaret Cleaves[6] have shown the need of education in sexual hygiene for the young men and women of the working classes. Bangs and Grandin[7] have asserted that the general public should be enlightened as to venereal diseases. Bransford Lewis[8] has shown the absurdity of false modesty. Education is our strongest weapon and the most rational means at our command in the fight, not only against the venereal diseases, but also against rape, criminal

abortion, infanticide, marital infelicity, divorce, prostitution, and sexual perversions and crimes. It will diminish masturbation and save many a young girl from seduction. It will restrict illegitimacy; it will tend to make the marriage contract a surety against the transmission of disease, and the perpetuation of degeneracy; it will help answer the alcohol question; it will add to the health and the happiness of humanity.

The general proposition is now very well understood, and the great majority of the thinking men in the profession acknowledge the advisability of instruction, and are coming pretty generally to a conclusion regarding the best means of furnishing the necessary knowledge.

The existence then of the venereal diseases should be made known to all and the possibility of innocent infection should be explained. Why not? The danger is imminent, the results are disastrous, the only possibility of safety consists in knowledge of the facts and the means of prevention. Do not say it is immodest. Would we hesitate, on account of modesty, to save a woman from drowning in the river just because she was nude? If we would not, we must not deny to those who are in danger of disease and death that knowledge which alone can save them. If we persist in such denial, we do not regard, as our first duty, the preservation of the human race, and we share in the responsibility of destruction by ignoring what we know to be the most rational means of prevention. It becomes therefore the duty of every practitioner of medicine, now more so than ever before, to give instruction regarding the venereal plague in its different relationships. Ignorance has been the curse of the past; knowledge will prove the salvation of the future. Prudery shall no longer deter us in the performance of our duty. With a persistent effort, with combined endeavor, we will dissipate the darkness of ignorance by an exposition of the facts that we know. Fearlessly, confidently, resolutely, let us bear the great light of truth into the world.

The Treatment of Epistaxis.—Mendini recommends the introduction into the bleeding nasal passage of a tampon soaked with one part of a 1-1000 adrenalin solution and ten parts of salt solution; if this does not control the hemorrhage the passage must be packed with strips of gauze. In most cases this will be sufficient and it is rarely necessary to place a tampon in the posterior nares. In removing the tampons it is advisable, after the first few strips have been taken out, to drop into the nostril a small quantity of a solution composed of cocaine hydrochlorate one-fifth, 1-1000 adrenalin solution one, and distilled water ten. The vasoconstriction caused by this application produces enough shrinkage of the nasal mucosa to permit the tampon to be removed *in toto* without difficulty.—*Nouveaux Remèdes.*

A RARE CASE OF PRESUMABLY CONGENITAL LUXATION OF THE ARYTENOID CARTILAGE.

By P. TETENS HALD, M.D.,
COPENHAGEN, DENMARK.
ASSISTANT SURGEON TO THE CLINIC FOR EAR AND THROAT DISEASES OF THE KOMMUNEHOSPITAL, COPENHAGEN.

Notwithstanding its minuteness the cricoarytenoid articulation is one of the most important and most used joints of the body, inasmuch as perpetual movements are performed by it during the whole postfetal life of the individual, both when he is awake and when he sleeps. With every inspiration the processus vocalis moves outwards, and during expiration it approaches the middle line again; the largest movements, however, are executed during phonation, to secure which the integrity of the arytenoid articulations is of high importance. For this reason very pronounced symptoms might be expected, when the articulation is diseased; but such symptoms are often absent when only one of the joints is pathologically altered, because the other normal one in these cases by making larger movements is able to perform the duties of both.

The disorders of the cricoarytenoid articulation, that will be discussed in the following lines viz., luxation, has evidently rarely been observed, as appears from the small number of published cases I have succeeded in collecting. Here, as in other joints one may distinguish between traumatic, pathological, and congenital luxations, while to classify them according to the direction in which the arytenoid cartilage is dislocated, can scarcely be of great practical importance. 1. The cricoarytenoid articulation lying well hidden and protected by the firm thyroid cartilage cannot be directly reached from the surface of the body, and for this reason traumatic luxations, produced by a cause acting from without must be very rare. I know of only one case having been published (by Hopmann[1]). A girl in falling down hurt her larynx against the edge of a table, and immediately afterward became aphonic with slight hemoptysis and painful swallowing. Besides other lesions, laryngocopy showed tumefaction of the right arytenoid cartilage. The cartilage was far broader than normal, rotated broader than normal, rotated inward and forward, and remained immovable during attempts at phonation. Also the vocal cords were injured as in the only case I have found, where the dislocation was produced by muscular action alone. This latter case is mentioned by Schnitzler[2] as "a classical observation of luxation of the arytenoid cartilage (caused by vomiting) accompanied by a longitudinal rent through the vocal cord of the same side. In Fig. 7 (phase of respiration) however only the mentioned rent in the right vocal cord is seen, but no luxation, while Fig. 8 (phase of phonation) shows a luxation of the left arytenoid cartilage without lesions of the vocal cords.

Without doubt the pathological luxations form the most numerous class of dislocations in the cricoarytenoid articulation, having been observed during the course of syphilis, tuberculosis, typhoid fever, variola and diphtheria. However the published cases are few in this group also. The first case, that of Sidlo,[3] is very interesting in several respects, amongst others because it shows how difficult it can be to diagnosticate even extensive alterations of the larynx from the laryngoscopic image. The trouble began rather suddenly with coughing, painful swallowing, and dyspnea; both inspiration and expiration were accompanied by a hissing sound that might be heard at a distance. Four weeks after the

beginning of the disease the patient was admitted to the hospital, and laryngoscopy then showed symptoms of a violent acute laryngitis. The swollen vocal cords touched each other in their foremost part and remained stationary during respiration; during phonation they approached, but the rima glottidis still gaped in its posterior part. Two months after admission to the hospital the appearance of the mucous membrane of the larynx was normal, but the arytenoid cartilages and the vocal cords had now approached each other closely, and the latter showed, "motus perversus" during respiration, approaching yet more closely during inspiration, while during expiration they separated just a little. As the arytenoid cartilages and the posterior wall of the larynx appeared normal, paralysis of both posterior cricoarytenoid muscles resulting from paralysis of the recurrent nerve was diagnosed. The linear rima glottidis, that in Sidlo's eyes "resembled a thread from which a Damocles' sword was suspended over the head of the patient," by catheterization was brought up to half its natural size, but six months after admission to the hospital the patient developed pneumonia and died, tracheotomy having been necessitated in a few days. The post-mortem examination showed[4] dislocation of both the arytenoid cartilages onto the anterior surface of the lamina cartilaginis cricoid., where they were placed in a horizontal position. Cicatricial tissue closely united the surfaces of the arytenoid cartilages facing each other; on the posterior wall of the larynx there was a stellate cicatrix, according to Prof. Toldt, of syphilitic origin. The posterior cricoarytenoid muscles and the interarytenoid muscles were atrophied, but the recurrent nerves were intact. The reason why no alteration of the posterior wall of the larynx had been observed with the laryngoscope was that large layers of muciparous glands were situated behind the arytenoid cartilages and simulated the normal configuration of this part of the larynx to such a degree that even at the post-mortem examination the true diagnosis was not made on inspection of the larynx, until its cavity had been laid open by severing of the anterior wall.

A rare case of luxation of both the arytenoid cartilages has been described by B. Fraenkel.[5] A patient became hoarse after an attack of typhoid fever, and three days after he got up sudden dyspnea came on, which necessitated immediate tracheotomy. Laryngoscopic examination showed the vocal cords completely immovable and close to each other during quiet respiration. The right arytenoid cartilage had fallen completely forward and to the left; its apex with the cartilago corniculatus crossed the middle line and approached the left ventricular band. The left arytenoid cartilage was situated quite posteriorly and to the right; its apex also crossed the middle line toward the right and filled the right recessus pyriform., so that it looked as if the apex of the cartilage had grown together with the posterior wall of the sinus. It was possible to lift up the arytenoid cartilages and to replace them in their normal position. They even were easily moved by the probe, but at once fell back in their abnormal luxated position. When the cannula was closed the patient could speak with a distinct and loud, but not very pure voice; on the other hand, even a forcible inspiration failed to enlarge the very narrow and almost invisible opening of the glottis. Luxation onto the anterior surface of the lamina cartilaginis cricoid, was also observed in a patient presented by Heymann[6] in the laryngological society of Berlin. Here the left arytenoid cartilage rested on the vocal cords; as the patient had diphtheria thirteen years before, I mention the case in this class (as a pathological luxation), having been unable to find a more explicit description of it.

In the mentioned cases of pathological luxation the dislocation must have been caused by inflammatory ulcerative processes in or in the vicinity of the articulation, perhaps, as Fränkel suggests, in many cases by a perichondritis cricoidea, perhaps also by the formation of shrinking cicatricial tissue. That no scars have been detected by the laryngoscopic examination is not astonishing, as these must have been situated on that part of the mucous membrane of the cartilages, which cannot be seen by the observer. In some cases also the muscles attached to the arytenoid cartilage may contribute to the production of the luxation. Far clearer is the etiology of the dislocation in those cases in which a tumor forces the cartilage to leave its normal position as in the two patients observed by Jurasz.[7] In the one patient a struma on the posterior wall of the pars laryngea pharyngis pressed the left arytenoid cartilage forward, and in the other the same cartilage was dislocated inward and forward by a cyst of the size of a hazel nut in the left plica aryepiglottica.

The published cases of the third class, the congenital luxations, seem not to be more than three, to which I am going to add a fourth, observed in the ear and throat clinic of the Kommune Hospital, Copenhagen. As will be seen from the following descriptions, the previous cases in all probability appertain to the second group, the laryngoscopic examination revealing alterations that must be considered as results of an inflammatory process. Stoerk has observed two patients with the disorder under discussion,[8] both of which had since their childhood spoken in falsetto. The first had diphtheria as a child, and Stoerk thinks it possible that the luxation in this case may have been caused by the formation of a scar; the other had not ever suffered from diphtheria. In the first case, where suffocation used to threaten during colds, laryngoscopic examination showed the right arytenoid cartilage pressed to the right but with rather normal outlines; the left was about four times its normal size, the mucous membrane, however, not being swollen, but the outlines were quite abnormal. Only so much could be observed that the left arytenoid cartilage with its vocal process and muscular process were not in the sagittal axis of the larynx but in the transverse, so that the vocal process crossed the middle line to the right. Even during forcible inspiration the vocal cords remained immovable (according to Stoerk's illustration nearly in cadaveric position), but closed during phonation. The second patient showed the vocal cords close together without the slightest motion during deep inspiration. The left arytenoid cartilage had three times its normal size, its outlines being quite distinct. As in the first case, it had changed its moral sagittal position to a transverse so that the left vocal process was found nearly where ordinarily the axial point of the right arytenoid cartilage is situated. The right arytenoid cartilage was pressed outward and backward and took a sagittal position. Provided that Stoerk's view of the cases as a luxation inwards together with a rotation round a vertical axis, causing the vocal process to cross the middle line, be correct,*

* Looking at Stoerk's illustrations, especially No. 1, I feel tempted to think that the left arytenoid cartilage has been luxated onto the anterior surface of the lamina cartilaginous cricoid (*i.e.* round a transverse axis), and that the luxated but otherwise only little altered arytenoid cartilage, seen from behind, has *simulated* an enlargement. But of course I dare not go against Stoerk's authority.

the considerable enlargement of the arytenoid cartilage can hardly be explained otherwise than as a result of a chronic perichondritis, passed without symptoms. Such a slow inflammatory process Semon also thinks may be the etiology of the luxation of the right arytenoid cartilage in the

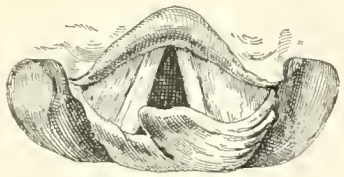

Fig. 1.—Laryngoscopic image during respiration.

case, observed and published by him.[9] The voice of this patient was a little hoarse, highpitched, but not falsetto. The left arytenoid cartilage and vocal cord remained immovable during respiration and phonation, the arytenoid cartilage being fixed in the phonatory position. The right arytenoid cartilage was placed directly behind the left, and even at some distance behind it. Both the arytenoid cartilages were somewhat tumefied, and the upper surface of the cricoid thickened. By attempts at phonation the right arytenoid cartilage moved from behind forward and towards the median line, which at even crossed; but even during phonation its anterior surface did not touch the posterior surface of its immovable left fellow. Semon's second conjecture, that the etiology might be found in a congenital malformation appears less probable to me on account of the mentioned ankylosis of the left arytenoid cartilage and the tumefaction of the arytenoids and cricoid.

The patient observed in the ear and throat clinic of the Kommune Hospital, Copenhagen, was a girl fourteen years old. Family history good. According to the mother's statement, the patient had been hoarse since her birth, and the hoarseness had only become a little more pronounced after a scarlatina in her childhood. The patient had never suffered from pain in the throat, accompanying speech or deglutition (excepting the onset of the scarlatina); neither had she suffered from dyspnea or coughing. In the fall of 1905 the patient was treated twice for rheumatic fever in the hospital. During her first stay in the hospital the patient suddenly became very hoarse and dyspneic; no sore throat or painful swallowing. At the request of the physician in charge, Prof. Flöystrup, a laryngoscopic examination was made and symptoms of an acute laryngitis detected besides the alterations described in the following lines after the notes taken during her last stay in the hospital. The right side of the larynx was quite normal, but the left wall of the vestibulum laryngis with the left arytenoid cartilage was turned over into the cavity in nearly a horizontal position and covered the posterior half of the rima glottidis and of the left ventricular band. The outlines of the left cartilaga corniculatus and cuneiformis were clearly visible. In trying to correct the deformity with a probe, a rather considerable resistance was felt, and the cartilages, when let go, at once recovered their former position. The left superior corner of the cricoid plate and its nearest surroundings seemed somewhat more protruding than on the right side. The left vocal cord remained totally immovable in slight abduction both during respiration and phonation; during the latter it appeared somewhat incurved and narrower than the right. The right vocal cord did not reach the left during phonation, but the apex of the left cartilage corniculatus penetrated a little into the right ventricular band, and the arytenoid and cuneiform cartilages on the right side were pressed towards the cavity, so that this part of the right wall of the vestibule of the larynx lay pressed firmly against the turned-over part of the left wall and partly covered it. The voice not properly to be called hoarse, but not pure; no dyspnea.*

This case of luxation in the left cricoarytenoid articulation is in all likelihood to be considered as a congenital malformation. That it is congenital must be inferred from the fact that the patient has been hoarse since her birth. And that it is not the result of an inflammatory process is probable because the luxated cartilages and parts of the mucous membrane have fully retained their normal appearance, just as also the right cricoarytenoid articulation is normal. Yet it would not be correct absolutely to deny the possibility of the dislocation having been caused by a very circumscript inflammatory process early in life (perhaps already in the fetal period). But the necessary supposition of so narrowly confined an inflammation—necessary because no other visible alteration of the tissues has been left save the luxation—makes this hypothesis improbable. Neither can arguments for the inflammatory hypothesis be taken from the fact that the left arytenoid cartilage made considerable resistance against attempts at reposition, as it is well known from other luxations that fibrous adhesions normally form between the luxated part and its new surroundings. For this reason and because the muscles (especially cricoarytenoid, post and lateral) have lost their power over the cartilage, the vocal cord necessarily remains immovable under phonation and respiration. One might perhaps feel tempted to consider the mentioned protrusion of the left superior corner of the cricoid plate as a result of a passed inflammatory process. More probable appears to me the assumption that the protrusion is seen because the outlines of the plate here become more distinct, the mucous membrane being tightened by the luxated arytenoid cartilage.

In order to make the analogy with luxations in other articulations still more complete, a habitual (sub-) luxation in the cricoarytenoid articulation has also been described. So Gradenigo[10] has observed in one of his patients how the right vocal cord sometimes, on phonation being attempted, suddenly remained immovable during the passage from respiratory to phonatory position. At the same time it became shorter, because the right arytenoid cartilage was moved by the m. vocalis and glided for-

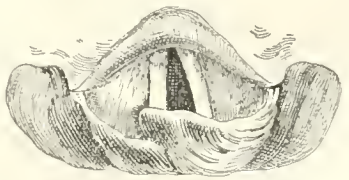

Fig. 2.—Laryngoscopic image during phonation.

ward on the articulating surface of the cricoid, making a rotatory movement round its vertical axis.

Finally I shall try to give a brief résumé of the picture characteristic of luxation of the arytenoid cartilage, as it can be formed from the above observations.

*For the opportunity of publishing this case I am indebted to the director of the clinic, Prof. Holger Mygind.

The Etiology is most often an inflammatory or ulcerative process in or in the vicinity of the cricoarytenoid articulation, rarely a trauma; less frequently still do congenital luxations seem to be observed.

Symptoms.—At times dyspnea, especially during intercurrent acute inflammations of the upper air passages. The dyspnea may increase to suffocation, particularly when both arytenoid cartilages are luxated, and necessitate tracheotomy. The voice may be hoarse, a falsetto, and so forth, but is generally well preserved. Pain accompanying deglutition is observed only during an acute stage of the causal inflammatory process. Laryngoscopic examination reveals the only pathognomonic symptom, the dislocation of the arytenoid cartilage with the contiguous aryepiglottic fold. The vocal cord on the same side during respiration remains immovable in the middle line, in cadaveric position or in a position between these two; during phonation in some cases it may approach to the middle line.

The diagnosis, made from the laryngoscopic image, cannot be confounded with other laryngeal disorders, if the cartilage and the mucous membrane have retained their normal appearance; otherwise confusions with new growths are possible. As shown by Sidlo's case, existing luxations (on both sides) cannot always be diagnosticated.

Therapy.—For those cases in which the cartilage can be moved, a reposition may be attempted with a probe or other suitable instrument, but the alterations of the articulating surfaces and their surroundings will, as a rule, make it impossible to get a good result from the manipulations. Stoerk has devised and tried an operation which consists in removal of some of the mucous membrane in such places where he could expect the resulting cicatrices to draw the luxated cartilage back to its old place. But only when the cartilage is easily moved or (Semon) the adhesions are easily destroyed may a satisfactory result be hoped for; Stoerk had none.

If dyspnea is present, dilatation of the rima glottidis ought to be tried, eventually tracheotomy.

A Fluid in which instruments may without detriment be allowed to lie during office hours is suggested by Wille. It consists of water with 1.5 per cent. of borax, 3 per cent. of carbolic acid, and 2 per cent. of formalin. After use the instruments are cleaned with soap and water, rinsed off, and returned to the fluid, the author's experience during four years having shown that the antisepsis secured by this means is sufficient to insure safety.—*Centralblatt für Gynäkologie.*

SOME CLINICAL REMARKS ON TRAUMATISM AS AN ETIOLOGICAL FACTOR IN APPENDICITIS.

By W. J. MACDONALD, M.D.,

ST. CATHARINES, ONTARIO.

Much has been written at various times concerning the probability of an external injury having any direct effect in the causation of appendicitis. In a somewhat comprehensive review of the literature one is struck by the tenacity with which all the early writers promulgate the theory of appendicitis being secondary only to infection somewhere else; and the great consensus of opinion was that in the cecum was to be found the original focus of disease. The memorable paper of Dr. Reginald Fitz of Boston, published in the *American Journal of the Medical Sciences* for October, 1880, marks the point to which the pendulum had swung in that direction, and, as a pendulum ever swings to extremes, may it not be that it has already swung far in the opposite direction?

Just as tenaciously as did the papers of Dupuytren, of Goldbeck, and of Albers ascribe the primary lesion to the cecum, do the textbooks of today hold to the contrary, some even saying that traumatism is scarcely to be considered as a cause of appendicitis.

With the pathology of this lesion as taught today, we are all familiar. The low vitality of a vestigial organ renders it capable of presenting but feeble resistance to bacterial infection, while circulatory disturbances readily produced by imprisoned fecal matter, or by the accidental twisting or kinking of the organ, greatly accelerate the probability of a speedy absorption of the products of the intestinal microorganisms. With this we are thoroughly in accord; but is it not possible, yea, even probable, that in some given cases the inflammatory condition in the appendix resulting in perforation may be propagated thereto by continuity of tissue? Whether it is of frequent occurrence, or the rare exception, remains to be learned from the deductions of the statistician. The question of how a blow, or a fall, or a strain can have any direct effect on this rudimentary organ, lying somewhat freely in the abdominal cavity, and well protected by superficial soft parts, must be somewhat problematical.

These patients give a somewhat different clinical history from those attacked in the usual orthodox fashion, and usually date their illness from some definite injury, external or internal. In this class of cases the death rate is particularly high, the inflammatory condition never being confined to the appendix at the commencement, but having spread there from some contiguous organ, where, with the help of the colon bacillus, or some other kindred infection, the condition becomes acute, a perforation occurs, and the patient quickly succumbs to general septic peritonitis. In this class of cases, too, even more than in some others, is the wisdom of early surgical intervention demonstrated. In a series of clinical histories given below I have endeavored to show how the subsequent appendicitis was directly due to a previous bodily injury, and it may be that this most frequent of all intraabdominal lesions is more frequently the direct result of a so-called accident than we are aware.

Case I.—Appendectomy; operation nine days after injury; tip of gangrenous appendix adherent

to right ovary; gangrene had spread to cecal wall; resection of gangrenous bowel by V-shaped incision; recovery. On Sunday evening, May 1, 1904, I was called to see Mrs. W. L., aged 24, who was complaining of nausea and "cramps in the stomach." Her face bore an anxious expression, and she presented the appearance of one extremely ill. On questioning her closely I obtained the following history: When a child of thirteen or fourteen she had fallen heavily, and suffered a severe blow on the lower part of the abdomen, following which she commenced to suffer from vague right-sided abdominal pain. Failing to obtain relief, her mother took her to Toronto, where she consulted two eminent surgeons, who pronounced the trouble chronic ovaritis. For a couple of years she continued to suffer more or less, but a trip South for the winter appeared to dispel the trouble, and she was again quite well. About one week previously to my having seen her, while sweeping the house, she had "overreached" herself, and severely strained the right side, when the symptoms of her old trouble at once reappeared. For a time she seemed quite crippled with it, but it gradually wore down to a dull ache, which constantly remained. On the Sunday morning in question while in church she was suddenly seized with abdominal pain, which she attributed to a tight belt which she was wearing. After luncheon she went for a short walk with her husband, but on account of the presence of constant pain, and much distress in the stomach, they returned home early, when, for the first time, she vomited freely. The pain now became general over the whole abdomen and quite severe. During the evening vomiting continued at intervals, the pain diminished, and by midnight when I saw her had apparently almost subsided. Her temperature was now normal and pulse eighty-six, though the peculiarly drawn and anxious expression referred to above impressed me at the time. On palpation the abdomen was slightly tender throughout, though nowhere could any hypersensitiveness be elicited, and the slightest rigidity was indiscernible.

Throughout Monday her condition remained unchanged, with the exception of a gradually rising pulse and temperature, and on Tuesday morning, when the pulse had risen to 102 and temperature to 101, I determined to open the abdomen. There was then no rigidity, and but very slight tenderness. A peculiar feature of the case was the intense desire of the patient to be operated on, and she kept telling us to hurry or it would be too late.

On opening the peritoneum the intestines presented a normal appearance, but the appendix was found totally gangrenous and adherent by its tip to the right ovary. The gangrene had spread to the cecal wall, of which a patch two inches in diameter presented a dark, glistening green color. A short transverse incision one and one-half inches in length was made downward and at right angles from the center of the original wound, to facilitate the resection of the gangrenous mass and separation of the ovarian adhesion. The mass was removed by a V-shaped incision in the bowel. There was no perforation. An uninterrupted recovery followed.

Was this case of appendicitis attributable in any way to either or both of the previous injuries? Did her first injury produce the ovaritis from which she was suffering, thus causing the tip of the appendix to become adherent thereto? Did the second injury revive the former trouble, and the inflammation quickly spread to the adherent appendix?

Case II.—Ileocecal intussusception carrying appendix with it; appendix acutely inflamed and perforated at base; fecal matter free in abdominal cavity; general septic peritonitis; reduction of intussusception; appendectomy; death. During the night of Thursday, June 16, 1904, I was called to see Mrs. M. B., aged 43, suffering from abdominal pain and complete constipation. Until the preceding Tuesday she had enjoyed the best of health, on which day she had driven to a neighboring town, and, when alighting from the vehicle, in order to protect her skirts from mud on the wheels, she had jumped to the ground, alighting rather heavily. On the way home she complained of some wandering pains in the abdomen, but, with the exception of vomiting two or three times, slept fairly well throughout the night. During Wednesday and Wednesday night the pain increased in severity, and several large doses of Epsom salts failed to procure a motion. On Thursday the pain began to subside, and when I saw her in the night she felt quite comfortable, I only being called to relieve the constipation.

I found her with a temperature of 101°, pulse, 144, and abdomen greatly distended and tympanitic. There was slight tenderness throughout, though nowhere was there any acute tenderness. Constipation was complete, neither feces nor flatus having been expelled since shortly after she jumped from the buggy on Tuesday. Abdominal palpation revealed nothing, but on rectal examination an indistinct hardened mass was discerned in the right lower abdomen. No traces of blood or bloody mucus had passed. The *facies hippocratica* was marked. Nothing was given by mouth, and high rectal enemas were negative of result. With a tentative diagnosis of intussusception immediate laparotomy was advised and performed.

On opening the abdomen to the right of the median line, and immediately over the situation of the mass indistinctly distinguished per rectum, the peritoneal cavity was found filled with acutely inflamed and greatly distended small intestine. Free fecal matter was present. The mass above referred to proved to be an ileocecal insussusception, which had progressed several inches, dragging the appendix with it, the tip of the latter organ, acutely inflamed, presenting from under cover of the insussusceptions. On accomplishing the reduction of the intussusception, a gangrenous perforation, the size of an ordinary slatepencil, was found near the base of the appendix, through which fecal matter was oozing. The appendix was removed, the abdomen cleansed as thoroughly as possible, and abundant drainage instituted. From the shock of operation the patient rallied well, the bowels moved on the second day, but on the third she rapidly sank and died.

Had the initial injury on Tuesday anything whatever to do with the final fatal peritonitis? This peritonitis was due to the escape of fecal matter through the appendiceal perforation, which in turn was the result of an acute inflammation in the appendix caused by compression between the intussuscipiens and the intussusceptum which interfered with the circulation, and established gangrene in the organ. Did the injury on Tuesday start the intussusception?

Case III.—Appendectomy; acute symptoms

supervened on injury to right testicle; operation four days after injury; appendix, of which the mucosal and submucosal coats were gangrenous, was removed; recovery. At 7 o'clock on Monday morning, October 10, 1904, I was called to see J. L., a young man of twenty, who had previously enjoyed the best of health. On the Friday before, while working on a ladder, he had slipped, and, alighting rather heavily on the perineum, had painfully bruised the right testicle. On Saturday he could not go to work, and on Sunday the testicle became increasingly tender and commenced to swell. About 4 o'clock on Monday morning he was awakened by intense testicular pain, so severe that he could not go to another part of the house to awaken his parents, and as calling out increased the pain to such an extent as to become almost unbearable, he was forced to lie as he was until morning. When I saw him the right testicle was as large as the closed fist and acutely tender; the tenderness had spread up the cord and manifested itself somewhat in the region of the bladder, though in the appendical region deep pressure could be made without producing any discomfort. He was vomiting at intervals, and his whole trouble appeared to be centered in an acute orchitis. Catheterization gave some relief, and, in order to procure as much ease as possible, was done every four hours. When I saw him later in the day he was much the same as in the morning, though the symptoms were somewhat accentuated. There was no abdominal pain, but deep palpation over the appendix at this time elicited exquisite tenderness. Temperature, 101°, pulse, 108. During the evening the testicular pain increased, and the organ became much more swollen. Abdominal tenderness on palpation became marked, though at no time was there any complaint of abdominal pain, this symptom being entirely referrable to the testicle. Late in the evening the temperature was 103 and pulse 120. Operation was advised, but declined. From this time until the next afternoon, when operation was performed, there were frequent attacks of vomiting, accompanied by exacerbations of pain in the testicle. Catheterization had to be more frequently performed, he expressing the opinion that it was the only thing which gave him any relief at all.

A right lateral incision, somewhat lower than the usual one for operations on the appendix, revealed an appendix, greatly darkened, and adherent by its tip to the right side of the fundus of the bladder. This adhesion was divided between two ligatures, and the appendix, of which the mucosal and submucosal coats were gangrenous, was removed. The abdomen was closed with layer sutures of catgut. The catheter had to be passed but once after operation. In twelve hours the testicular pain had disappeared, and in forty-eight the organ had almost regained its normal size. An uninterrupted and speedy recovery followed.

Although no history of any previous abdominal trouble was forthcoming, still such must, at some time, have been present to produce the adhesion above referred to. Did the aforementioned injury on the ladder cause this adhesion to stretch, and, by so doing, limit the circulation in the appendix, and thus cause it to become a prey to acute infection? Did the accumulation of urine in the bladder cause tension on the inflamed organ, and was this the reason that catheterization gave such relief?

DEATHS OF ATHLETES AND FATALITIES IN ATHLETIC GAMES DURING THE YEAR.*

By ROBERT E. COUGHLIN, M.D.,

BROOKLYN, N. Y.

Late in the year 1904 the writer determined to collect the statistics relating to the deaths of athletes and the fatalities in athletic games during the year 1905, hoping in doing so to decide if possible the susceptibility of athletes to certain diseased conditions, and the most dangerous or fatal games indulged in.

The whole number of deaths collected amounted to one hundred and twenty-eight, of which fifty were due to diseases and seventy-eight to accidents of different kinds. Cerebrospinal meningitis was stated to be the cause of death in nine cases; cardiac disease in eight; pneumonia in seven; pulmonary tuberculosis in seven; Bright's disease in five; appendicitis in four; typhoid fever in four; suicide in two; apoplexy in one; suppurative tonsillitis in one; splenic anemia in one; senility in one.

In the accidental deaths football was the game mentioned in twenty-eight cases; baseball in twelve; horse racing in nine; boxing in six; gymnasium feats in three; auto driving in two; the other fatalities being equally divided between golf playing, hammer throwing, bicycle coasting, handball, polo playing and wrestling. Of the fifty deaths due to disease the ages at death were stated in twenty-nine instances, the average age being thirty-one years, the oldest age eighty-seven years, and the youngest eighteen years. In the accidental deaths the ages were stated in thirty-nine cases, the average age at death being twenty years; the oldest age sixty years, and the youngest twelve. The average age at death of the whole number was twenty-six years and one month.

The causes of death in football were stated as follows: Abdominal injuries, seven; dislocation of spine with paralysis, three; concussion of brain, five; fracture of skull, five; cerebral hemorrhage, two; fracture of rib (the same being driven into the heart), two; fracture of spine, one; acute peritonitis, one; convulsions, one; infected wound of knee-joint, one. The causes of death in baseball were stated as follows: Shock (from blow over cardiac area), five; head injuries, four; cardiac failure while running to base, one; blow in abdomen, one; heat exhaustion, one. Fractures of the skull were the causes of death in the nine jockeys. In the swimming accidents exhaustion by being caught in a current was the cause of death in three cases. Cramp caused one death. The causes of death in the remaining two cases could not be determined. In the boxing accidents blood clot in brain was the autopsy report in two cases. Shock from blow over heart was the cause of death in one case. In the other three the cause of death was not determined. In the three gymnasium accidents fracture of the cervical vertebræ was the cause of death in all three cases, one of the victims being a young girl of sixteen years. One individual died from cardiac paralysis while playing handball, another sustained a fracture of the skull while bicycle coasting, another died from a fracture of the skull which was caused by the blow of a golf stick, while another died from a fractured skull, the result of a false hammer throw.

There were other accidental deaths of athletes having nothing to do with athletics, such as rail-

*Read before the Norwegian Hospital Alumni Association, March, 1906.

road accidents, street fights, etc. One peculiar instance may be related in which a young and very promising athlete came to his death while splitting wood, a piece of the splintered wood being driven into his abdomen with a promptly fatal result.

Cerebrospinal meningitis being the cause of death in nine victims first attracts our attention, but we can very readily pass over this disease as the number of cases mentioned was undoubtedly due to a continuance and more extended prevalence of the disease from the excess of 1904, which, as we know, was an epidemic year for this disease. It would appear to prove, however, the assertion previously made by the writer[1] of this article, that athletes succumb from infectious diseases as readily as others, and that in some instances they appear to be peculiarly susceptible to infectious diseases.

The next disease or condition to be considered in this connection is known as cardiac disease, which, of course, means any of the cardiac diseases which can be differentiated by the careful diagnostician. Eliminating cerebrospinal meningitis for the reasons stated, we have as a great cause of death in athletes cardiac disease. It may be noted that many of the accidental deaths already related had as their chief characteristic a sudden failure of the heart. Pneumonia ranks high as a cause of death in athletes for the same reason, viz., a damaged heart. Although the best authorities agree that athletics have a tendency to impair the heart, only lately we have the opinion from Dr. Anderson of Yale that he has statistics[2] which appear to prove the contrary. Since the year 1855 there have been fifty-one deaths of Yale athletes out of a total of 761, with heart disease as the cause of death in two. To quote the *Medical Director*: "It is a widespread opinion that athletes are liable to heart trouble, but only two Yale men of this sturdy little army have died from this cause."

President Eliot[3] of Harvard says: "I would say that there are no more fatalities from heart disease among athletes than would be natural in the same number of men anywhere."

The other side of the subject may be reviewed by noting the opinions of different writers who have made athletics more or less a study. Professor James[4] of the Illinois State University declares on the subject that nearly all football players, baseball men, and lawn tennis experts have weak hearts and are more liable to diseases of other forms than men who exercise moderately. Regarding the crack tennis player, he says: "There is scarcely one of the top-notchers but has suffered from heart disease, many of them in severe form. Many have died of heart disease between the ages of forty and forty-five years, when they should have been at their best physically."

Dr. William W. Hitchcock,[5] in an article entitled "The Importance of the Early Recognition of Arterial Changes and of Chronic Vascular Hypertension in Relation to Life Insurance," says: "Athletes with arterial hypertrophy suffer frequently from high tension, with its entailed dangers."

H. B. Anderson[6] in the *British Medical Journal* declares that we need only recall how often it happens that the cardiac muscle is insufficient to withstand the requirements of ordinary quiet life, to understand how powerful a cause of mischief severe exertion may be.

As to the effect of repeated or habitual exertion within wise limits, it is known that athletic and other exercises, when properly regulated, are beneficial to the heart by producing physiological hypertrophy of the organ and lowering the average of peripheral resistance. Clinically speaking, the military surgeons first directed attention to, and carefully investigated the effects of overexertion on the heart. It was found that many cases of cardiac trouble existed in the otherwise healthy soldiers. Aside from certain modifying conditions in soldiers' surroundings, which appear to increase the liability to injury from overstrain, the tendency of overexertion in civil and military life is to produce cardiovascular lesions. Exercises in which the legs are employed are especially likely to be associated with cardiac trouble. These cases of overstrain may be classified as acute and chronic. The former is generally noted in the young, weakly, or untrained, as the result of severe or prolonged exertion. The "irritable" heart is more often the result of repeated or prolonged exertion, or of overexertion developing gradually. Mechanical stress not only injures the myocardium, but it is also a cause of aortic valvular lesions. It may even damage sound valves. In the obese there is a condition of chronic overstrain, for there is a relative disproportion between the size of the heart and the work it has to perform. The size of the heart is proportionate to the size of the skeletal muscles under ordinary circumstances, and the work of the heart is proportionate to the bulk of the body.

Maurice Champeaux[7] declares that it is a fact well established by physiology that the amount of food ingested ought to be in relation to the work done by the body. When the work increases, food ought to be increased in proportion. Training brings about an overworked condition, and the organism becomes a prey to intoxication. Discord then exists between the necessities and conditions of life. On the other hand, the term adaptation represents the physiological state exactly opposed to that of training. The bodily functions are at a maximum. There is an absolute accord between the necessities and conditions of life. In the army the aim should be toward adaptation and not toward training. It is necessary to work with moderation and with reason. An overworked condition should be avoided, and each organism should be adapted to the exigencies of its particular physiological condition.

Pneumonia and pulmonary tuberculosis rank third as causes of death here detailed. In New York State for the year 1905[8] pneumonia was the chief cause of death (10.4 per cent.), with tuberculosis second and giving 10 per cent. Anderson's schedule of Yale athletes before referred to ranks tuberculosis as the chief cause of death, with pneumonia second on the list. J. W. Fisher of one of our large life insurance companies presents the following causes of death among the insured: Tuberculosis, 13 per cent.; pneumonia, 9 per cent.; casualties, 7 per cent.; kidney disease, 6 per cent.; cardiac disease, 6 per cent.; typhoid fever, 6 per cent.; cancer, 5 per cent.; suicide, 2 per cent.

A comparison of the foregoing statistics would make it appear that athletes die most frequently from cardiac diseases, pneumonia, and tuberculosis.

The one death mentioned at the age of eighty-seven was due to old age. This old athlete was a boxing instructor who was known always to have led the strenuous life in all things as well as athletics, vices included. Of the accidental deaths, the first game to be considered is football. In the statistics herein collected we find that twenty-eight deaths, or 33 1-3 per cent., were due to this popular game. Of these twenty-eight football players, seventeen were high school players, all immature boys of eighteen years or under. Three were physically fit college men. The others were amateurs. The majority of these fatalities occurred during what is

called mass play. A few of the victims had been warned by their medical attendants to refrain from indulging in the game, owing to weak hearts, weak constitutions, etc. Fatalities and serious accidents have become so numerous in football that many opinions in a direction to annihilate the game have been expressed by different men and writers of note. Some of them are as follows: W. C. Redfield[9] believes that football has become more dangerous than war, a percentage of deaths and injuries for 1905 being greater than the number killed in the Japanese navy during the Russian-Japanese war. Dr. S. Weir Mitchell[10] considers football barbarous in the extreme. President Eliot of Harvard declares the evils of football as follows: It causes an unreasonable number of serious injuries and deaths: not one in five of the men that play football several seasons escapes without injury properly called serious, and of the twenty to thirty picked players who play hard throughout a season hardly a man escapes serious injury. The public has been kept in ignorance concerning the number and gravity of these injuries, the prevailing practice being to make light of or conceal the injuries sustained. Many of the serious injuries are of such a nature—sprains, strains, wrenches, dislocations, ruptures of ligaments and muscles, and shocks to the brain—that in all probability they can never be perfectly repaired. In any hard-fought game many of the actions of the players are invisible to the spectators, and even to the referee and umpire: hence much profitable foul play escapes notice. The game offers many opportunities for several players to combine in violently attacking one player. Regarded as a combat between highly-trained men, the prize ring has great advantages over football, for the rules of the prize ring are more humane than those of football, and they can be and are often enforced. The fight in a prize ring between two men facing each other is perfectly visible, so that there are no secret abominations as in football. Yet prize fighting is illegal.

In an article, "The Physical Aspect of American Football,"[11] Nicols and Smith give their experience as physicians to the football squad of Harvard University during the last football season, extending from September 14 to November 25, 1905. Each player was required to report every injury, no matter how trivial it seemed to him, to the surgeon in charge. The list of the injuries received was 145. The authors came to the following conclusions: (1) The number, severity, and permanence of the injuries which are received in playing football are very much greater than generally is credited or believed. (2) The greater number of the injuries come in the "pile" and not in the open plays, although serious injuries are received in the open. (3) The number of injuries is adherent in the game itself, and is not due especially to close competition, as is shown by the fact that the proportion of injuries received in games and in practice is about the same. (4) A large proportion of the injuries is unavoidable. (5) The proportion of injuries is incomparably greater in football than in any other of the major sports. (6) The game does not develop the best type of men physically, because too great prominence is given to weight without corresponding nervous energy. (7) Constant medical supervision of the game where large numbers of men are engaged is a necessity and not a luxury, although it is a question if a game requiring the constant attendance of two trained surgeons is played under desirable conditions. (8) The percentage of injury is much too great for any mere sport.

One college has taken such a decided stand against the game of football that two large donations have been made by sympathizers, the donations amounting in the aggregate to $250,000. The financial aspect of the matter undoubtedly has a great deal to do with the continuance of football among college athletics, for the reason that it pays better than all the other college athletics combined. That the game is brutal and as a rule rather uninteresting to the spectators, except where the loyalty to one side or the other is concerned, there can be no doubt or question.

Twelve deaths from baseball is not a large number when one considers that the game is played seven months in the year, as compared with the short football season, lasting about one month and a half, and that almost all the deaths were purely accidental and not because of some trick or maneuver in the game. Fatal blows over the cardiac area, as well as misdirected abdominal blows are simply accidents more or less unavoidable, where so many indulge in a game. The sport, in other words, cannot be called brutal because of these accidents any more than it could be blamed for one player dropping dead while running to first base, or for the death of another from sunstroke or heat exhaustion.

In the swimming accidents one thing might be pointed out, which is that the heart should be in very good condition before one ventures into the water, for the reason that there is so much resistance to overcome that the circulatory organs are staggered perceptibly unless in very good condition. A person with any kind of a diseased cardiac condition should take a milder form of exercise.

In the six deaths caused by boxing it is interesting to note the small proportion of fatalities due to this sport, and that all the accidents were in young men who did not excel in the art. As a rule they were amateurs with very little ring experience. In this connection it may not be amiss to state that no serious injury or death has occurred in the prize ring among top-notchers in fifteen years' time, the last death being that of one Bowen, who fell, striking his head against a brick wall which was a part of a poorly constructed ring. A first-class boxer always trains faithfully for a bout, and he is as a rule in the best possible condition at such times to receive punishment. He is by nature a rugged specimen of humanity with a naturally strong constitution, else he would never take to or choose such a rough game. These are probably a few of the reasons so few accidents occur in the ring, as well as the privilege a contestant has at any time to discontinue in a contest when he sees that it will injure him to continue further. The average well-contested boxing bout is not considered brutal, yet glove contests are allowed in only three states in the Union. There has never been a law enacted against football in America. Of two evils, the law discriminates against the lesser in this instance.

As a matter of history, football was prohibited in Scotland by James II and James IV, and in England Edward II held out pains and penalties for "hustling over large balls." It was also declared illegal in the time of Henry VIII, and strenuous efforts were made by Elizabethan statesmen to suppress the game, but without success.

Conclusions.—First: That athletes are prone to cardiac lesions, whether a simple physiological hypertrophy, a hypertrophy with dilatation, an endocarditis, a white spot on the heart, or myocarditis, as pointed out by Richardson[13] of London, or the different valvular conditions.

Second: That pneumonia ranks high as a cause

of death in athletes because of the cardiac embarrassment in connection with this disease.

Third: That athletes appear to be susceptible to infectious diseases, and when affected with these diseases succumb to them as readily as others.

Fourth: That pulmonary tuberculosis is a cause of death in a large percentage of athletes.

Fifth: That the average age at death of athletes is far below that of the average person in the ordinary walks of life.

Sixth: That the game of football as played in America during the season of 1905 was the cause of an appalling number of serious injuries and fatalities, and that it is very evident that something will have to be done to eliminate the dangerous features in the game, especially mass play.

Seventh: The idea in all kinds of athletics should be to improve and make men, not to maim, cripple, and bury them.

TREATMENT OF TYPHOID FEVER.

By J. R. LANDERS, M.D.,

BERNADOTTE, ILL.

William Ewart, in the *British Medical Journal* of recent date, states that he believes that the aim in the treatment of typhoid fever most requisite is to feed the patient and starve the disease, remarking also that as it is hopeless to disinfect the feces, the only course left is to suppress them. Agents employed in local treatment are paraffin and charcoal, neither of which, he says, is capable of arresting the growth of Eberth's bacillus in the bowels, but he asserts that they both are nevertheless used in the cases with benefit. The maximum adult dose he has used is two teaspoonfuls of liquid paraffin every four hours. This he considers a non-irritating mechanical laxative, emphasizing that frequency of dose is indicated, both for the sake of lubrication and cleansing. The use of charcoal is advocated with the statement that although not a germicide, nevertheless it absorbs the toxins. He further makes use of castor oil every morning if the bowels fail to act at least once a day, and considers it an important part of his treatment, for the reason that under empty bowel conditions, paraffin and charcoal are brought into direct contact with the diseased surface. He specifies that mineral salts, organic acids, etc., should be derived from a vegetable diet—their natural source—though he allows phosphates, given in syrup, as a medical food. Watery extracts of vegetables and fruits, freed by boiling from excess of coagulable albumen, are given.

From the statement I have quoted Ewart would have us infer that the food should be of such a character as to leave no organic residue, no chemical precipitate. The aim to feed the patient and starve the disease may be all right, but it may be that we find the charge misses the bull's-eye or is impracticable; however, we will not question it further. But that "it is hopeless to disinfect the feces," I fear is a point not well taken, conspicuously so when in the very next paragraph he says the only course left is to suppress them, also that if the bowels do not act at least once a day, castor oil is to be given.

I am not ready to contend that we can absolutely and certainly disinfect the feces, but I do contend that we can do so relatively or up to a normal condition, *i. e.* that we can render the alimentary tract normally clean and the fecal contents as aseptic as they are in health, which answers all practical purposes. Anyway, I am ready to state and believe it can be demonstrated that surely it is as feasible and as practical to disinfect the feces as it is to suppress them, and when we have used intestinal antiseptics with the result of less odorous, less offensive, stools, we have more nearly accomplished our purpose of disinfecting than Ewart has attained the object of suppressing, especially since he orders castor oil to move the bowels daily, obviously and evidently not expecting or looking for suppression. When giving intestinal antiseptics, we hope and expect to disinfect the feces, and when we have put a stop to intestinal putrefaction and the stools become inodorous, we have realized our expectation. As to absolute positive asepsis, I fear it is seldom attained even of the surgeon's hands and field of operation, but practical asepsis can be obtained and is of none the less utility because not absolute. I do not see why Dr. Ewart emphasizes the necessity for the frequent doses of paraffin "for the sake of lubrication and cleansing," because he intimates that a clean tract is impossible. And if we do not try to disinfect the feces because it cannot be done absolutely, why try to cleanse the tract when it cannot be done positively and absolutely. Notwithstanding, if paraffin is cleansing, we will not question its use further. Charcoal is used not as a germicide, but because it absorbs the toxins. Then there is no use doing this unless the charcoal absorbs *all* toxins.

I am treating this matter thus for the reason that I have noticed that not a few have denounced and decried the use of intestinal antiseptics because we can not render the intestinal tract positively aseptic. To say the least, this is small ground to stand on, too circumscribed for argument. If forty men are drowning, don't save one because you can't save the other thirty-nine, or, more aptly, don't save the thirty-nine because the fortieth is hopelessly beyond reach. Such is to my mind substantially the argument against the use of intestinal antiseptics. However, I may add *en passant* that many have found out contrary to their belief or expectation that intestinal antiseptics is no "*ignis fatuus*," but has come to stay because it has been proven and is being proven every day that it is a power immeasurable, most frequently applicable, and without a peer in the whole field of therapeutic endeavor.

That the intestinal canal is the place where the typhoid bacillus takes up its abode, there with the *bacillus coli commune* finds a congenial habitat from whence it is revived, refreshed and sends out reinforcement, certainly none have disapproved. That saprophytic bacteria and their toxins are potent auxiliaries and contribute no little to the virulence of the bacillus of Eberth, and are possibly necessary to insure infection, I have not seen disputed, and I verily believe. It is not difficult of belief that the bacillus of typhoid fever could pass through the alimentary tract in colonies upon colonies without harm, detriment, or damage to its host if it failed to meet its congeners, the *Bacillus coli commune* and other saprophytes and their toxins. In other words, if the *prima via* is in a normal condition or the con-

tents in a normally aseptic state, infection could not, would not occur. So then if we render the breeding ground disagreeable, uncongenial, and unsuitable for bacillic generation and multiplication, we destroy the ability of the bacilli to send reinforcements by limiting and curtailing recruiting power, to the end that the phagocytes do not find the enemy invading the blood in increasing numbers to overwhelm them, but decreasing from want of reinforcements. Then if simultaneously with intestinal antiseptics we increase the phagocytes, we have the case in hand so those dangerous conditions which show up in later stages of typhoid fever, such as hemorrhage, perforation, phlebitis, etc., do not occur and consequently require no mention of treatment.

The sulphocarbolates of lime, sodium and zinc have been my preference as intestinal antiseptics, as they are with thousands of other physicians. I have tried many intestinal antiseptics, but nothing has seemed so satisfactory as the chemically pure sulphocarbolates of lime, sodium and zinc, but they MUST be pure, and it is *not every specimen* found in the drugstore that comes up to the standard. If diarrhea exists, the zinc salt is indicated. If there is the opposite condition or the astringency of the zinc salt is not wanted, or is not well borne by the stomach, the sodium salt is satisfactory. If there is rapid destruction of tissue, the sulphocarbolate of lime meets the requirements. If you do not believe in the antiseptic action of these salts, if you will exhibit them singly or combined in any case when you have intestinal sepsis with malodorous mephitic stools, give daily from one to four scruples of these salts—one scruple and one-half to two is usually sufficient—and note the change in the character and odor of the stools. The result will surely be convincing. The stools will not be surgically aseptic, and no one would care to use them as an ointment, but they will be practically, normally aseptic, and as aseptic as socalled healthy stools should be. But if further test is needed or desired, the bismuth test of Bouchard may be employed. If you give the sulphocarbolates in typhoid and give to effect till the stools become inodorous, the temperature will be found nearing the normal and all symptoms will be ameliorated. Jactitation, headache, restlessness, delirium, all disappear, or are markedly improved. It is not expected that this can be done unless the sulphocarbolates are effectively and promptly put to work at the beginning and pushed persistently till inodorous stools are in evidence. It is *not* claimed that the sulphocarbolates will do miracles and bring about recovery after fatal conditions have supervened, though the prompt, decided and continuous improvement that frequently follows their use as compared with their non-use is truly extraordinary and remarkable. So then, I would say, be sure of the purity of these salts and give boldly till the effect desired is produced, for we may rest assured they will do the work.

This done, we have inhibited the growth and prevented multiplication of all saprophytes as well as the bacillus of Eberth and, at the same time, lessened and prevented not only absorption of these poisons from the alimentary tract, but any and all poisons that are hurtful or injurious; which leaves the system to fight and dispose of the bacilli and toxins *only* that have already got into the blood when the phagocytic action of the leucocytes is required to assail and destroy these invaders. Then comes the question as to whether or not the leucocytes have the strength to do this, and if they have not, how can we increase the phagocytic power in the system? It has been demonstrated that by exhibiting nuclein we can increase the white blood cell at will. Whether this is done by causing a rapid maturation and division of the leucocytes wholly or otherwise, is not the province of this paper to discuss. Suffice it to say that by the administration of nuclein we can reinforce or augment leucocytosis to almost any necessary degree to the complete overthrow of invading bacteria. This done, there scarcely remain conditions calling for other treatment except possibly insomnia or delirium, which, in high tension, calls for veratrine or aconitine or gelsemine, monobromate of camphor for low muttering, and hyoscyamine in hallucinations and insomnia. Meet the cause of insomnia with the indicated remedy. If the bacilli and toxins have not been allowed full sway and to become thoroughly intrenched in the system, the call for hypnotics, etc., will not be material.

As to the diet, I have not intended to say much. The patient should have a diet that he can handle and appropriate. The socalled antipyretics have no place in this disease, unless, perchance, in very sthenic cases. They depress the heart and will frequently deceive or delude unless the temperature in the rectum be relied upon. The sponge or full bath is preferable and should be used, looking to the preservation of blood integrity and central nerve cell security. If to what has been said we add mild salines as required to keep the bowel cleared out, and do not after the beginning attempt to stimulate the liver until high fever has passed, it will be noticed the disease has run a mild course without adverse resultant conditions, the sequel of hyperpyrexia and of allowing the poisons a free hand, or overwhelming the patient with antipyretics, marked by ataxia, etc. Alarming hemorrhages do not occur. Perforation has not taken place in my knowledge, neither have I seen phlebitis result.

I have used the method as briefly outlined for years and have no reason to regret it, no death has occurred in my practice. I have treated cases alongside of other physicians in the same family, my longest illness was three weeks, others' longest illness ten weeks. I have not intended to enter into the minutiæ of treatment or prophylaxis. I simply give a general outline, and let each one mature his own treatment for the individual case. I mean to state positively that the method will absolutely prove efficient; I do not mean mayhap or perchance it will, but I make the positive assertion—*it will.* Very many other remedies aside from what I have mentioned may be called for and should be used to meet the conditions that may arise.

To clean and keep clean—normally aseptic—the *primæ viæ;* to disinfect the feces until inodorous; to reinforce the leucocytes to increase and intensify phagocytic effort; to prevent unwarranted destruction of tissue from high temperature, is the dominant idea in treating typhoid fever. The treatment as outlined is the dominant one, which, when abbreviated, amplified, or varied to suit the individual case, if intelligently directed and faithfully carried out, I do confidently believe will so modify the course and lessen the mortality that it can no longer be said that the tendency of typhoid fever is to death and that the disease runs its course, at all hazards, regardless, and in spite of, all treatment. But it will supplant the hopelessness of nihilism and lift the Cimmerian clouds of pessimistic despair and give the cheering, hope-inspiring sunshine of optimism portending the more auspicious, gratifying, confident therapeutics which we ardently and fervently hope may ultimately prevail.

SUMMER DIARRHEA IN INFANCY.*

By GEORGE THOMAS MYERS, M.D.,

NORFOLK, VIRGINIA.

THE conditions included under the head of summer diarrhea in infancy are the most perplexing the practitioner is called upon to treat. None require closer study and observation of individual cases, considering the early age of the patient, the undeveloped organs of digestion, energetic and proper treatment from the beginning. I shall speak of the various forms as they exist primarily, collectively with ileocolitis, and cholera infantum, considering the latter as more virulent infections due to the same cause. In a large majority of instances, from a clinical and pathological standpoint, it is extremely difficult and in some cases almost impossible to differentiate one form from the other. This assertion has been proven at the bedside and by autopsy. Our only correct means of ever classifying summer diarrhea will be from bacteriological examinations of the stools. The various workers along this line have enlightened us little at present concerning the exact microorganisms found at different stages of the condition, and parts of the digestive canal most affected. Bassett, Duval, Booker, Baginsky, Flexner, and Cohen have been energetic workers in this direction. In a broad sense, summer diarrhea is spoken of as too frequent and loose bowel movements, arising from an increased motor and secretory activity of the intestinal canal. Scientifically, it is an existing symptom of many pathological conditions in the alimentary tract. If we will believe, as Kerley well puts it: "It is a disease due to virulent microorganisms, and the child is poisoned when ill from this disorder," much will be accomplished.

These organisms at present have not been isolated. They may be found as normal inhabitants of the intestinal canal, and as a result of any abnormal local irritation become pathogenic, most often from improper feeding. This is especially true of the colon group of bacilli, any marked disturbance of digestion causing them to become virulent. The streptococcus, *Bacillus proteus vulgaris, Bacillus pyocyaneus,* Shiga bacilli, and any number of saprophytic bacteria, invariably entering the body with the food in some manner, as in contaminated milk, supposed to be concerned in the causation of the disease, are abnormal inhabitants of the intestinal canal. This is the direct mode of infection. Undigested milk furnishes an ideal culture medium for the growth of bacteria at the temperature of the body, resulting in autoinfection. The disease is more prevalent in hot weather, beginning the latter part of May, continuing through June, July, and August with great virulence, decreasing in severity in September, ending the latter part of October in many cases. I have seen several cases in which it was impossible to get the patient upon the weakest modified milk formula until November without a reappearance of a diarrhea. The thermic changes cause a weakened digestion, and the heat of the summer months a proliferation of the bacteria in the milk, putrefactive toxic material resulting. When infants are fed on such milk absorption is the natural occurrence.

The infectious origin of diarrhea is the prevailing opinion of many. Bad hygienic surroundings, institutional life where children do not get the necessary amount of fresh air and sunshine, feeble constitution, those suffering from malnutrition and athrepsia or any slight digestive disorder causing a diarrhea predisposes to the disorder. Undigested food acting as a foreign body produces an inflammation of the already weakened mucous membrane of the intestines.

The age most frequently affected (from personal statistics and a conservative comparison of various authors), is from the fourth to the twentieth month, artificially fed infants more than when breast fed. The greatest factor concerned in the production, in my mind, is the feeding of infants upon cow's milk that has been brought from a distance in warm weather and kept in hot cans before being prepared for feedings. Milk in the summer months should be kept below 45° F. for artificially feeding infants. The younger the infant, especially when artificially fed, the greater will be the mortality. The lesions, found at autopsy, vary considerably in different parts of the canal, in severity, and in different cases. Holt, in his postmortem examinations, found the colon, lower ileum, and stomach most frequently involved, duodenum and jejunum next. Kerley found in his postmortem examinations, in the severe toxic cases that die within a few days, slight changes in the intestines, small areas of congestion, a few areas of desquamated epithelium, and minute swellings of the lymph nodes. The intestines may be the seat of all degrees of inflammation, from simple catarrhal, and simple follicular hyperplasia, to follicular ulceration, and false membrane formation. In the subacute and chronic cases, dying after two to six weeks' illness, the pathological findings vary from a slight superficial abrasion of the mucous membrane, to large deep ulcerations, involving all coats of the bowels with a degeneration and spreading of the epithelium lining the lower part of the ileum and colon. Booker found streptococci present constantly in the deep ulcerations. In these cases the stools are numerous, eight to twenty-four in twenty-four hours, yellow, yellowish green, green, brown in color, small in amount with undigested milk, no odor at first.

In a few days blood and mucus appear in the stools. I have seen in a few cases pus and large quantities of exfoliated membrane giving a horrible odor. Fecal matter is small in amount, often well digested. When the stools are green, having mucus and blood, the mucus predominating, no odor is appreciable. Vomiting is not always present, the temperature runs from 100° F. to 104° F. The abdomen is painful and tender, especially so over the colon, meteorism is marked, tenesmus is characteristic and frequently causes a prolapse of the anus with each stool.

Under prompt treatment these symptoms generally abate in a week to ten days, blood disappearing from the stools, more fecal matter appearing in each defecation, tenesmus and pain not so pronounced, temperature lower and the child's expression brighter. Mucus and the green color may persist for weeks in each stool. This illustrates a typical case of ileocolitis. In speaking briefly of cholera infantum, the prevailing opinion among many pediatrists is that it is extremely rare, and in nearly every case it is fatal. Cotton, in his article on summer diarrhea, states, speaking of an eminent pediatrist, that it is very rare, having seen only three cases of undoubted existence. During my service at the New York Infant Asylum I saw one case which presented the symptoms written of this form of summer diarrhea. The history and symptoms, from my note at the time, are as follows: The child in perfect health, about eight months old, weight seventeen and a half pounds, bottle fed after two months, never had been sick prior to this acute attack of illness, excepting a mild diarrhea three months previously, responding in three days after withdrawing

*Read before the Norfolk, Virginia, Medical Society, May 9, 1905.

the formula, and administering two teaspoonfuls of castor oil; bismuth mixture, two teaspoonfuls every two hours; barley water No. 2, four ounces at a feeding, seven feedings, with plenty of cooled boiled water during the intervals of feeding. The stools appearing normal on the third day, a weak modified milk formula was begun, with no bad results. This was pushed every fourth day in strength, until the infant at the time of this attack of so-called cholera infantum, was getting the following: Cream, 5 ounces; milk, 20 ounces; barley water No. 2, 23 ounces; granulated sugar, 2 ounces; eight ounces at a feeding, six feedings. I was called to see the child the afternoon of July 25, 1903, and the nurse reported that the infant was having severe convulsions; rectal temperature, 105° F. Visiting the ward at once, I found it having severe clonic convulsions, with short intervals of relaxation, vomiting sour curdled milk, offensive serous discharges from the bowels, skin cold and clammy, radial pulsation not perceptible, heart-beats 180 per minute, feet and hands cold, with marked cyanosis. Features drawn, abdomen distended and tympanitic. I immediately gave lavage with normal saline solution, temperature 100° F., having the nurse irrigate the colon with normal saline solution 60° F. I then administered hypodermatically morphine sulphate 1-100 gr., with atropin sulphate 1-600 gr., and repeated the dose every two hours, the convulsions and bowel movements continuing. The stools being constant, I ordered in an hour an irrigation of 2 per cent. tannic acid solution. No improvement resulting in the child's condition after three hours I administered subcutaneously normal saline solution, four ounces, with brandy, one ounce, in the cellular tissue between the scapula. The child died in eight hours from the beginning of the attack, vomiting and purging, with convulsions until death. Unfortunately an autopsy was not permitted.

The most frequent cases we are called upon to treat are milder in character, not in 1 per cent. of summer diarrhea having severe direct infection from the beginning. Nearly all the cases start gradually with eructations of undigested milk and vomiting, or a convulsion may be the only premonitory symptom. The temperature may range from 101° F. to 103° F. After a few bowel movements the stools are yellowish green, loose and more frequent, containing undigested milk, gas with each marked. Shortly the stools become green, or dark brown with larger particles of undigested milk, and more frequent in occurrence, the odor becoming offensive. In a few days the stools contain mucus, and from eight to twenty-four occur in as many hours. The infant is fretful, pale, losing its plump contour, the muscles are flabby, there is great thirst, a wearing cry, the tongue is often coated, the mucous membrane of the mouth is congested, stomatitis and thrush frequently develop. The weight chart shows an appreciable loss, which in the mildest cases is five to six ounces, in the more severe cases twelve to fourteen ounces a week. I have records of one particular baby which lost a pound and a half from Monday until Friday. The buttocks often become excoriated and in a few cases have the appearance of being scalded. A rash often appears over the body. In the subacute and chronic cases furuncles appear over different parts of the body, and decubitus is a troublesome complication. If the case is not properly treated from the onset ulceration of the intestines takes place and ileocolitis develops. A sudden diarrhea often develops in breast-fed children. I do not intend to differentiate the diseases that are ushered in with diarrheal symptoms, simply naming them. The exanthemata, often pneumonia, tonsillitis, and malaria. Making a careful physical examination at each visit, the symptoms of these diseases will be evident. Before entering upon the treatment of summer diarrhea I wish to impress upon you forcibly a practical point advanced by Kerley. "Primarily in summer diarrhea we do not have an inflammation or an 'itis' to deal with." The trouble is in the intestinal contents, and not the intestinal structure. Taking this fact into consideration, and removing the cause, the infant in a large percentage of cases will have a quick and favorable recovery. Upon the first indication of altered digestion, discontinue the milk at once, whether artificially or breast fed. There is a diversity of opinion when to resume the weakest modified milk formula. This will depend upon the individual case. In the large majority of instances it is not wise to do so until the normal function is restored. Then do so gradually with low proportions of fat and proteids upon rational methods. Percentage feedings are theoretical. First of all remove the cause. If vomiting is present give lavage with boric acid solution, 1 to 2 per cent., or normal saline solution. I prefer to introduce a small rubber catheter (No. 13 American scale), through either naris, lubricated only with the solution, having it attached to a small glass funnel with patient in dorsal position upon table and head turned to either side. The solution should be 100° F., in a quart pitcher, and the lavage should be continued until the solution returns clear. I have never seen any bad results following this method. After lavage give calomel, 1-10 grain doses every half hour, until one or two grains have been given, according to age. I follow the calomel in six hours with one to two teaspoonfuls of castor oil. For cases not having vomiting give calomel in fractional doses, frequently repeated, or castor oil, one to two teaspoonfuls administered without lavage, according to age. Never administer castor oil if vomiting is present. Other cathartics that have proven useful are gray powder, 1-4 grain doses every half hour, according to age; bichloride, 1-200 to 1-100 grain, repeated in accordance with the age. The stools after the administration of mercury are naturally turned green. My experience with the various intestinal antiseptics advocated from time to time in this disease have not been satisfactory; I confine myself to the preparations of bismuth, frequently repeated in large doses. At the New York Infant Asylum the following mixture was very beneficial: Bismuth salicylate, 1 to 5 grains; bismuth subnitrate, 10 to 20 grains; aromatic syrup of rhubarb, 2 to 6 minims; distilled water to make 1 to 2 drams, and repeated every two hours. The preparations of bismuth should be pushed until the stools assume a blackish color. It is well to irrigate the bowel with normal saline solution, or boric acid solution, 1 to 2 per cent., at a temperature of 100° F., in the beginning of the attack once every day. Have the child in bed, turned upon its left side, the right thigh flexed over the left, the buttocks slightly elevated, and use a small rubber catheter (No. 14 American), attached to a fountain syringe, elevated only three feet. Lubricate the catheter with vaseline, pass the tube into the bowel, while the solution is flowing; this will distend the intestine in advance of the tube, and facilitate its passage with less probability of rupture; the tube should be inserted as high as possible into the bowel. When the stools are frequent, twenty to twenty-four in a day, rectal irrigation is contraindicated; if they are infrequent with blood and mucus and are very foul, irrigate once or twice a day. Frequently when rectal irrigations are given every four hours, mucus persists in the stools, and it is extremely depressing

to the infant. Irrigation never should be sanctioned oftener than twice a day. Kerley advocates using a solution of tannic acid, 1 to 2 per cent., in cases having much blood and mucus. I have seen good results following its use. In all irrigations of the bowel with boric acid solution, and normal saline solution, the quantity necessary depends upon how much is required for it to return clear, generally from one to two pints. When heart stimulants are required preparations of alcohol should not be used as a routine. They often cause derangement of the stomach. Brandy, one to two teaspoonfuls, well diluted, is the best form to use; administer it in the feedings or alone, well diluted with cooled boiled water. Strophanthus, digitalis, and strychnine are useful heart stimulants in this disease, preferably administered hypodermatically, as the absorptive power of the stomach is doubtful. When given by the mouth strophanthus causes less gastric disturbance than digitalis. The temperature can be controlled by cold packs, sponging, and saline rectal irrigations at a temperature of 60° F.; this should be given with caution, as often the infant collapses after its use. Opium in any form should not be used to control the diarrhea if the condition looks at all favorable to other measures, and not then unless the stools are eight to ten in twenty-four hours, frequent and watery. Of the various preparations Dover's powder, ¼ to ½ grain according to age, is the best form to use. Deodorized tincture of opium, ¼ to 1 minim; paregoric, 5 to 10 minims, are used according to age. It is imperative in this disease to have hot water bags to the feet. In the large majority of cases the peripheral circulation is poor. The most important indication in the treatment of the disease is the feedings, after the withdrawal of the milk. I am in favor of dextrinized gruels, preferably barley water made as follows: Barley flour, ½ ounce, made into a paste, then add a pint of warm water, boil for twenty minutes and add enough boiled water to make it a pint. Allow to cool to a temperature of 100° F. and strain. This mixture we designated at the Infant Asylum, Barley Water No. 1. It approximately contains proteid, .1 per cent.; fat, .014 per cent.; carbohydrates, 1 per cent. Barley Water No. 2 contained barley flour, one ounce to the pint, prepared in the same manner. Arrowroot water, and rice water, are also useful, prepared in the same manner. In each of these gruels salt and sugar can be added according to the desire of the physician. Albumen water contains approximately in nutritive value two-thirds of an ounce of milk; consequently many children fail to digest it, causing as much trouble as the milk. Beef-juice as ordinarily prepared contains .6 per cent fat, proteid 2.9 per cent. Broths contain approximately 1 per cent. of proteids. In view of these approximate nutritive ingredients, it is evident that they may cause disturbances of an already existing condition. Breast-fed infants should be treated by starvation from twenty-four to forty-eight hours, and then be given Barley Water No. 2 and cooled boiled water with sugar often during the day. In critical cases, diluting the breast milk with cooled boiled water often proves serviceable. In one particular case, premature birth seven and a half months, the only thing the child would retain was a solution of gum arabic, one ounce to the pint, prepared as the barley water mixtures. This in composition is identical to cane sugar. This was continued for forty-eight hours, when the stools and regurgitation discontinued. After two days one teaspoonful of whole milk was added to twenty-four hour feedings, increasing the milk gradually each day. The child at present is twenty-two months old, perfectly healthy, and weighing twenty-seven pounds on the 8th of the past March. No evidence of rickets. I will state that in connection with the feedings it received inunctions of sweet oil, one ounce every day, after its morning bath, when it was very ill. Lime water added to feedings should only be considered as a diluent, not as an antacid.

Breast milk and cow's milk are both acid. Therefore alkalies have been used empirically. They prevent the formation of dense curds that would leave the stomach slowly, and be difficult of digestion in the intestines. Whey is a useful article to add as a diluent in beginning milk formulas, and is prepared from whole or skimmed milk, preferably the latter in severe cases. To one pint of milk add one teaspoonful of essence of pepsin; heat to 110° F. until coagulation takes place. Break up and strain through cheesecloth. This approximately contains 1 per cent. fat and proteids, sugar 5 per cent.; when from skimmed milk, not any fat. In cases having persistent vomiting with a slight diarrhea the feedings should be given by gavage, making the intervals of feeding longer than usual. Always give lavage once a day, in the morning, when feeding by gavage. This method is warmly advocated by Kerley, and has proven exceptionally satisfactory in the hands of many pediatrists. As so many complicated methods are in general use to feed infants, in this condition when they can withstand milk, I shall only mention the one I used at the New York Infant Asylum, a modification of Kerley's. It is simple, practical, with approximate percentages. One pint was the basis of measure that we all are familiar with. Whole milk was used in different proportions, adding gravity cream when necessary. Whole milk generally contains in nutritive value, fat 4 per cent. proteid 3.5 per cent., and carbohydrates 4.5 per cent. Gravity cream generally contains, fat 16. per cent., proteid 3.2 per cent., carbohydrates 3.2 per cent.

Mixtures as follows: Milk, 2 ounces; barley water, 14 ounces; granulated sugar, 1 ounce. Fat, .549 per cent.; proteid, .578 per cent.; carbohydrate, 5.5 per cent.

Milk, 4 ounces; barley water, 12 ounces; granulated sugar, 1 ounce. Fat, 1.042 per cent.; proteid, 1.067 per cent.; carbohydrate, 5.5 per cent.

Milk, 8 ounces; barley water, 12 ounces; granulated sugar, 1 ounce. Fat, 2.025 per cent.; proteid, 2.045 per cent.; carbohydrate, 5.5 per cent.

Gravity cream, 1 ounce; barley water, 15 ounces; granulated sugar, 1 ounce. Fat, 1.052 per cent; proteid, .2084 per cent.; carbohydrate, 5.5 per cent.

Gravity cream, 2 ounces; barley water, 14 ounces; granulated sugar, 1 ounce. Fat, 2.012 per cent.; proteid, .4022 per cent.; carbohydrate, 5.5 per cent.

Gravity cream, 1 ounce; milk, 2 ounces; barley water, 13 ounces; granulated sugar, 1 ounce. Fat, 1.552 per cent.; proteid, .773 per cent.; carbohydrate, 5.5 per cent.

Gravity cream, 2 ounces; milk, 2 ounces; barley water, 12 ounces; granulated sugar, 1 ounce. Fat, 2.542 per cent.; proteid, .967 per cent.; carbohydrate, 5.5 per cent.

Gravity cream, 2 ounces; milk, 4 ounces; barley water, 10 ounces; granulated sugar, 1 ounce. Fat, 3.035 per cent; proteid, 1.456 per cent.; carbohydrate, 5.5 per cent.

Gravity cream, 3 ounces; milk, 2 ounces; barley water, 11 ounces; granulated sugar, 1 ounce. Fat, 3.538 per cent.; proteid, 1.162 per cent.; carbohydrate, 5.5 per cent.

Multiples of these formulas were used when more than a pint was necessary for twenty-four hours' feedings. Condensed milk diluted with barley water in proportions 1-32, 1-24, 1-12, is beneficial for a

short period to tide over difficult cases that are unable to tolerate cow's milk in any dilution. Barley water is the best diluent to use immediately after a diarrhea. Dextrinized mixtures are serviceable in converting the starch into maltose, rendering them easier to digest. All feedings in summer, and after slight diarrheal conditions, should be reduced in nutritive strength from a quarter to a half, by the addition of either barley water or boiled water in place of the milk. Plenty of cooled boiled water between feedings is essential. Among the essential things to observe in this disease are the following: The usual symptoms of too strong milk mixtures are anorexia and vomiting. Too much fat causes colic, green stools, increased peristalsis, and regurgitating undigested curds. Proteid in excess is followed by colic, curds in the stools and constipation. Proteid causes most of the trouble in infants' digestion. Sugar in excess causes acid stools, regurgitating small amount of food after feedings, meteorism, and colic. Infants generally digest carbohydrates well. Sterilization and Pasteurization should not be practised if the milk can be kept below 45° F., since these procedures render the milk harder to digest, and do not kill the spores. A suitable raw whole milk properly modified is the ideal method of treating summer diarrhea cases when milk can be tolerated. Change of air from the city to the country, and to the seashore, is extremely beneficial to these infants. The large floating hospitals leaving New York daily during the summer months for several hours a day have diminished the mortality greatly in that city in this disease. In conclusion it is important to bear in mind these practical points: 1. Warm sponge bath daily. 2. Clean utensils in preparing the feedings. 3. Make twenty-four hours feedings, keep on ice and use as required. 4. Milk kept below 45° F. for infant feedings. 5. Nipples kept in boric acid solution after using, having only one hole; infant held upon nurse's lap during feedings. 6. Scald bottle after each nursing. 7. Feedings should always be given warm, at a temperature of 100° F.; cold mixtures cause regurgitation and diarrhea. 8. Plenty of cooled boiled water during intervals of feedings. 9. Wash mouth before and after feedings with boric acid solution. 10. Gavage in difficult cases. 11. Dextrinize gruels and modified milk formulas. 12. Remove napkin and disinfect soon as soiled. 13. Stools turn green from oxygen of the air after standing. 14. For convulsions and poor circulation give a mustard bath. 15. Give inunctions of cocoa butter and sweet oil, one ounce, after morning bath in feeble and athrepsia cases. 16. Plenty of fresh air daily. 17. Clothing should be light; often in the tenement houses in New York City the mother has enough clothes upon the infant for the coldest day in winter. 18. Isolate diarrheal cases.

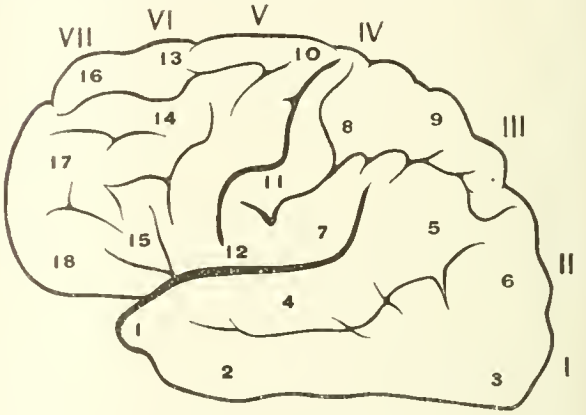
CEREBRAL SEGMENTATION.

A NEW METHOD OF READING THE BRAIN.

BY WALLACE WOOD, M.D.,

NEW YORK.

THE most interesting thing in the world, the most important, the most vital, that crumpled-up sheet of



LEFT HEMISPHERE.

FIG. 1.—Left hemisphere, with indications of lobules and suggested function: 1, 2, 3, the segment of the posterior base—nutritive sensibility, visceral sensibility, generative sensibility; 4, 5, 6, audition, written words, vision; 7, 8, 9, pain, pleasure, and personal sensibility; 10, 11, 12, the Rolandic lobe—spirit of the legs, arms, and mouth; 13, 14, 15, the expressional segment—gestures, writing, speech; 16, 17, 18, zone of the "head and eyes."

wax, the cerebral cortex, is a manuscript in hieroglyphics which we have barely begun to decipher.

How are we taught to read the cortex? We read

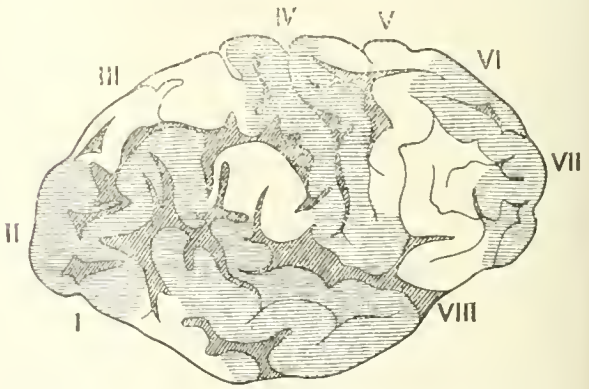


FIG. 2.—The right hemicerebrum, the transverse zones being shaded alternately; II, the auditory visual zone; III, the parietal sensory zone; IV, the Rolandic lobe; V, the pre-Rolandic (experimental) zone; VI, the second prefrontal zone; VII, the first prefrontal zone; VIII, the sub-prorean region.

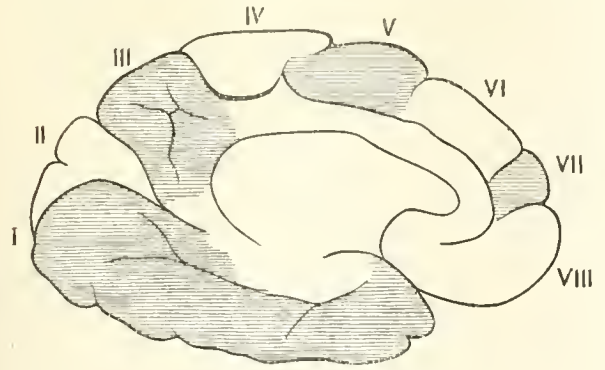
first the great lobes, the frontal, parietal, occipital; next we read the fissures, the Rolando, the Silvius, then the gyri, first frontal gyrus, second frontal

gyrus; next the physiological centers, "leg," "arm," "mouth," "taste," "vision."

That the cerebrum of the larger mammalia in its development undergoes lateral segmentation is



Lobules of a Left Hemisphere.

Fig. 3.—The left hemisphere, mesial surface, the key lobules which ndicate the heads of segments being alternately shaded; the following are the suggested functions: I, the suboccipital (secretory); II, the cuneus (visual); III, the quadrate (sensory); IV, the paracentral (motor); V, the posterior; metopic (gestures language); VI, the anterior metopic (head uphft); VII, the rectangle (attention; abstraction); VIII, the gyrus vestibuli (volition).

plain. We see and demonstrate the long, longitudinal fissures in sheep, ox, dog, or man. That the cerebrum of primates, more especially man, tends to undergo also transverse segmentation will be found on closer inspection.

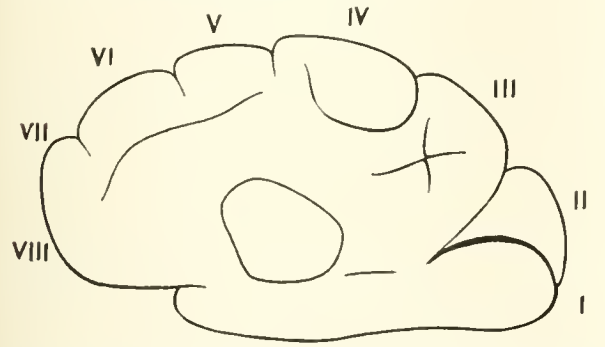


Fig. 4.—The right cerebral hemisphere, mesial surface, the marginal lobules being partially indicated: I, the suboccipital; II, the cuneus; III, the quadrate; IV, the paracentral; V, the posterior metopic; VI, the anterior metopic; VII, the retangle; VIII, the gyrus rectus; each of these lobules is the head of a possible segment.

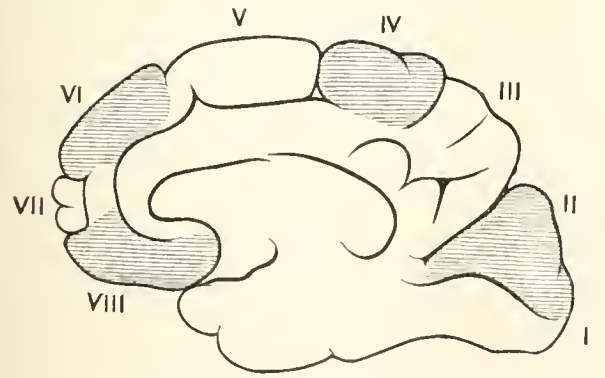
The fissure of Rolando is most clearly one of these transverse tendencies. In front of it appears another transverse fissure which is broken by a gyrus. Posterior to the Rolandic is the parietal



Lobules of a Right Hemisphere.

Fig. 5.—The right hemisphere (from the Atlas of Brissaud); the light marginal lobules are carefully studied out: I, lingualis; II, cuneus; III, quadrate; IV, paracentral; V, posterior metopic; VI, anterior metopic; VII, rectangle; VIII, sub-prorean.

fissure both wide and deep; the occipital fissure cuts in the same direction, while further on the intertemporal fissure, and lastly the Sylvian itself will be found to fall into this line.

We now begin closer inspection. The cortical surface tends to form lobules of definite shape, and these tend to form lines of segmentation.

The human cerebrum tends to be segmented like an annelid or like the vertebral column.

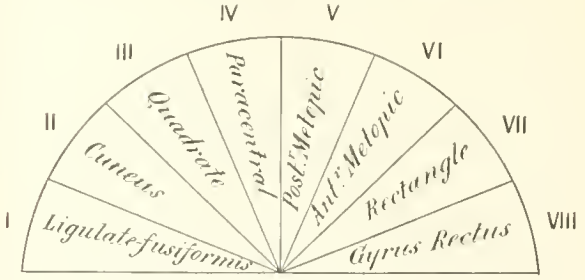


Fig. 6.—Schema for the eight marginal lobules of the mesial surface of the left hemisphere.

One of the transverse segments lies so clear cut and so plainly in view as hardly to require demonstration. This is the Rolandic region, or zone, divided into three lobules. This stands as the type of this segment. In front of this lies another transverse region, the zone of expression, while behind it lies a third, described by C. K. Mills and designated "sensory."

Three transverse zones then are well defined—the sensational, the motor, and the expressional. These dominate the cortex and the others fall into line before and behind them.

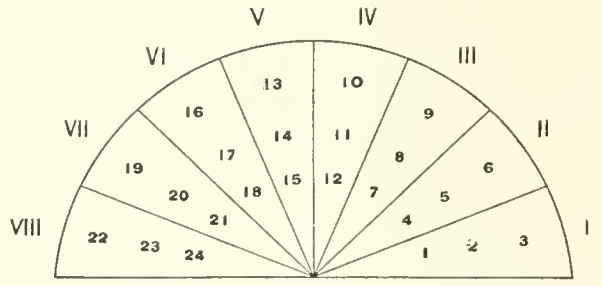

Fig. 7.—Brain Reading. Practical method of reading the cortex (physiological, pathological, or psychological); the division is into eight natural segments, each into three lobules or parts of the segments.

The front of the expressional segment is the pre-expressional, while posterior to the "sensory," the parietal, lies very clearly the associated auditory and visual in a line extending from the temporal eminence to the occiput.

This segmented arrangement is not arbitrary, but

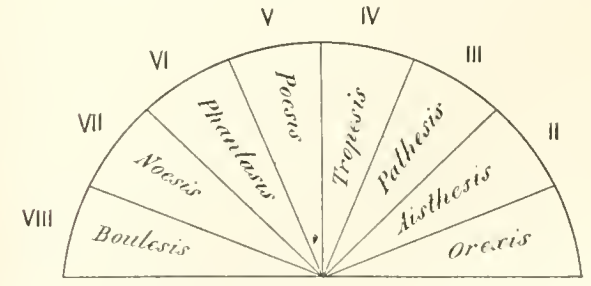

Fig. 8.—Psychological Functions. Suggested psychological functions of the eight cerebral zones or segments.

real; the key to it is found by turning the hemisphere over and inspecting the mesial surface.

Let us go round the sphere and count the lobules from pole to pole; they are eight in number, they are perfectly well defined, and each lobule is the head of a cerebral segment. We enumerate from posterior to anterior: 1. The ligulate-fusiformis, the under occipital lobe; 2. the cuneus; 3. the pre-

cuneus or quadrate; 4. the oval or paracentral; 5. the posterior metopic of Brissaud, the vertical or preparacentral; 6. the anterior metopic of Brissaud, the crest or coronal, the counter balance apparently of the quadrate; 7. the rectangle or prorean directly in front; 8. the gyrus rectus or subprorean lobule which broadens the orbit and terminates the marginal gyrus.

As a verification one may take any collection of hemicerebrums or look through the atlas of Retzius or that of Brissaud, these eight marginal lobules are unmistakable.

Each of these mesial lobules is the head of a transverse cerebral zone or segment.

Turn the hemisphere over. Let us consider these zones or segments seriatim.

First, the temporal base of the brain, which is also the spheroido-occipital zone or segment and shows three lobules, the spheroidal pole seat of gustatory sensibility, the under temporal lobule seat of visceral sensibility, and the under occipital lobule seat of genital sensibility.

Second, the temporo-occipital zone or segment, the three lobules of which are the temporal eminence (auditory area), the angular gyrus (memory of written words, etc.), and the over occipital lobe the area of vision, of which the cuneus is a mesial fold.

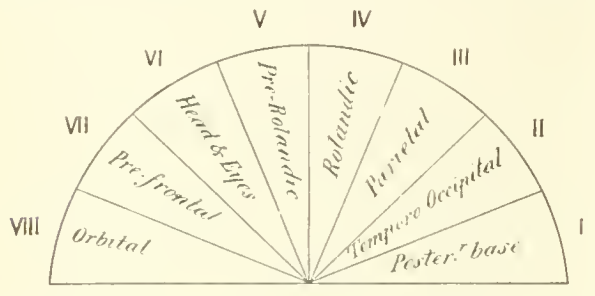

Fig. 9.—Cranial Surface. Schema for the eight segments or zones of the cortex, the key to which is found in the lobules of the mesial surface.

The third zone or segment is the parietal, consisting of three lobules, the quadrate, the superior parietal lobule, and the very small lobule, anterosuperior to the auditory area, which in animals is the motor for the ear and in the physiological diagrams is marked muscular sensibility. Psychologically it ought to be the lobule of the temper. This parietal zone has been especially studied by C. K. Mills.

The fourth transverse zone, the strongest of all, the keystone of the area, is the Rolandic area, the Rolondo zone, the Ferrier motor.

Here are three pairs of very powerful psychodynamos. These are the cerebral haunches, the cerebral arms, and the cerebral jaws. In this zone lies the spirit of the whole range of the mililant and industrial activities.

We come now to the fifth or prerolandic zone, the segment of expression. The lowest link is in the thin frontal gyrus, it is the cap and foot of motor speech brought to light by Broca. Look a little higher, above it is the cap and foot of written speech; and this is not all, for above this on the margin we may see the cap and foot of still other speech or language, the cap and foot of speech shrugged, implored, or gesticulated. Such is surely the meaning of the movements of the posterior metopic lobule.

In front of this expressional segment or zone of communication is an area marked "Head and Eyes," and here we appear to arrive at the acme centers of altruism and imagination, while still further, prefrontal, in a descending curve, lie the centers of attention, abstraction, volition.

Thus from stern to prow we are enabled by means of the mesial key lobules to mark out all the ribs of the ship.

That the cerebrum should be found to be articulated from stem to stern like a ship, like a myriapod, or like a vertebrate, need be no surprise. Articulation is the law of nature.

The cerebral segments are well defined on the mesial surface in the embryo. See the atlas of Retzius. An unexpected proof of the theory is to be seen on the diagrams in the histological researches of Campbell, the recent work subsidized by the Royal Institution.

The schema here presented is believed to be practical and convenient for every kind of localization, anatomic, physiological, pathological, and psychological.

New York University, Washington Square, April 10, 1906.

A MODIFICATION OF THE INCISION FOR EXPOSING THE MASTOID BONE.*

By L. J. HAMMOND, M.D.,

PHILADELPHIA.

SURGEON TO THE METHODIST EPISCOPAL HOSPITAL.

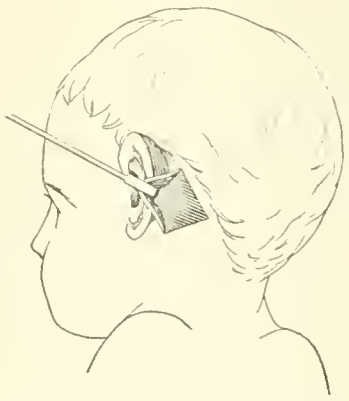
One might naturally be expected to offer an apology for undertaking to suggest the modification of an incision which has so long been universally accepted as the rational procedure for exposing the mastoid bone. The post-auricular incision, however, has been employed, as have so many other accepted methods of operating, more because surgeons of the present and immediate past, either through lack of time or inclination, have been more desirous to explore newer fields of surgery than to perfect those methods already long ago devised and employed with reasonable success. While the modification that I have recently been employing for operation on the mastoid bone may not be regarded in the light of an innovation, it does possess advantages that seem rational, as will be observed from the accompanying diagrams.

The incision is triangular instead of being straight or slightly semicircular as in the usual method, beginning about one-half inch back of the superior post-auricular attachment, extending through all the tissues obliquely backward and downward along the hairy margin, to a point just below the middle of the posterior border. From this point the incision is again carried through all the soft tissues forward and downward to the posterior border of the digastric fossa. By this incision one avoids all the post-auricular vessels and nerves, except possibly some of the minute auricular branches of the occipital, and even they may be avoided if the lower incision of the triangle does not have to be extended too obliquely downward. It is of no little importance to avoid division of both vessels and nerves, and especially the vessels, in this region, as about all the blood supply comes from the carotid arteries, and the extensive sloughing which often occurs after division of the post-auricular vessels will be prevented if the blood supply can be preserved and trauma from retraction of the flaps is avoided.

It becomes, therefore, a decided advantage in

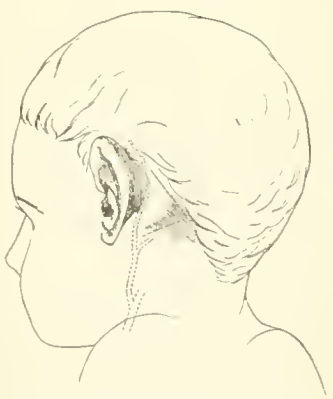
*Read at the meeting of the Philadelphia County Medical Society, February 28, 1906.

the steps of the operation of exposing this bone for the purpose of exenterating its cavity, at the same time to employ an incision that seems to me to supply every necessity. In the first place, it furnishes a roomy field for dealing directly with the bone; secondly, the entire soft tissues over-



lying the mastoid, which are always infected, are lifted, together with their periosteum, in one sheet, and it is usually possible to include within this single flap all the infected tissue over the mastoid. This is an important step towards lessening subsequent extension of the infection to the surrounding tissues, as so often happens when the incision is made, as ordinarily, through the infected area. As a further step toward lessening the extension of the infection through this infected flap tissue, packing can be so placed within the bony cavity as completely to separate the flap from the outer incised margin, and so leave it apart from the surrounding tissues for seventy-two hours, at the expiration of which time the perfect drainage which takes place from the two planes will have lessened, if not entirely removed, all infection within it, when suturing can be employed, or it can be left to heal by granulation.

Drainage from the bony cavity will be perfect, as the lower incision of the triangle, extending from above downward, will insure drainage from



the entire mastoid surface. There will be no necessity for traction, other than is required to hold the single flap forward, which can best be done by using a single tenaculum. This should be an additional means of lessening the sloughing which commonly results from the forcible retraction of the two flaps when the usual post-auricular incision is employed.

The flap as here indicated will also conform very closely to the outline of the mastoid bone, and, when considered safe to replace the flap immediately after operation, it will come directly in contact with the exenterated bone cavity and thus favor prompt dermatization. The lateral sinus can be explored through this incision without extending it backward, and scarring will be less conspicuous because of its proximity to the hairy margin.

Osteoperiosteal Lipomata.—Schwartz and Chevrier, in summing up the treatment of periosteal lipomata, liken it to that of lipomata in general. The method of choice is extirpation. This method, however, may be subject to question when the lipoma is of slow growth, for in that case the tumor is benign. The size of the tumor, and certain rare functional troubles which may result from its exaggerated development, and its situation, must be considered. In cases of rapid evolution, extirpation should be immediate. Later the growth may be difficult to enucleate, and in certain cases the general condition is affected, as in very young children. Extirpation should be complete in order to avoid recurrence. Sometimes such extirpation present difficulties. Careful dissection is necessary in certain cases. Sometimes several incisions are indicated. In some cases the operation demands two sittings separated by days or weeks. The pedicle should be entirely detached from the periosteum. Sometimes it is well even to take away the periosteum at this point, and it is better to resect an exostosis if the tumor is attached to one. It must be admitted that periosteal lipomata demand more complex intervention than do ordinary growths of this nature.—*Revue de Chirurgie.*

Diplococcemia in Croupous Pneumonia.—Guglielmo Memmi says that it is universally admitted that the blood of pneumonia patients may contain the bacillus of Fränkel, but there is considerable difference of opinion as to the frequency of their appearance, and its significance. The author's observations include eighty cases, in all of which he made bacteriological examinations of the blood. There were twenty-five positive results. Of the whole number of patients fifty-six recovered, and in only six of them was the bacillus of pneumonia found in the blood. Of twenty-four fatal cases, the bacilli were found in the blood of nineteen. The bacilli are found in the blood very early, even as early as the second day; in the period of resolution and during convalescence they were not found. In most cases the bacillus was of the characteristic form; in fifteen cases the virulence of the bacilli was tested by inoculation of animals. In seven cases it was highly virulent, the animals dying within twenty-four hours. The author concludes that there may be bacilli in the blood without a true pneumococcic septicemia.—*La Riforma Medica.*

Results Obtained at the Hérold Hospital from the Fresh-Air Treatment of Tuberculous Children During the Years 1903, 1904, and 1905.—M. H. Barbier speaks of the excellent results that have been attained by the fresh-air treatment in the case of tuberculous children. Every arrangement is made for the comfort and protection of these little patients at this hospital in the outskirts of Paris. The site of this institution commands an extensive view. When the temperature permits, the children pass all of the time out of doors. In the summer they are under cover only at night. The diet is that of the hospital, to which is added the yolks of two eggs and from one hundred to one hundred and twenty grams of raw meat. The writer reports encouraging results from this method of treatment, giving a list of the various lesions affecting the patients. In a large number of the patients there has been an increase in weight and strength; the chest has broadened, the color has returned. In brief, the symptoms of tuberculous intoxication have disappeared and the blood has become regenerated. This report offers another proof of the efficacy of pure air in the treatment of this disease.—*Gazette des Hôpitaux Civils et Militaires.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, June 2, 1906.

WEICHARDT'S TOXIN OF FATIGUE.

IN the *Centralblatt für Bakteriologie* for March 10, 1906, there appears an article by Wolff-Eisner which deals with the recent work done by Weichardt upon the problem of muscle fatigue. The observations of this investigator have not been extensively repeated, in spite of his own urgent request for confirmation, for the purpose of which he has given detailed descriptions of his technique, and it does not appear that the subject has aroused the interest in the scientific world which its extraordinary promise both in therapeutic possibilities and in etiological revelations seems to merit.

Among the most puzzling problems with which physiology has had to deal has been the question of muscle fatigue. It has long been assumed that during this process of diminishing irritability which we know as fatigue, substances are produced which exerted a poisonous influence upon the muscle tissue. This opinion is based upon the facts that a tired muscle can be restored almost completely by being flushed out, through its own vessels, with salt solution; and that fatigue can be rapidly produced in a normal muscle by injection into it of the extractives obtained from muscles already fatigued. Exactly what these toxic substances were was not known, but it was supposed that they were definite products of metabolism, and sarcolactic acid, creatin, creatinin, with various other proteid derivatives, have been held responsible.

This was, crudely stated, the position taken by physiologists until 1904, when Weichardt came forward with a startling hypothesis. He stated that he believed fatigue to be due to a definite toxin, analogous entirely to the toxins of tetanus and diphtheria, or to poisons of the ricin and abrin type, and against which a specific antitoxin could be produced. To him the previously accepted views did not seem satisfactorily to explain the phenomena observed during the "training" of athletes or of soldiers, in which prolonged and disciplined exercise make it possible for individuals to support easily an amount of work which would prove exhausting or even fatal to the untrained. Increased work, under any circumstances, means increased metabolism, and a consequently more rapid accumulation of its products. It is therefore entirely reasonable on these grounds to doubt the existing opinion on the subject. Weichardt believed that the explanation for these phenomena of "training" must lie in the possession by the athlete of a specific "antibody" which neutralizes the "fatigue toxin" as soon as it is formed.

With this idea before him, Weichardt produced fatigue in guinea pigs by forcing them to pull against resistance, and then the muscles of these animals were removed under the most stringent aseptic precautions. All fluid as far as possible was pressed out of them and from this muscle juice all the products of metabolism heretofore held responsible for fatigue were removed by dialysis. The substance thus obtained was found to follow, in most respects, the laws governing other toxins. By its injection into animals, Weichardt could produce, by small doses, rapid fatigue; by large doses, death, accompanied by all the symptoms observed in the original animals during the process of mechanical tiring. The temperature in both cases acted identically; at first rising, then rapidly falling, and continuing to do so until death. The substance was very sensitive to heat, its toxicity being destroyed by an exposure to 56° C., and in solution it became ineffectual after only a few hours' standing, unless kept at extremely low temperatures. Finally, it was possible, by the treatment of horses with this material, to produce an antibody in the serum of these animals which neutralized the action of the toxin both *in vivo* and *in vitro*.

Weichardt has gone further in his work to determine the more intimate nature of the toxin, a question which cannot well be followed here. At any rate, his results, surprising as they are, are based upon conscientious scientific research, and should others follow the confirmatory work of Wolff-Eisner they would threaten to revolutionize our present views of muscle fatigue. A direct result of his observations upon animals undergoing extreme fatigue, the influence upon the temperature, might already be put to practical use, in that an individual undergoing the physical strain of an athletic contest or a forced march, would seem to have entered into a period of danger as soon as his temperature had begun to sink below normal.

The new paths of theory as to the etiology of many clinical conditions marked by great physical depression, and the therapeutic conclusions to be deduced therefrom, tempting as they are, cannot be entered upon until there has been further confirmation of the attractive theory of the "fatigue toxin."

THE CLINICAL SIGNIFICANCE OF CASTS IN THE URINE, IN THE LIGHT OF MODERN RESEARCH.

SINCE casts of the renal tubules were first described by Henle in 1842, speculation, based on clinical and experimental study, has been going on as to their true meaning as evidences of renal disease. The mode of origin of casts is still unsettled, the older view of Rovida being that they are products of secretion of the tubular epithelium, while Ribbert's experiments on animals showed later that casts are probably the results of an exudative process within the tubules.

Nearly all the modern text-books on urinary examination consider casts as pathological elements—

as signs of some renal derangement. Thus Heitzmann ("Urinary Analysis," etc., New York, 1906) says that since casts are always the products of an inflammatory process, they cannot occur without an inflammation in the kidney. Lenhartz ("Clinical Microscopy," etc., 1904) avers that casts are always evidences of an inflammatory process in the kidneys, and in the majority of cases are indications of a true nephritis. Ogden ("Clinical Examination of the Urine" 1903) regards hyaline and granular casts as signs of some form of renal disease, though not characteristic of any one form. According to Croftan ("Clinical Urinology," 1904) hyaline casts are not indications of an existing nephritis, but show that such a process is about to begin, and they are always associated with at least a functional derangement of the kidney. Purdy, whose text-book is still a standard, states that he never has seen hyaline casts without an existing or preexisting albuminuria, and goes so far as to consider small hyaline casts as the chief "evidences of an interstitial nephritis." Nevertheless, the accumulating evidence of the last few years unquestionably points to the frequent occurrence of casts in the urine of persons with apparently normal kidneys, and although the presence of hyaline casts is still regarded as an evidence of "bad risk" by many life insurance companies, a few of the modern text-books on the urine admit the frequent absence of clinical significance, at least in the hyaline type of renal cylinders. Among the authors who take this view of the matter may be mentioned von Jaksch, who emphatically states that casts in themselves are not pathognomonic of disease of the kidneys; Tyson who says that casts are found frequently in urine free from albumin, and in perfectly healthy people; Hensel and Weil ("Urine and Feces," 1905), who found hyaline casts frequently in normal urine, and who believe that these casts by no means always imply a nephritis; and Saxe ("Examination of the Urine," 1904), who maintains that hyaline casts are found in practically every specimen of urine, if carefully looked for, and are certainly met with in the urine of persons in whom no albuminuria or any other sign of renal involvement had ever been observed.

In view of the differences of opinion among the authors quoted, the question as to the true meaning of casts still remains an open one. The occurrence of casts, particularly of the hyaline, granular, and epithelial types, in diseases other than those of the kidneys, is now well established through the researches of Nothnagel, Knecht, Mayer, Kossler, Wallerstein, Senator, Kobler, and others. The occurrence of casts in the urine of persons with normal kidneys and in apparently perfect health after the ingestion of alcohol or irritating foods, and after violent and prolonged exercise, has also been studied in detail by Penzoldt, Hubach, Lutje, and others. Penzoldt, as well as Lutje, regards casts as pathological phenomena, and Hubach was unable to find casts after the ingestion of irritating articles of food (mustard, radishes, etc.).

One of the most interesting of the recent articles on this subject is that of Klieneberger and Oxenius (*Deutsches Archiv für klinische Medicin*, Vol. LXXX), who examined 93 apparently healthy young men, and found casts in 89.24 per cent. Of these, 76.28 per cent. had hyaline casts; 4.30 per cent. granular casts, and 4.30 per cent. epithelial casts, while albumin was present in 58.06 per cent. of these subjects. The authors believe that the majority of these young men had suffered from contagious affections in childhood, and that these had left traces in their kidneys in later life. It seems scarcely credible, however, that in 89 per cent. of healthy young men there should be renal lesions such as we have been accustomed to associate with the presence of casts.

Philosofoff of St. Petersburg (*Russkii Vratch*, No. 50, 1905) is the most recent contributor to this discussion. His experimental study aimed to determine whether the occasional occurrence of casts in the urine of healthy people is physiological, or is an early sign of nephritis. For this purpose he examined the urine of fifty healthy young men, whose history was free from alcoholism and acute nephritis, and who had been under observation for a long time on ordinary hospital diet. These men were kept completely at rest during the period of observation. In seventeen of these he found hyaline casts; in twelve he found granular casts, and in thirteen, cylindroids. In other words, in 52 per cent. of these young men there was some type of cylindrical element in the urine.

In another series of experiments on individuals free from renal disease, Philosofoff gave a diet which included pepper, onions, mustard, alcohol, and turpentine in considerable amounts. The urine was examined within from five to fifteen hours after the ingestion of these irritants, and in six out of nine cases—that is, in 6 per cent.—hyaline casts were found; in three, or 33 per cent., granular casts were discovered. It was further noted that in all these cases the number of casts was greater than in subjects who had been kept on a normal diet, but it is possible that in the cases in which irritants were taken there was a more rapid precipitation of the casts owing to the presence of a more abundant deposit of oxalates.

These experiments seem to justify the conclusion that the presence of casts is not necessarily an evidence of kidney disease, and that the occurrence of a few isolated hyaline or even granular casts, as for example one or two of these elements on each slide, does not seem to offer positive proof of a renal disorder.

ATROPHY OF THE GLANDS AT THE BASE OF THE TONGUE AS A SIGN OF SYPHILIS.

A CORRECT decision in the diagnosis of syphilis is always important, though at times exceedingly difficult. The primary lesion may be overlooked or forgotten, and the secondary phenomena may be little marked and fail to attract attention, so that the question as to the nature of the antecedent disease may be raised only on the appearance of obscure tertiary symptoms or the development of grave parasyphilitic sequels. While the recognition of any disease may at times be possible from the presence of one or perhaps a few distinctive symptoms, it is the part of wisdom not to reach a conclusion in this connection too hastily or without full consideration of all the data in any given case. Syphilis assumes many guises, and failure in its identification is to be

avoided only through most careful observation and intelligent analysis of the evidence at hand. The clinician will therefore be grateful for knowledge of any symptom that helps to make or to exclude the diagnosis. A good many years ago Virchow pointed out a smooth atrophy of the follicles at the base of the tongue in cases of late syphilis, the glands normally present in that situation being diminished both in number and in size. The histological alterations were supposed to result from injury to the glandular structure by the immigration or new formation of syphilitic tissue cells, with secondary death and extrusion of the cells; or perhaps from impaired nutrition of the glands in consequence of syphilitic endarteritis. The condition has since been studied by other investigators, with, however, somewhat contradictory results.

For the purpose of determining the usefulness of the sign in the diagnosis of syphilis during life, Dr. N. B. Potter (*Boston Medical and Surgical Journal*, March 8, 1906) made a study of upward of 300 cases of various kinds, finding the symptom present in about one-half of the patients exhibiting what was considered reasonable evidence of previous syphilis and in only about 10 per cent. of cases without satisfactory evidence of previous syphilitic infection. The observations were made by palpation, as visual examination proved entirely untrustworthy. The patient is instructed to protrude his tongue as far as possible, and it is grasped by the left hand of the observer with a piece of gauze or a soft towel, while the index finger of the right hand is carefully introduced along the dorsum of the tongue to the circumvallate papillæ. The territory behind the triangle of papillæ is now delicately explored. From these observations the conclusion is reached that when the papillary glands at the root of the tongue are normal syphilis is probably to be excluded, while typical atrophy of these glands in an individual below the age of fifty years is indicative of syphilis. On the other hand, a moderate or slight degree of atrophy is of little diagnostic significance. The observation is so readily made and the results it is capable of yielding are often of such great importance that the sign should be invariably looked for, so that its relative frequency and its value as a diagnostic sign may be placed on a firm basis.

An International Society of Tropical Medicine.

The commercial exploitation of the various tropical possessions of the civilized nations and the awakening of medical interest in the diseases of these regions which has attended the march of empire, has led to the accumulation of a great stock of observations of all sorts relating to conditions and possibilities the stay-at-home practitioner has very little occasion to bother his head about. The number of important discoveries in relation to the diseases of hot countries that have been made within the last few years is very considerable, and for the delvers in this virgin soil there still remain many nuggets of medical lore to be uncovered. Tropical diseases are assuming greater importance for the inhabitants of the temperate latitudes also, as the possibility of their importation increases together with the growing amplitude of communication with the hitherto neglected portions of the earth, so that it behooves the medical profession to lose no opportunity for facilitating research into these maladies. Even from the standpoint of numbers alone the medical men whose field of activity is "somewhere East of Suez," are now entitled to consideration, so that it is rather astonishing to learn that at the coming meeting of the British Medical Association, to be held at Toronto, a section of tropical diseases finds no place on the program. In an appeal for greater recognition of the work of tropical investigators appearing in *The Journal of Tropical Medicine*, James Cantlie deplores this omission at the Toronto meeting and states that although efforts have been made to induce those in authority to remedy this defect, nothing has come of it. The interest evoked by the Society of Tropical Medicine in this country has been sufficiently great to demonstrate the value of association in the study of disease in hot countries, and we echo Dr. Cantlie's regret that this opportunity for the interchange of views by those especially versed in the subjects coming under this head should not be granted. Dr. Cantlie is led by this rebuff to suggest the formation of "A Tropical Medicine Association," which will be able to secure for tropical medicine the recognition in Great Britain which its importance demands. The proposal is a good one, for such an independent society would doubtless do better work than it could as a mere section of the British Medical Association. The idea might be worth developing to the extent of establishing an international society. Such a course would have many self-evident advantages, and we commend a consideration of it to those specially interested in the study of the pathological conditions peculiar to hot climates.

Governmental Meat Inspection.

Whatever may be the feelings with which those interested in the livestock and meat packing industries regard the Beveridge Meat Inspection bill, which was passed by the Senate on May 25, there is no doubt that the people of the country at large will be greatly relieved when its provisions are put into force. While no layman can realize to the full the disgusting possibilities and actual perils to health that attend meat packing done in a slovenly or dishonest way, or even meat packing carried on under conditions in which any solitary precaution that ingenuity can devise is neglected to the slightest degree, the nauseating details said to attend the preparation of this class of foodstuffs have lately been so forcibly presented to the public through various literary channels that the psychological moment for reform seems truly at hand. If the conditions in the great packing houses are as bad as they have been painted, no legislation intended for their improvement can be too drastic, while if the packers are innocent of wrongdoing they have nothing to fear from the proposal to make the inspections more rigid. It is, unfortunately, not very probable that the secrets of the packing house have been exaggerated in the telling, and we can but hope that the entire matter will now be put on so firm a basis of governmental supervision that even the pathologically trained imagination of the physician need conjure up no unpleasant specters of diseased animals, filthy surroundings, or unclean workmen, when he partakes of such flesh food as his nature may incline him to use.

Ringworm in School Children.

Some weeks ago the Medical Record spoke in terms of commendation of a plan of treatment for ringworm advocated by Dr. David Walch of London. The essential feature of this procedure was

the application of a coating of collodion to the affected area in order to prevent the spread of the infection to other children. That this plan is thoroughly practical is attested by the fact that the method has been in use by the New York Health Department during the past ten years, therefore long before Dr. Walch published the details of his method. The instructions issued by the Department for the guidance of the nurses to whom the children requiring such treatment are sent by the medical school inspectors, contain the following directions for the treatment of favus or ringworm of the scalp: In mild cases, the affected areas are to be scrubbed with green soap, epilated, and covered with flexible collodion. In severe cases the diseased patch is to be painted with tincture of iodine before it is covered with the collodion. Ringworm of the face and body is treated by scrubbing with green soap and painting with flexible collodion. In this connection it may be of interest to reproduce also the Department's routine for the treatment of pediculosis capitis, naturally a condition frequently encountered. The hair is to be thoroughly saturated with a mixture consisting of equal parts of kerosene and sweet oil. The next day this application is removed by the use of a solution of potassium carbonate, one teaspoonful to a quart of water, followed by soap and water. Hot vinegar is advised for the removal of the "nits."

News of the Week.

The San Francisco Relief Contributions.—The Secretary of the Medical Relief Committee has rendered a statement of the amount that has been so far raised by the medical men of Manhattan, Bronx, and Richmond. The sum is over $6,000, and there is every reason to anticipate the receipt of another thousand. It is understood that the physicians of Kings County (Brooklyn) have raised about $1,500 or $2,000. Through the instrumentality of one of the Fellows of the New York Academy of Medicine the Chamber of Commerce has set aside $5,000 to be used for the special relief of medical men and their families, in connection with the fund being raised by the Medical Relief Committee, so that altogether, directly and indirectly, the medical men of Greater New York will have raised about $14,000 or $15,000.

A New Georgia State Medical Association.—The organizers of a new Georgia State medical association have been holding a meeting at Atlanta for the purpose of perfecting the details of the project. The new society is intended to be independent of the national association, and membership in it is open to all duly qualified regular practitioners of Georgia. The circular letters sent out are said to have met with a very favorable reception throughout the State.

Examinations for the Army Medical Corps.—A preliminary examination of applicants for appointments in the Medical Corps of the Army will be held at various military posts throughout the United States on July 31, 1906. The prescribed maximum age is thirty years, and persons whose age exceeds that limit are not eligible. Applications must be filed prior to June 30. Full information may be obtained from the office of the Surgeon-General of the Army, War Department, Washington, D. C.

Atlantic City Academy of Medicine.—At a meeting of this society, on May 11, Dr. Charles L. Dana read a paper on cerebral vertigo, and Dr. William Seaman Bainbridge one entitled "A Brief Résumé of the World's Recent Cancer Research, With a Report of a Few Cases of Special Interest."

The Autopsy Question.—The Board of Coroners of Manhattan has held a special meeting to consider what action to take regarding the new form of death certificate issued by the Board of Health. This makes no mention of coroner or coroner's physician, and by implication gives to hospital pathologists the authority to make autopsies at discretion. The coroner's office has notified the hospitals that trouble would follow any attempt to alter the old order of procedure and that any hospital pathologist performing autopsies without the permission of the friends of the deceased would be prosecuted. The Board of Coroners adopted a resolution censuring the Board of Health for printing the new form of certificate, and another one denouncing physicians who obtained consents to autopsies by fraud. An ordinance was also drafted which is to be presented to the Board of Aldermen and is intended to prevent the transfer of dangerously sick patients from one hospital to another.

American Society for the Study of Alcoholic Inebriety, and Other Narcotics.—The thirty-sixth annual meeting of this society will be held in the Hotel Vendome, Boston, Mass., June 5, 6, and 7, 1906. The Sessions will be held from 9 A. M. to 10.30 A. M. each day. The president of the society is Dr. W. S. Hall of Chicago, and the secretary, Dr. T. D. Crothers of Hartford, Conn.

New York Academy of Medicine.—The Council of the Academy of Medicine states that it wishes to secure for the library all such material as will illustrate the historical growth of medicine and the development of its special branches. It is desired to secure old instruments illustrating earlier methods and the development of new procedures in surgery, physical examination, and diagnosis. Prints and portraits showing modes of life and practice, costumes and customs are desired. Fellows of the Academy are requested to present such material to the Library's Museum Department. They will be carefully preserved, classified, and, so far as the accommodation allows, will be displayed.

American Laryngological, Rhinological and Otological Society.—The twelfth annual meeting of this society will be held in Kansas City, Mo., on June 11, 12, and 13, 1906. The profession is invited to attend the various sessions of the society. The president is Dr. Jas. E. Logan of Kansas City, and the secretary is Dr. Wendell C. Phillips of New York.

Jewish Maternity Hospital.—This institution has recently been incorporated by the State Board of Charities and the Board of Directors has under consideration several plots of land on the lower East Side of this city. As soon as the selection has been made, ground will be broken for the erection of a hospital building which is to be thoroughly modern in its equipment. Until this building is ready for the reception of patients, an outdoor service will be carried on. Physicians desiring to be appointed to the outdoor service, which will be inaugurated in about a month, are requested to apply to Dr. A. M. Hilkowich, 207 East Broadway.

National Volunteer Emergency Service Medical Corps.—In a circular letter issued by this organization, physicians, pharmacists, nurses, and medical students are invited to become members, as it is desired to have representatives in every city and town. The object of the association is to provide aid to sufferers from great calamities such as fires, floods, earthquakes, epidemics, etc. It is stated that this

purpose is not antagonistic to the work of the Red Cross Society, with whose operation it is not intended to interfere, the projected scope being more technical and professional in nature. Dr. J. Adelphi Gottlieb is the Surgeon Major-General and Mr. Percival Kuhne is Paymaster-General. Dr. Nicholas Senn is President of the Advisory Medical Council. The temporary office of the organization is at 225 W. One Hundred and Sixth street, New York City.

A Tragic Occurrence was the death of the prominent Portuguese oculist, Dr. Mascaro, who suddenly became unconscious while reading a paper before the section on ophthalmology at the Lisbon Congress. He did not recover consciousness, and died on the same day. Dr. Mascaro was independent of practice and devoted himself to the treatment of the poor, for whom he had founded a private free hospital and training school for the blind.

Smoke Nuisance Fine.—The engineer in charge of the plant of an electric lighting concern was sentenced on May 21 to pay a fine of $50, or serve ten days in the city prison, for having violated the smoke ordinance. Seventeen other smoke nuisance cases were on the calendar that day: four were held over for trial at a later date and the other offenders were allowed to go under suspended sentence.

Cures of Leprosy Reported.—According to the daily papers, three cases of leprosy have been discharged as cured from the State Lepers' Home at Indian Camp, Iberville Parish, La. The patients were two women aged 50 and 30 years respectively, and a boy of 13 years, and had been inmates of the institution for several years. The plan of treatment pursued is said to have included the use of icthyol, potassium chlorate, strychnine, salicylate of sodium, arsenic, and chaulmoogra oil. A report on the subject has been submitted to Governor Blanchard by the Board of Control of the Louisiana Leper Home.

Chicago Health Matters.—Except for diphtheria and scarlet fever, the number of cases of the contagious diseases reported to the Department for the week ended May 19 shows a decrease from the preceding week, and for the first time since the early part of last December, no influenza bacilli were found in any of the cultures examined in the laboratory. Three cases of smallpox were discovered during the week and removed to the Isolation Hospital. Of these patients one was a resident of the city, 21 years old, never vaccinated. The source of infection was not ascertained. The second case was that of a colored woman from Texas, in the eruptive stage on arrival. The remaining case, that of a colored man from Memphis, Tenn., was in the fifth day of the eruption on arrival. Neither of these had ever been vaccinated. There are now eleven smallpox patients in the Isolation Hospital. This time last year there were eighty-five.

Red Cross Hospital.—The cornerstone of the New York Red Cross Hospital was laid on May 22 by Mr. William T. Wardwell, the president of the institution. The plot of ground on Central Park West, between Ninety-ninth and One Hundredth streets, on which the building is to be erected, was the donation of Mr. Wardwell. The building will have a frontage of 80 feet and a depth of 67 feet, and is planned with a wing at either side and a court in the center opening on the avenue. It is to be four stories high, but it is planned to increase this later by several stories. The wards will accommodate 125 patients and there will be a number of rooms for private patients. The hospital will maintain an ambulance service and is intended to serve the district on the upper West Side between Roosevelt Hospital and St. Luke's Hospital.

The New Bellevue Hospital.—Dr. John W. Brannan, President of the Board of Trustees of Bellevue Hospital, has been served with an order to show cause before Judge H. Fitts of the Supreme Court at Albany, why a peremptory mandamus should not be issued compelling the Board of Trustees of Bellevue Hospital to submit to the State Board of Charities plans and specifications for the $15,000,000 worth of improvements contemplated at Bellevue Hospital in alterations, repairs, and the erection of Pavilions A and B. If the mandamus should be issued and the State Board of Charities decide against the present plans, the work would be greatly delayed, as the present contracts would be canceled and possibly suits for damages would be brought against the city by the contractors.

Dr. G. Walsh, who has been in the United States Medical Corps in Panama, will soon return to Chicago and assume the post of Senior Physician at the Dunning Infirmary.

Dr. S. G. Cook has resigned his position of chief of the Board of Police Surgeons on account of his health. Dr. J. J. Quigley has been appointed to succeed him.

Cuban Quarantine.—The sanitary authorities of Havana have issued an order declaring a quarantine, beginning on May 24, against ports in Louisiana, Mississippi, Alabama, and Texas, the presence of yellow fever in these States being suspected.

New Immigration Law.—The Dillingham Immigration bill, which was passed by the Senate on May 23, contains several provisions which radically alter the existing law. Among other changes, the head tax is raised from $2 to $5, and an illiteracy clause is inserted which draws the line sharply at all intending immigrants who are unable to read.

Conviction of an Illegal Practitioner.—A young woman, claiming to be a "supernatural interpreter of disease" and known as the "girl with the *x*-ray eyes," was convicted last week of practising medicine without a license and sentenced to pay a fine of $150 or go to prison for sixty days. The woman's arrest was secured through the agents of the County Medical Society, which conducted the prosecution through its counsel.

The New York Association for Improving the Condition of the Poor began its fresh-air season on May 23, when 175 women and children were taken to Sea Breeze, Twenty-ninth street and Surf avenue, West Coney Island. While the association cannot care for all the needy mothers and babies in New York City, it has invited hospitals, clinics, dispensaries, schools, physicians, and employers to inform it of those in need. The association will act promptly and will undertake to have done all that is possible, considering the needs of the family and the resources of the city.

Arkansas State Medical Association.—The next annual meeting of this society will be held at Little Rock. The election of officers at the Hot Springs meeting on May 10 resulted as follows: *President,* Dr. C. T. Duennen, Hot Springs; *First Vice-President,* Dr. St. Cloud Cooper, Fort Smith; *Second Vice-President,* Dr. J. J. Morrow, Cotter; *Third Vice-President,* Dr. L. J. Gillespie, Hope; *Secretary,* Dr. C. C. Stephenson, Little Rock.

Illinois State Medical Association.—The following officers have been elected by this society for the ensuing year: *President,* Dr. J. F. Percy, Galesburg; *First Vice-President,* Dr. H. A. Nickerson, Quincy;

Second Vice-President, Dr. J. H. Stowell, Chicago; *Treasurer*, Dr. J. Brown, Decatur; *Secretary*, Dr. E. W. Weis, Ottawa. The next meeting will be held at Rockford.

Obituary Notes.—Dr. Boerne Bettman formerly President of the Illinois State Board of Charities and Instructor on the Staff of the College of Physicians and Surgeons, and for years a prominent practitioner in Chicago, died on May 25. He was born in Cincinnati in 1858, where his father was a physician. He received his medical education in Cincinnati, but took a graduate course at Heidelberg. He then came to Chicago, where he had since been engaged in the practice of medicine, giving also much time and care to matters of public health. Dr. Bettman is survived by a widow and two children, a son and a daughter.

Dr. William J. Gilfillan died on May 23 at the home of his nephew, Dr. George G. Cochran, in Brooklyn. He was born in Ireland sixty-six years ago, and was educated at Queen's College, Dublin. He studied both law and medicine at Columbia University, and served in the Civil War as Naval Surgeon. He had been connected with the Brooklyn Health Department for many years.

Dr. J. F. Edwards of Raritan, N. J., died on May 23. He was graduated from the New York University Medical College in 1848.

Dr. Jacob F. Raub of Washington, D. C., died on May 21, at the age of sixty-six years. He served in the Civil War and went to Washington from Bethlehem, Pa., in 1890. For years he had been medical examiner in the pension office.

Dr. N. J. A. Mueller of Dyersville, Ia., died on May 17 at the age of sixty-two years. Dr. Mueller was born in Germany and had practised in Iowa since 1866.

Dr. Lyman Skeen of Ogden, Utah, died on May 14 at the age of thirty-four years, after an illness of two weeks from tuberculous meningitis. He was born in Utah and received his medical degree from the University of Virginia. He had practised in Ogden since 1903.

Dr. J. J. Trudell of Rutland, Vt., died of tuberculosis on May 18, at the age of forty-three years. He was born in Canada and received medical degrees from the College of Physicians and Surgeons in Montreal, and the University of Vermont. He practised in Amesbury, Mass., for ten years and removed to Rutland in 1897.

Dr. Cornelius Beard of New Orleans died on May 15, at the age of seventy-nine years. Formerly he was well known as an oculist, but he gave up practice years ago.

Dr. T. C. Montague of Fredericksburg, Va., died on May 16, at the age of sixty-eight years. He was graduated from the Richmond Medical College in 1860 and served through the Civil War as surgeon in the Ninth Virginia Cavalry. At the close of the war he removed to Roseville, where he practised for some years, and in 1891 he removed to Fredericksburg.

Dr. Henry Lee Cabell of Cedarville, Va., died on May 17, at the age of seventy-eight years. He received his medical degree from the University of Pennsylvania in 1851 and fought in the Mexican War and in the Confederate Army.

Dr. Henry A. Brous of Philadelphia died on May 10, at the age of fifty-one years. He was graduated from the Kansas Agricultural College in 1874 and from the Jefferson Medical College in 1878. Seven years ago he left Philadelphia and went to Manhattan, Kansas, where he remained till the time of his death.

Correspondence.

FIFTEENTH INTERNATIONAL MEDICAL CONGRESS.

(From Our Special Correspondent.)

FIRST-AID DRESSINGS—YELLOW FEVER—TROPICAL HEMOGLOBINURIA—EXAMINATION OF BLOOD SPOTS—PATHOLOGY OF TABES—GENERAL PARALYSIS—DEMENTIA PRÆCOX.

Lisbon, April 29, 1906.

Barthélémy discussed the question of first-aid dressings in the Navy. He described his experiences with field dressings during the Dahomey war in 1892 to 1893. The dressing material was arranged in such a way that slight wounds could be dressed in two minutes and more serious injuries in five. Since 1903 dressings of this sort had been used in the French navy in three different sizes. Such dressings were also most useful in the merchant marine and were particularly suitable for use on vessels not provided with a surgeon. The author also discussed the application of first-aid dressings on the battlefield and stated that by their use the care of the wounded could be greatly expedited.

Gorgas of U. S. Army presented a communication on the etiology and prophylaxis of yellow fever. The American Commission which in 1900 investigated the question in Cuba had established the fact that the stegomyia mosquito transmitted the disease and that the period of incubation was three to six days. The most important element in prophylaxis was the extermination of the insects. He described the manner in which all collections of stagnant water were either to be done away with altogether or covered with a layer of oil at least once a week in order to destroy the mosquito larvæ. All windows and other openings were to be provided with screens, and the houses should be fumigated frequently. During the first days of the disease it was particularly necessary to guard against the bites of the stegomyia.

Moffat of Uganda read a paper on the prophylaxis and treatment of tropical hemoglobinuria. After fifteen years of experience with this condition he had reached the conclusion that out of one hundred cases of hemoglobinuria fifty would recover without any treatment, thirty-five would get well under proper care, and fifteen patients would die in spite of all efforts. He considered hemoglobinuria a complication of swamp fever, and therefore the best treatment of hemoglobinuria was the prophylaxis of swamp fever. Every patient should be put to bed immediately and not leave it until twenty-four hours after the disappearance of the last symptom of the malady. Quinine could be given in very large doses in hemoglobinuria, and the cold coal tar products, morphine, and strychnine were the most satisfactory other remedies.

The same subject was also discussed by Spindion of Athens. He considered that in addition to swamp fever there was a form of the disease produced by the administration of quinine and its salts, and he laid stress on the difficulty and importance of differentiating these conditions.

Ferreira Da Silva of Oporto reached the following conclusions regarding the medicolegal examination of blood spots: (1) The spectroscope and Teichmann's test sufficed for the identification of blood. (2) It was advisable to treat the spots with van Deen's or Richter's reagent. (3) Riegler's test had not been sufficiently tested for ordinary use. (4) The tests of Meyer, Rossel, and Klunge should be used in doubtful cases to supplement the preceding. (5) and (6) On account of its importance from a forensic standpoint the differentiation of the varieties of blood should be attempted only in well-equipped laboratories. (7) This was best to be effected by the Uhlenhuth-Wassermann method. (8) In order to differentiate the blood of closely related animals the potency of the antiserum was to be standardized very carefully according to Uhlenhuth's recently published technique. (9) If the results were not consistent no definite diagnosis could be made. (10) The methods of Marx-Ehrenroth and Sachs-Neisser required considerable time, but were useful when extremely small blood spots were to be investigated.

David Ferrier of London presented a report on the pathology of tabes. He first considered the lesions of the disease and then from the standpoint of the anatomical changes he criticised the current theories of the etiology of the malady. These comprised the following: The theory of interstitial sclerosis following endarteritis, Redlich and Obersteiner's theory of leptomeningitis, Marie's theory, according to which tabes is the result of syphilis of the lymphatic system of the spinal membranes; the theory of neuritis following a localized meningitis, and finally, the theory of Thomas and Hauser, according to which tabes is to be regarded as a dystrophy, affecting principally the sensory neurons. Ferrier regarded this last view as the proper one. He then discussed the rôle played by syphilis in tabes and

in general paralysis, which he regarded only as a different localization of the same disease. In the former disease there existed abnormal activity of the sensory neurons and in the latter it was the pyschomotor neurons that were affected. In the last portion of his discourse Ferrier sought to explain the pathological physiology of the atactic symptoms in tabes by ascribing them to an impairment of the conductivity of the nerves leading to a lack of harmony between the cortical and spinal centers.

Morini contributed a study on general paralysis in Spain. He said that in most of the asylums in that country from 5 to 6 per cent. of the patients suffered from general paralysis, though this percentage was somewhat greater in the northern part of the peninsula, where alcoholism was more general. Among the female patients only 1 per cent. had this disease. Most of the cases were in those between thirty-two and forty years of age. Dwellers in cities were twice as liable to general paralysis as those living in the country, and the disease was commoner among the married and those having responsible positions. In 90 per cent. of the cases syphilis was thought to be the underlying cause, while in 8 per cent. alcoholism was considered etiologically important. In 2 per cent. of the cases no cause could be discovered.

Tschisch of Dorpat read a paper on the forms and pathology of dementia præcox. He considered that in all cases of this disease a hereditary tendency might be traced, but the first evidences developed very early. The child was backward in development, became more and more stupid from year to year, and finally ceased entirely to progress. The disease was not amenable to treatment and developed regardless of external conditions. It was as frequently observed in the country as in the city, and masturbation played no part in its origin. In general, it might be said that the disease was the more severe the earlier it began. Cases of dementia præcox were observed which did not begin until the age of eighteen or twenty years and in which the acute period was so slight that only very good observers could detect the disease. When it developed very late the disease might resemble the picture of paranoia with delusions of grandeur and of persecution. While cases kept under careful supervision improved enough so that light work could be performed, this was not usually the case, and cure was impossible.

Mott of London stated that in general paralysis there were infiltrations of the pia mater and the arachnoid with lymphocytes and embryonal cells. A similar condition existed in the lymphatics accompanying the vessels, and there was also a new formation of capillaries and neuroglia tissues. The ganglion cells were deformed, degenerated, and had lost their connections with each other. The fibers, especially the association tracts, were atrophied. He also discussed the morphological changes in the alcoholic psychoses and in dementia præcox.

OUR LONDON LETTER.

BARON TAKAKI — CLASSIFICATION OF STREPTOCOCCI — MALIGNANT DISEASE OF VULVA — ST. BARTHOLOMEW'S — KINGS COLLEGE HOSPITAL — BOLINGBROKE HOSPITAL — OPEN-AIR LEAGUE — INQUEST — OBITUARY.

LONDON, May 11, 1906.

BARON TAKAKI, formerly Director-General of the Medical Department of the Japanese Navy, has this week delivered three lectures at St. Thomas's Hospital, where he became a student in 1874 and greatly distinguished himself. He won, among other prizes, the Treasurer's Gold Medal and the Cheselden Medal for Surgery. He then filled the surgical and medical residential appointments, and he has since, in the course of a brilliant career in his own country, retained a high regard for his old English hospital.

Drs. Andrewes and Horder have made a preliminary communication to the Pathological Society on the classification of the streptococci which are pathogenic to man. They found the chemical tests introduced by Dr. London gave constant results, but other characters had to be taken into consideration. Five groups of pathogenic forms could be recognized by (1) *Streptococcus pyogenes* and *erysipelatos*, (2) a type related to the *Streptococcus brevis* of the mouth and intestines, (3) *Streptococcus fæcalis*, (4) ordinary pneumococcus, (5) an aberrant pneumococcus. Intermediate forms occurred. It was suggested that a given streptococcus could be referred to one of these five types and antisera prepared accordingly. This was illustrated by malignant endocarditis. The commonest type present in this is not *Streptococcus pyogenes*, but one of those saprophytic organisms found in the intestine or mouth. Sixteen cases were examined, thirteen of them by blood culture on one or more occasions during life. Of the sixteen, only two were certainly *Streptococcus pyogenes*. No fewer than eight were of the unnamed type common in the saliva. Four were specimens of *Streptococcus fæcalis*. In two the reactions were not satisfactorily completed. The organisms isolated during life were mostly verified by the same reactions post-mortem. The two cases in which *Streptococcus pyogenes* was present were very acute, indicating that in subacute or chronic cases one of the other types was probably the cause. This observation is not without significance clinically and pathologically. It traces the source of the organisms most often picked up from the blood-stream by a damaged valve and explains the disappointing results of serum treatment in malignant cases, as well as the chronicity of other cases which may exist for a considerable time without much constitutional disturbance.

Dr. Lewers read notes of three cases of malignant disease of the vulva at the Obstetrical Society on May 2. 1. Squamous carcinoma in a primipara aged 47, recurring and removed four times. Now well, four years after the last operation. 2. Squamous also, in a multipara of 52; removed, with glands, September, 1899. Free from recurrence, March, 1906. 3. Multipara of 34, eight months pregnant, operated on for carcinoma, March, 1905; delivered naturally four days later. Recurrence in May. Glands removed. Recurrence in June; removal, and another recurrence. *x*-rays tried without effect, and she died three months later. Case 3 is noteworthy from the age of the patient and complication with pregnancy. Dr. Lewers thought Paquelin's cautery better than the knife in these cases, and in this was supported by Dr. Inglis Parsons, though another member preferred the knife and suture. That cancer can be inoculated seems a reason for using cautery. That local recurrence in the vulva is not altogether unfavorable may be argued from Case 1.

St. Bartholomew's Hospital was thrown open to visitors on Wednesday. The new out-patient and special department, having risen forty feet above ground, was inspected. The cost of the extension is to be £120,000, towards which £100,000 has been received. It is now decided to build a pathological block at a cost of about £20,000. Towards this £120 was produced by an entertainment held the same evening in the great hall of the hospital. This was somewhat of a novelty, being a series of dances arranged to illustrate the music and dance of Europe in the sixteenth, seventeenth and eighteenth centuries. Before each dance Mr. Cunningham Woods briefly recapitulated its history and the relation of its music to the forms adopted by some of the great composers.

The Drapers' Company promised conditionally £5,000 to the Kings College Hospital removal fund and afterward doubled the amount. The company has now canceled the condition and presented the £10,000 to the fund.

The Princess Royal, on Saturday, laid the first stone of a new block of the Bolingbroke Hospital, which is being reconstructed at a cost of some £30,000 and is to consist of three blocks of wards and one for offices and residential quarters. This hospital has for some years been conducted as a paying one for middle class patients. The Duke of Fife who accompanied the Princess, commended the paying principle as the wisest of all, and said if more generally adopted it would meet to some extent the financial difficulties which hampered all our hospitals.

An "open-air league" has been started to cooperate with other agencies in the crusade against consumption. Lectures, pamphlets, and house-to-house visitation are to be employed to educate the public on the value of open windows. The establishment of efficient sanatoria at low cost is to be attempted. It is stated that this can be done for £100 per bed. A farm-sanatorium for the cured patients is another item of htis new association, on the advisory committee of which are several well-known physicians.

The inquest concerning the death of Major Whyte, to which I referred last week, has again been adjourned after hearing some of the almost incredible evidence of several "practitioners of Christian Science."

Professor Metchnikoff is coming to London and will deliver the Harben lectures of the Royal Institute of Public Health on the 25th, 28th and 30th of May.

Surgeon-General Sibthorpe, C.B., I.M.S., died on May 4, aged 59. He took his L.R.C.S.I. in 1869 and became a Fellow of the sister college in 1880. He served in the Burmese campaign, 1885-6, was present at the capture of King Thebaw, was mentioned in dispatches and awarded the medal and clasp. He also served in the Afghan war and received similar distinctions. In 1897 he received the C.B. He was the author of a work on Clinical Research in India.

Dr. Matthew Baines, late Surgeon-Lieut.-Colonel First Middlesex Royal Engineer Volunteers, died on the 5th inst., at an advanced age. He had been during his long career on the staff of the West London Eye Infirmary and other institutions. He was an associate of Kings College, of which he was a student, and Knight of Grace of St. John of Jerusalem. He took his first qualifications as long ago as

1845. In the same year he added M.B., Lond., taking the Gold Medal and the University Medical Scholarship. In 1850 he proceeded to the M.D. He wrote a little on sanitary questions.

The death of another aged officer is also announced, Dr.-Inspector-General T. R. Warren, R.N. He joined the navy soon after taking his M.R.C.S. in 1832. Served in the China war, 1856, and received the medal and clasp. When at the West Indies Station he received special marks for service rendered voluntarily in Granada during an epidemic. He was in the fleet that accompanied the King to India when Prince of Wales. Subsequently he served at Malta and Plymouth. On retirement he was awarded a Greenwich Hospital pension.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

ACETONE BODIES IN GYNECOLOGICAL AFFECTIONS—PROTARGON—SKIN GRAFTING—PULSATING LIVER—ANEURYSM OF THE INNOMINATE—HABITUATION TO ARSENIC.

VIENNA, May 5, 1906.

At the meeting of the Association of Physicians Baumgarten and Popper presented a preliminary report on the excretion of acetone in diseases of the female pelvic organs. In 100 cases of gynecological affections of the most varied sorts, including normal or complicated pregnancy, inflammatory conditions, puerperal sepsis, abortion with and without fever, carcinoma of the uterus, fibroid tumors, menorrhagia, and a cyst with torsion of the pedicle, Legal's test was negative or only traces of acetone were indicated by it, and diacetic acid was never present. On the other hand, considerable amounts of acetone and diacetic acid were detected in seven cases of extrauterine pregnancy. Oxybutyric acid could not be demonstrated. Of these cases three were instances of tubal pregnancy with rupture accompanied by considerable hemorrhage, for which laparotomy and salpingectomy were necessary. Four were cases of hematocele, of which two were treated by laparotomy and two by vaginal incision and drainage. As regards the etiology of the excretion of such considerable amounts of acetone bodies it was said that the abnormalities of metabolism usually regarded as underlying acetonuria could be excluded in these cases. In some cases in which the history and physical signs appeared to indicate the presence of a hematocele but acetone and diacetic acid were not present, operation showed that ectoptic pregnancy did not exist. The authors therefore believed that in difficult cases which required differentiation between adnexal tumors and cysts on the one side, and hematocele on the other, the persistent appearance of large quantities of acetone and diacetic acid in the urine might be regarded as corroborative evidence in favor of the diagnosis of hematocele.

Stoerk has described some recent observations on protargon. This body was obtained by Liebreich from the central nervous system in 1865. Stoerk has discovered that this substance causes the white color of the kidney of pregnancy, as it is deposited in the form of polygonal granules or needle-shaped crystals at the base of the epithelial cells of the renal tubules together with globules of fat. It is taken up from this situation by phagocytic cells, for which it seems to have a chemotactic attraction. Protargon is also found in the atheromatous or syphilitic patches of the blood-vessels and in neoplasms, especially in xanthoma and xanthelasma, as well as in the adrenals. It may be distinguished from fat through its optical properties. The protargon obtained from the adrenals or from the central nervous system differs from that obtained from pathological structures in containing phosphorus and nitrogen, which elements are absent in protargon obtained from the latter source. There is therefore some doubt whether the latter substances should be considered as protargon, and it seems likely that they are decomposition products of protoplasm.

Lotheissen has operated on a girl of twenty years who was completely scalped in a machinery accident. The denuded area measured 36 by 28 cm., but it was completely covered with Thiersch grafts in several sittings. As closure of the eyelids was impossible and the eyebrows were lacking, hairy flaps were grafted in from the pubic region. Some of the hairs were retained and closure of the eyelids could be effected. The prognosis of this unusual injury has become much more favorable since the practice of skin grafting has been introduced, for now cure may be expected in about five months, whereas formerly almost half of the patients died of erysipelas, pyemia, or meningitis.

Jagic observed in Nothnagel's clinic a woman thirty-six years old who presented a genuine pulsating liver. Four years ago she had suffered from articular rheumatism; at present there were the signs of a stenosis of the left venous ostium, and further examination revealed marked negative venous pulsation in the neck and distinct pulsation of the somewhat enlarged liver; this was not due to transmission of the apex beat to the liver, but was a true liver pulse which was synchronous with the cervical venous pulse. The liver collapsed at the time of the apex beat and expanded during diastole. Possibly in this case there was a combination of mitral stenosis with patent foramen ovale.

Brosch has described the following interesting case which came under his observation in the military hospital. A man of thirty-seven years, of athletic build, died suddenly after a short illness. The autopsy revealed dilatation of the heart and of the entire aorta, and an aneurysm of the innominate artery as large as an egg. The right subclavian artery and the carotid sprang from the median lateral aspect of the sac by an almost completely closed linear opening. A further abnormality which may have had some connection with the development of the aortic disease was found in the larynx. Almost the entire upper third of the epiglottis was missing and the upper edge of this structure was formed by a fairly horizontal, somewhat rounded, ragged border. The microscopical examination of the numerous elevated patches present in the aorta showed swelling, fatty degeneration, and moderate calcification in the intima. In the aneurysmal sac and in its neighborhood there were also marked changes in the media, the muscle fibers having completely disappeared in some places and numerous cellular foci being present. These lesions indicated that the condition was probably the result of a syphilitic infection acquired years ago and apparently cured, since the patient was the father of three living children.

Hausmann has made experiments relating to the subject of habituation to arsenic. He was able to produce habituation to the drug in chickens and to a less extent in dogs. A conspicuous feature was the very great individual differences presented by the experimental animals in their tolerance of the arsenic, so that in some cases it was possible to produce habituation while in others this result could not be reached. At first the poison is excreted almost entirely through the feces, and then there is a period during which the amount of the stools decreases very considerably while that present in the urine does not exhibit any increase. It is therefore likely that the long-continued administration of the drug causes it to be eliminated in some other form, but in what way this is effected cannot as yet be determined. Hausmann has never yet observed any abstinence symptoms even when the drug had been used in large amounts for years. The accounts of the injurious effect of the sudden stopping of the administration of arsenic in man are probably to be explained on the ground that the condition of the patient is usually abnormal when the use of the remedy is begun, so that a rapid relapse after temporary improvement may easily simulate abstinence symptoms.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

VITILIGO — APPENDICOSTOMY FOR SPRUE — PROPHYLAXIS OF CHOLERA—MULTIPLE KELOIDS FOLLOWING HYPODERMIC INJECTIONS—THE PLAGUE—MALARIA.

MANILA, P. I., April 11, 1906.

THE regular monthly meeting of the Manila Medical Society took place at St. Paul's Hospital at 8.30 P.M., April 9, 1906.

Several clinical cases of vitiligo were presented by Dr. Bartels. He stated that his observation in the Philippines was that these cases occurred only in females. Dr. McDill also presented several cases, one of them a tuberculous elbow. He remarked that in the United States tuberculosis formed about 15 per cent. of all the surgical cases, but that in the Philippines he believed that the percentage was very much less. He stated that he was not yet prepared to speak definitely upon this subject, because his experience had not been large enough, but the indications were that surgical tuberculosis was a rather rare affliction in the Philippine Islands, and this was particularly strange in view of the fact that pulmonary tuberculosis is so very common among the natives.

He presented another case, one of sprue, in which an opening had been made in the appendix for the purpose of irrigating the colon, which had been regularly done for some days. He stated that, so far as he was aware, this was the first case on record in which surgical relief of this kind had been attempted for that disease. The prognosis in this particular case was not very favorable.

Dr. Ralph T. Edwards of the Bureau of Science gave a brief description of his experience in "Provincial Inoculation with Cholera Prophylactic." He stated that the prophylactic used was that prepared by Dr. R. P. Strong. In his experience in inoculating about six thousand persons, he found that the reaction was very slight, and that the only disturbance felt was a slight fever, and anorexia the next day, but that twenty-four hours later the symptoms of

the inoculation passed away. No untoward results were encountered. He stated that, while it was impossible to demonstrate beyond question that the prophylactic was of assistance in stamping out the cholera in the towns in which it had been used, yet he was inclined to the belief that, judging from the rapid cessation of the disease in those villages in which inoculation was done, it had a decided influence in that direction.

In the discussion that followed, one of the speakers stated that it was to be very much regretted that the present outbreak of cholera in the Philippines did not afford an opportunity for making a proper and adequate test of the usefulness of stamping out cholera by means of the cholera prophylactic. He said it had been used in Bilibid Prison, and that about two thousand of the four thousand inmates in that institution were inoculated; that the disease disappeared four days after the inoculations commenced, but that it was also true that no cases occurred among the uninoculated. Therefore the results could perhaps with more justice be credited to the ordinary sanitary measures which were used than to the prophylactic.

In the town of Angat, where the prophylactic was used, the sanitary measures with the view of combating the disease were started at the same time that the inoculations were begun, and in a few days the disease completely disappeared; in this instance the good results could scarcely be credited to the inoculations; that in the town of Siniloan, where such remarkable success was had in stamping out the disease, the sanitary measures were started a few days before the work of inoculation began, and three days after the arrival of the inoculators the disease had entirely disappeared. This town has a population of about four thousand, and only about two thousand were inoculated. In view of the fact that no further cases occurred among uninoculated as well as among inoculated, this again was an unsatisfactory test.

The general impression seems to be rapidly gaining ground that while the prophylactic inoculations against cholera will be of some assistance in stamping out the disease in the future, yet it can never take the place of the ordinary sanitary measures, owing to the physical impossibility of inoculating a large number of people in a short period of time. It will be valuable principally in affording those an opportunity who desire to be protected from cholera to come forward and be inoculated, and will be especially important for sanitary inspectors, physicians, and others whose work is at short range with the disease.

Dr. Maximilian Herzog of the Bureau of Science gave brief notes on "Three Cases of Multiple Keloids in Chinamen, Following the Habitual Hypodermic Use of Morphia," and presented a number of photographic illustrations of cases. He stated that in his experience in other countries no cases of this kind had come under his observation.

The annual increase in the number of cases of plague, which occurs about this season each year, particularly in China, has commenced somewhat earlier in Amoy and Hong Kong than heretofore; accordingly the Quarantine Service has imposed a quarantine against steerage passengers bound from Amoy to the Philippines.

In Manila, for the first time in more than a year, plague-infected rats have again been found. The Bureau of Health is taking the same measures in the district in which the infected rats were obtained as if the cases actually occurred among human beings. It is hoped that the outbreak can be avoided altogether, or, at least, greatly minimized by the measures which are being taken.

The lay press reports a severe outbreak of malarial fever among the troops at Camp Stotsenburg. This is a matter of considerable importance to the military authorities at this time, because the two regiments which are now en route to the Philippines are to be stationed at that post, in addition to the three that are already there. One hundred and forty-three cases are reported in the hospital.

OVARIAN GRAFTING.

To the Editor of the Medical Record:

Sir:—The query as to who was the mother of the child, in the case of ovarian grafting reported in the Medical Record for May 5 is being discussed from various points of view, the general sentiment being in favor apparently of considering the mother who bore the child as the real mother. The position taken by Dr. Perry of Avon must, however, be given serious consideration. He says that the mother who bore the child (Mrs. W.) simply carried the product of the fusion of the sex cell from Mrs. P. and the sex cell from the husband of Mrs. W. The child was then simply parasitically carried by Mrs. W., and Mrs. P.'s sex cell did not forfeit its ancestry, however much it may have adapted itself to its environment in the new hostess. The child and its two mothers have not as yet been brought together, as it is too early to note definite characteristics of resemblance. The question which Dr. Perry brings up relative to the postoperative development of ova from latent embryonic cells of the broad ligament in Mrs. W., must receive consideration in a scientific discussion, but it seems too far away to be given important bearing, on the ground that the experiments of Simon show that grafted ovaries undergo changes which leave them in a condition eventually to furnish ova. The question as to any portion of ovary having been left after the operation upon Mrs. W. is really quibbling. No part of either ovary was left. That point was one that had been eliminated as a practical fact, and it needs no genuine consideration.

Robert T. Morris, M.D.

616 Madison Avenue, New York.

Progress of Medical Science.

Boston Medical and Surgical Journal, May 24, 1906.

Remarks on the Infections of Joints.—R. W. Lovett recognizes (exclusive of tuberculous and chronic disease), four groups of joint infections: (1) Acute osteomyelitis of the articular end of one of the long bones involving the joint secondarily; (2) acute suppurative synovitis or joint abscess; (3) acute plastic synovitis leading to joint obliteration and (4) acute serous synovitis. With reference to the exact nature of acute rheumatic arthritis, he finds that the synovitis of this disease does not differ clinically or pathologically from the synovitis of infectious diseases, except that it is more benignant. It can be produced by the injection of cultures of pyogenic organisms, and pyogenic organisms have been found in the joint effusions. The specific character of these has not been accepted. No satisfactory explanation of rheumatism has ever been offered, and the history of late years shows a steadily larger number of "rheumatic" cases constantly being classed among the infections. It cannot as yet be regarded as a specific infectious disease, but the evidence rather tends to identify it as an "attenuated pyemia," as it has been called. The evidence is not yet conclusive, and the fact that the symptoms are so readily controlled by salicylic acid in many instances is not in accord with what we know of infections. The author summarizes his views by stating that acute infections of the joints of undoubted bacterial origin occur in all grades of severity in connection with many infections. As a rule any one of two or three types of joint inflammation may occur in connection with any one infection, no one type of joint disease constantly accompanying any one infection. In many cases the source of infection cannot be established, and in such cases the importance of remembering the function of the tonsils and the presence of pyogenic bacteria in the mouth as a ready source of infection is of importance. That acute articular rheumatism is an infection seems probable from bacterial and especially from clinical evidence, but this cannot yet be regarded as definitely proved.

Pruritus Ani: Its Etiology and Treatment.—A series of clinical histories is given by T. C. Hill who classifies the exciting causes as (1) ulcerations or abrasions of the anal canal; treatment, cocaine anesthesia, galvanocautery, vaseline, opium suppository; (2) local catarrh; treatment, secure soft evacuations by aperients, wash the bowel daily with a four per cent. boric acid solution, apply stimulating silver nitrate solutions or Peruvian balsam to any remaining abrasions or ulcerations; (3) external hemorrhoids; treatment, removal under cocaine anesthesia; if the base of the pile is broad it is better to close it with catgut sutures, otherwise it may be allowed to heal by granulations; (4) pockets in the mucosa above Hilton's white line; treatment, swab out with balsam or silver as above noted. (5) Small polyps of the anal canal, protruding internal piles, prolapse of the rectum and anal fissures, as well as other conditions, do doubtless occasionally cause itching about the anus, but very seldom in the writer's experience are they the cause of an old chronic or inveterate pruritus ani. When encountered, however, associated with pruritus, they should be dealt with according to their special surgical indications. To bring about the renewal of new skin which is tough and leathery and covered with dead and sodden epithelium, the author has found nothing better than silver nitrate solution and citrine ointment.

New York Medical Journal, May 19, 1906.

Rectal Anastomosis of the Ureters.—After a brief review of recent advances in the surgery of the ureters, Carl Beck refers particularly to the work of Maydl who showed the profession how to preserve the sphincteric

action of the ureters by implanting their ends together with the vesical trigonum into the sigmoid flexure. Beck himself has performed the operation but once, his patient being a boy of nine years with extrophy of the bladder. Several autoplastic operations had failed. Finally he made a semilunar incision around the upper border of the wall of the bladder and divided the peritoneum underneath in a longitudinal direction. For exact localization small catheters had been introduced into the ureters before. Then the opening was so far enlarged that the ureters could be isolated, so that finally it was possible to suspend the bladder fragment, so to speak, on the ureteral pedicles. The vesical trigonum, together with the ureters, was then exsected in a rhomboid shape and implanted into a longitudinal slit made in the anterior surface of the sigmoid flexure, which was found immediately behind the posterior wall of the bladder on the left. Mucous as well as serous membranes were individually united. For the inner (continuous) suture thin silk was used, while for the serous coats catgut (interrupted) was selected. The afferent portion of the flexure was clamped off before incision. The laparotomy wound could be united after the inner margins were equalized, and the inner borders of the recti muscles mobilized so that they could be brought into apposition. A tube was introduced into the rectum. In spite of severe reaction the boy recovered. He controlled the sphincter well and could at times go for five hours without passing urine. He had, however, occasional irritation of the mucous membrane of the rectum and diarrhea. He died suddenly of pneumonia fourteen months after operation.

Myomectomy.—C. P. Noble traces the historical development of this operation and tabulates his personal cases, consisting of 44 vaginal myomectomies and 22 others in which the myomectomy (abdominal) was combined with some other operative procedure. In the former series there was one pregnancy with delivery at full term, while in the latter there were two pregnancies with one delivery at full term and one miscarriage. One question of practical importance is the relative value of hysteromyomectomy and myomectomy in curing the patient of her symptoms. The author's figures do not vary greatly from those of Winckler, who declared that myomectomy is curative in 73 per cent. while the radical operation is curative in 97.5 per cent. As to the relative dangers of the two operations, statistics of different authorities are given. In the author's own experience in 42 vaginal myomectomies there were 2 deaths, one from embolism after the removal of a sloughing fibrous polyp and the other from an endocarditis which antedated the operation, after the removal of a sloughing fibroid polyp. In the abdominal myomectomies there was one death due to infection of the perineum following a closure of the latter done at the same time. According to the author the field for myomectomy is a limited one. In his own practice there have been sixty-six myomectomies out of a total of 337 operations for fibroid tumors. He is not inclined to broaden the field of myomectomy beyond this proportion. If he were to make any change in his practice, it would be, he says, in the direction of increasing the proportion of vaginal myomectomies in comparatively young women in whom it is still desirable for pregnancy to occur. Vaginal hysterotomy, combined with anterior colpotomy, will enable the surgeon to remove submucous and partly intramural fibroids with safety in many cases.

The Surgical Treatment of Chronic Dyspepsia.—G. E. Brewer notes the advance in the accurate diagnosis of various lesions and symptoms formerly grouped under the indefinite title of "dyspepsia," and calls attention to the surgical measures now in vogue for the relief of respectively ulcer, cancer, and benign pyloric stenosis. The latest statistics of surgical treatment of cancer of the stomach while still unsatisfactory are far in advance of those of other organs such as the uterus, rectum, tongue, and breast taken at the same period after inauguration of radical surgery in these regions. In view of these facts Brewer declares that the physician has no more right to deny his patient with suspected cancer of the stomach an opportunity for radical removal than he has to discourage operation in case of gunshot wound of the abdomen, or to withhold antitoxin from the patient with malignant diphtheria. As to ulcer, the indications for treatment are uncomplicated as open cases are. (1) Intelligent medical treatment for all primary cases of simple round ulcer. (2) If unrelieved after six weeks of this treatment, operation should be advised. (3) Operation in all cases of indurated chronic ulcer, and in all cases of recurrent symptoms after a primary cure. The nature of the operation to be determined after the abdomen is opened, and the condition accurately diagnosticated by inspection and palpation. The symptomatology of benign pyloric stenosis is passed in review and statistics given of the results of surgical intervention in this locality. He believes that the latter warrant the statement that in progressive cases except those due to gumma and those whose condition forbids the use of a general anesthesia, a gastroenterostomy should be performed as soon as the diagnosis is made.

Delayed Value of Surgery in Epilepsy in Certain Cases.—The main argument of W. P. Spratling is that in many cases of surgery of the brain for the relief of epilepsy, favorable results may be delayed for months and even years. Epilepsy from trauma may not arise until years after the receipt of the injury. Certain tissue changes in the meninges must have time to occur, and they are often of slow progression. Surgical operations for the relief of such conditions may do the patient no apparent good at the time, but they may also mark the beginning of an era of improvement that not infrequently terminates in a complete cure. In some of these cases the value of such treatment does not seem to come so much through the removal of pathological tissue, or of irritating agencies whose power to irritate may have become innocuous, as it does through the general impression the operation makes upon the organism. One special case is referred to which illustrates the fact above mentioned.

Journal of the American Medical Association, May 26, 1906.

Mesenteric Diverticulitis.—H. C. Gordinier and John A. Sampson publish the report of a case of intestinal obstruction due to an inflamed intramesenteric diverticulum of the small intestine, in which the puckering and thickening of the mesentery caused an angular bending of the gut with the result mentioned. They discuss the general subject of such diverticula and conclude that they occur more frequently in the small intestine than the autopsy records would indicate, and may frequently have been the cause of minor symptoms, and sometimes may even have endangered life, without the true cause of the trouble being recognized. They are usually multiple, and may involve long areas of the intestine. They consist of hernial protrusions of the mucosa and submucosa through a weakened place in the intestinal wall, usually alongside of the blood vessels at the mesenteric border and push between the two folds of the mesentery. This location renders them less liable to pathological changes than if they hung free or were attached to the abdominal wall, and the semifluid contents of the small intestine also render them less a menace than similar formations of the large intestine. In case they become inflamed, a mesenteritis is likely to occur, with possible results as in the case reported. Their multiple character and the fact that they are commonly intimately associated with the larger blood vessels render them ill-adapted to safe operative procedures. When operative treatment is indicated it must be adapted to the special needs of the case. Acquired diverticula of the large intestine may occur at weakened points in any part of its circumference, and their occurrence on the free border and the harder contents make them more productive of disturbance; a number of cases have been reported. The difficulty of diagnosing the strictures and inflammatory tumors from this cause from cancer and the fact that intestinal diverticula are a frequent source of vesicointestinal fistulæ are mentioned as of especial interest. The authors suggest that these diverticula receive more attention.

The Faucial Tonsil.—After describing Waldeyer's ring and the normal proportions and development of the tonsils, J. G. Wilson notes certain points of surgical interest. The blood supply of the tonsil, instead of being derived from the lingual artery as stated by Gray, comes mainly, he states, from the facial artery in man, either through a distinct tonsillar artery, or, as is more common, from the tonsillar branch of the ascending palatine of the facial. The danger of injury to the internal carotid in operations on the tonsil he considers minimal, with 1.5 cm. of loose areolar tissue in the way, and the ease with which the tonsil can be pulled forward, leaving the artery in place. Hemorrhage may be due in rare instances to an abnormal position of this artery, but the chief source is the tonsillar artery. Ordinarily the risk is slight as the vessels usually contract well. Other vessels, injury of which may cause troublesome hemorrhage, are the ascending pharyngeal, the lingual branches of the anterior and the posterior pillars and plica triangularis, and a branch of the superior palatine artery. Wilson discusses the comparative

anatomy and development of the tonsil with reference to the question of whether or not it is a phylogenetic residue, and concludes from all the facts that there is little support for the opinion that it is a vestigeal organ. As regards the function and secretion of the tonsil, the first fact that presents itself, he says, is that we have here a definite organ actively engaged in the production of lymphocytes, which pass either directly into the lymphatics or through the mucous membrane into the mouth. Concerning this mouth secretion there has been much discussion as to whether it is protective as Metchnikoff thinks, or whether it is not more of an excretion of already utilized products. The general belief seems to be that the tonsil is one of several similar organs surrounding the upper alimentary tract, very liable to disturbance and infection, whose physiological function is somehow concerned with active processes at the beginnings of this tract. One function may be to act as a defensive barrier against microorganisms and, it may be, against other injurious bodies. He thinks too little consideration has been given to the question of the effect of diseases demanding increased leucocytosis on the tonsillar exudations in the mouth, and the relation of this to the disturbances of buccal and gastric activity that occur in these diseases.

Some Common Dermatoses.—Oliver S. Ormsby considers the points of interest in some of the common diseases of the skin which are accompanied by the sensation of itching, with special reference to their differential diagnosis. He defines the terms prurigo, pruritus and itching and states that they have been used so often interchangeably that they would seem synonymous. He states that prurigo is now restricted to the disease first described by Hebra and states that it is a chronic and usually incurable disease. The earliest lesions, he says, are urticarial, after which the classic lesion, a colorless, slightly reddened papule appears. The essential cause is unknown, but the disease is generally classed as neurosis. Poverty and unsanitary conditions are predisposing causes, and males are more often attacked than females. Pruritus, Ormsby states, is a disease, not a symptom. It is a sensory neurosis, in which itching is the sole essential symptom. It occurs usually in adults, a common example being the so-called senile pruritus. In local pruritus the areas most often attacked are the anal, vulvar and scrotal regions, while occasionally the palms, face and scalp are also involved. He reviews the etiology of the condition at some length. He describes the lesions of scabies with the differential diagnosis. In the treatment of this condition he states that sulphur heads the list of remedial agents. In the treatment of pruritus he states that local remedial agents are very important and if properly selected and applied are of great value. The best of these, he states, are carbolic acid in oil or lotion: thymol or menthol, 1 to 4 per cent. in an ointment; resorcin, 0.5 to 2 per cent. in a lotion; camphor in an ointment or dusting powder; chloral in an ointment or lotion, and tar preparations. He also recommends hot water, electricity, and radiotherapy. In all cases free elimination should be encouraged by salines and other laxatives. He outlines in detail the treatment in a case of anal pruritus.

Dyspepsia in Elderly Individuals.—J. S. McLester calls attention to the possibility of gastric cancer when symptoms of indigestion appear for the first time in elderly people or as exacerbations of a previously mild condition. Such cases are naturally first seen by the family physician, and on him devolves the responsibility of seeing that nothing is omitted that will aid in arriving at a proper diagnosis. We have come to suspect cancer when uterine hemorrhage occurs after the menopause, and why, he asks, should we not give to the stomach the same consideration as regards the pathological possibilities when in advanced life it begins to show signs of disease. Examples of overlooked cancer under these conditions, he says, are common, and he reports three cases of his own observation, all hopeless when received at the hospital, which could possibly have been saved with an earlier diagnosis. In these cases of gastric disorder in elderly persons every means of diagnosis should be employed, even to exploratory incision when other methods still leave a reasonable doubt.

The Lancet, May 12, 1906.

Invisible Surgery.—J. L. A. Aymard advocates the use in division of the skin of oblique incision instead of division at right angles to the surface. In view of the thinness of the skin in most places, he believes that except in the immediate proximity of a suture, the tendency of the ordinarily applied dressing is to cause rather separation than approximation of the wound edges. In a slanting cut through the skin, contact is perfect and the greater the pressure, within limits, the better. Healing proceeds as usual, but the granulation tissue with subsequent fibrous and scar tissue is reduced to a minimum. The author describes the details of an ordinary operation as practised in accordance with the ideas above expressed and makes a plea for the massage of wounds and scars, claiming that in this way, in any ordinary wound involving the whole thickness of the skin, the scar may be prevented from forming adhesions.

Primary Intestinal Anthrax in Man; Septicemia; Hemorrhagic Septomeningitis.—The case is elaborately reported by J. H. Teacher, whose patient was a man of thirty-six years. Clinically the case was one of an acute illness, terminating fatally within twenty-four hours, the prominent features being headache, cerebral irritation manifesting itself in restlessness, delirium, and finally convulsions. There was also slight abdominal tenderness which might have suggested peritonitis, but there was no pyrexia. The history afforded no hint as to the nature of the disease. At the post-mortem examination the case presented the features of an acute septicemia and early peritonitis which appeared to spread from a hemorrhagic lesion of the small intestine with ulceration and necrosis internally and signs of an infective process extending up the mesentery. The nervous phenomena were explained by the discovery of a diffuse hemorrhagic condition of the pia-arachnoid, which microscopical examination demonstrated to be an early meningitis due to the bacillus anthracis. The identity of the organism was proved by cultivation and inoculation experiments. The intestinal lesion was clearly the oldest and the conclusion appears fully warranted that the case was anthrax septicemia due to intestinal infection caused most probably by the ingestion of a quantity of anthrax bacilli or spores in food.

The Technique of Colon Irrigation in a Case of Appendicostomy for Colitis.—In a certain case W. Ewart employed for the irrigation of the cecum and colon a No. 8 male India rubber catheter with a soft, pliable copper wire slightly bent on itself at the end so as to avoid injury of the mucosa. The catheter is dipped in glycerine and passed for a few inches. As much as twenty pints of fluid may be used, the patient in the dorsal position being supplied with a good-sized rectal tube with attached outflow pipe. To irrigate the lower ileum the catheter is bent, not too sharply, to about 110°—two and a half inches from its tip. It should be passed downward, inward, and backward. The assurance that the catheter has entered the small intestine is given by the greater length introduced (maximum in this case nine inches), by the subjective sensations of the patient experienced in the hypogastrium even so far as the middle line, by the direct palpation through the abdominal wall sometimes obtained by the operator, and by the skiagram of the stilet *in situ*. Systematic lavage of the lower ileum such as would be suitable for typhoid ulcers, is best performed with two tubes instead of one. The author is satisfied that it is possible to irrigate in this way the lower foot or two of the ileum. He uses a No. 2 and a No. 6 gum catheter. The smaller catheter is passed through the valve first, in the manner described, to the distance desired, and the larger one is then introduced into the cecum, where it acts as a draw-off for the fluid injected higher up. This arrangement might enable antiseptics to be used locally which it might not be desirable to expose to absorption by the mucous membrane of the entire colon. The quantity injected being noted, evidence would be obtained that it had been duly recovered from the cecum either by simple syphonage or if necessary by aspiration with the syringe. For this lavage the patient should assume a three-quarters right lateral decubitus to promote the descent of the injected fluid into the cecum.

Bronchopneumonia and Pyemia.—J. Mackenzie records one fatal case, the primary disease having been measles in a boy of twenty months. Originally strong and well nourished, he was when first seen suffering from measles associated with delirium. Rash appeared on the fourth day, at which time the case presented, except for the delirium, nothing unusual. On the sixth and seventh days of illness the rash had almost gone, but the temperature had not settled and the child was very restless and delirious. Evidence of commencing pulmonary consolidation could be detected at the left base but the nervous symptoms were not such as one might expect at the beginning of an uncomplicated pneumonia with moderate temperature (102°). Examination of the nervous system and of the bones afforded

no evidence of the presence of meningitis or osteomyelitis. On the ninth day of illness delirium was still present and consolidation at the left base was so advanced as to suggest the presence of fluid. The patient died on the eleventh day from the onset of the measles symptoms and on the eighth day from the appearance of the rash and on the fifth day from the detection of the bronchopneumonic signs. The most prominent features of the case were the persistent delirium with moderate temperature and the very rapid and advanced consolidation of the left pulmonary base. Full autopsy findings are given together with bacteriological findings. The author would regard the case as (1) an inflammation due to a virulent *staphylococcus aureus*, which first attacked the smaller bronchi and led to the appearance of signs of pulmonary consolidation; (2) the rapid progress and profuse infiltration and exudation giving rise to complete consolidation and atelectasis of the left lower lobe, and (3) the exalted virulence of the organism producing such a growth in the blood as to give rise to embolic infections of the various internal organs, leading to small abscess formations; and (4) the whole process resulting from infection by a highly virulent organism, the constitutional symptoms of intoxication overshadowed the effects of the local pulmonary lesion.

British Medical Journal, May 12, 1906.

Eucalyptus Poisoning.—J. Orr saw a boy of two years and nine months fifteen minutes after the child had swallowed two drams of oil of eucalyptus. He was unconscious, collapsed, with rapid pulse, stertor, and pin-point pupils. He had already vomited and had begun to purge. Orr gave ten grains of zinc sulphate and later, the child having vomited again, a dram of whiskey. The state of collapse still persisted and strong coffee was given. Soon the pupils began to dilate, consciousness returned, and in one hour the child seemed quite well. There were no sequelæ.

Post-mortem Cesarean Section.—P. Tytler records the case of a woman of twenty-six years who died in his presence from coma following fourteen days of meningitis near the end of the eighth month of pregnancy. Immediate delivery was attempted per vaginam, but it was not possible to dilate the cervix sufficiently to introduce the hand, so a cesarean section was performed with a histoury and the child extracted by the leg. It cried after a few seconds and was soon breathing well and was doing well at the age of ten weeks, though it had a small umbilical hernia. The placenta lay in the line of incision and bled freely.

Berliner klinische Wochenschrift, May 7, 1906.

Disappointment and Hope in the Treatment of Tuberculosis.—Renzi describes as disappointments attempts which he made to improve the condition of tuberculous patients by the use of carbon dioxide, and experiments on tuberculous animals intended to imitate the beneficial influence of emphysema in the human being. These efforts proved fruitless, however, and have been abandoned. The hopeful features of the treatment lie in the application of the principles of pure air, hyperalimentation, and rest. The influence of the former is ascribed not to its excess of oxygen nor to its deficiency in bacteria, but to the absence of the toxic principles present in impure air which greatly lessen the powers of resistance to the tuberculous infection. In this connection the author states that no person reaches the age of thirty years without having acquired a tuberculous infection. In considering the subject of hyperalimentation he states that one of the most important factors is to secure great variety in the diet. The use of sugars appears to be particularly advantageous from time to time, and levulose is the most effective of the list. Dextrin is less useful but on account of its cheapness is to be recommended for poor patients. The effect of rest in the treatment of tuberculosis was demonstrated by the author's experiments on two sets of tuberculous guinea pigs. One set kept in a cage that was maintained in constant motion by mechanical means succumbed to the disease much earlier than the control animals. The inhalation of oxygen was found distinctly advantageous in animal experimentation, but clinical tests have so far proved inconclusive. The author also lauds highly the value of sodium salicylate in tuberculosis, stating that it effects a firmer combination of oxygen with the hemoglobin.

Ochronosus.—Pick describes a case of this extremely rare form of general pigmentation, and in closing his long discussion of the subject states that the pigment deposited is chemically closely related to the melanins. The pigment dissolved in the blood is first precipitated in cartilage and cartilaginous tissues, but later invades also the connective tissue muscle fibers and epithelial cells without impairing their vitality. The coloration produced may give rise to an extremely characteristic pigmentation of the exposed portions of the body such as the ears, sclera, face, lips, and hands so that the diagnosis may be made during life. The kidney may be affected by the process and the pigment or an antecedent of it may be excreted in the urine. The long-continued use of small amounts of carbolic acid may give rise to the condition, as in the author's case, and the endogenous form may be the result of the action of tyrosinase on the alkapton bodies present in the excretions of those suffering from alkaptonuria. The same thing may occur in individuals in whom aromatic hydroxyl products are formed from the albumin molecule through autolytic, intravital, cellular degeneration.

Münchener medizinische Wochenschrift, May 8, 1906.

Anesthesia in Minor Surgery.—Verth describes in detail the technique of the various methods of producing local insensibility to pain that are available for use in minor surgery. These are now so numerous, he says, and can be combined so advantageously as to make it possible to spare the patient almost all pain in most operative procedures. He first describes the method of inducing primary ether anesthesia, which he says suffices for many operations, and is entirely free from danger. It is his practice to give a hypodermic injection of morphine half an hour beforehand. This insures the development of the anesthetic stage after a few inhalations of the ether and protracts its duration, so that usually it is not necessary to repeat the use of the anesthetic. The details of securing infiltration anesthesia are also set forth, and the author calls attention to the fact that this method is not well suited for use in regions that are the seat of inflammatory changes, both because the injections are painful under these conditions and because there is danger of disseminating infection and of lowering the powers of resistance of the tissues. Spinal anesthesia is not considered suitable for minor surgery, but the various forms of nerve blocking are said to be very useful, and their mode of application is given.

Determinations of the Viscosity of Human Blood.—Determann describes an improved form of apparatus for this purpose, the principal advantage of which is that it permits the blood to be taken from the ear by an ordinary puncture instead of requiring aspiration of a considerable quantity from a vein with a syringe as is necessary in the older procedures. In this way alterations of viscosity produced by the excess of carbon dioxide present in blood obtained from a vein that had been congested by the application of a ligature are avoided. Another improvement to which the author attaches considerable importance is the use of hirudin to prevent coagulation of the blood during the time needed for carrying out the determination. An extremely small particle of hirudin, only about 0.00001 gram being necessary, is placed on the skin at the site of puncture before this is made and the outflowing blood becoming subjected to the influence of the hirudin is rendered incapable of clotting for a considerable length of time. Details of technique for the use of the instrument are given.

Symmetrical Gangrene of the Eyelids Following Injury to the Forehead.—Apetz says that symmetrical gangrene of the eyelid is extremely rare, although gangrene of one side or the other not infrequently is seen in certain inflammatory conditions. He describes a case in which both eyelids were affected in this way following trauma to a part situated at some distance from the lid. The patient was an infant of eighteen months that had fallen and received an insignificant abrasion at the left side of the forehead. The wound apparently did well, but on the third day edema of the forehead and of the eyelid appeared, which on the fifth day had become severe and was accompanied by evidences of beginning gangrene of the skin and subcutaneous tissues of all four lids. This progressed until the loss of tissue was of considerable size, but the free border of the lid in each instance was spared by the process. Under appropriate treatment the necrotic areas healed, and when the child was seen, two months later, it was astonishing to find how little deformity remained. There was neither ectropion nor distortion of the cilia. Examination of the pus obtained from the frontal abscess and from the necrotic areas revealed the presence of the streptococcus pyogenes.

Deutsche medizinische Wochenschrift, May 10, 1906

A Diagnostic Serum Reaction in Syphilis.—Wassermann, Neisser, and Bruck describe a method by means of which they have been enabled to obtain a specific

serum reaction for syphilitic material. The procedure consists in mixing inactive serum of monkeys that have been adapted by injections of luetic material, with organic extract or serum from syphilitic individuals and then adding to the mixture fresh normal guinea-pig serum to furnish the necessary complement. The mixture is allowed to stand in order to give time for combination to take place, and then whether or not the complement has been anchored wholly or in part is tested by the addition of an inactivated specific hemolytic serum with the corresponding corpuscles. If the former is the case hemolysis will be wholly absent or greatly diminished. While the method has apparently not yet been perfected to such a degree as to make it available for clinical use, it does afford the possibility of determining whether there are present in the human serum or immune serum specific antibodies against the products of the syphilis organism, and it is therefore possible to determine the presence of syphilitic products in a given organ.

Myiasis and Its Treatment.—Smit describes the symptomatology and treatment of this unusual disease, of which he has observed a number of cases. The flies which most often deposit their ova in the human body are *Lucilia hominivora, Calliphora anthropophaga,* and those belonging to the genue *Œstrus.* The insects choose as sites of predilection for the disposition of their ova diseased or ulcerated tissues such as are found in suppurative conditions of the nose or ear, and in leg ulcers. The symptomatology depends very largely on the region affected, and when the nose or ear is invaded the suffering may be extreme and the prognosis very grave owing to the possibility of cerebral complications. Many methods of treatment have been advocated, but most of them are rather unsatisfactory. The one most often tried, that of mechanical removal of the larvæ is usually very difficult, especially in the nose, owing to the activity of the larvæ in retiring into their little submucous burrows. After trying various other plans the author has found that by far the most satisfactory results are to be obtained by the generous use of calomel as a dusting powder, and he gives the histories of two cases in which this treatment afforded very prompt relief and brought about death of all the embryos in a very short time.

French and Italian Journals.

Typhoid Fever and Pulmonary Gangrene.—Ch. Lesieur and J. Froment cite the history of this case. The patient, a man thirty years old, was brought to the hospital on the eighth day of typhoid. The patient was an alcoholic. The urine was strongly albuminous. Delirium and meningitic symptoms developed. In the fourth week bed sores appeared in the lumbar and dorsal regions, and at the same time an abscess on the elbow. Congestion of the lungs was followed by bronchopneumonia. The patient expectorated large quantities of blackish sputum, which was horribly fetid. Physical examination gave evidence of cavity formation at the base of the right lung. Autopsy showed simple congestion of the left lung. Gangrene had involved the base of the right lung. Peyer's patches were for the most part normal. The encephalon was normal. Cultures from the base of the right lung showed probable Eberth's bacillus. Culture from the pus of the elbow abscess showed staphylococci. Serum agglutination in this case was late, occurring on the thirty-fifth day. Eberth's bacillus was found in the blood on the third day, but disappeared on the thirty-seventh day.—*Lyon Médical,* April 22, 1906.

Ophthalmia of a New-born Child, of Pneumococcic Origin, with Grave Lesions of the Cornea.—F. Chaillous observed this patient, a child seven weeks old. There was an abundant conjunctival discharge and serious corneal lesions. Chaillous, whose first impression was that he was dealing with an ophthalmia of gonococcic nature, made an immediate bacteriological examination of the conjunctival secretion, and discovered in the preparation numerous diplococci. These microorganisms were found mostly among the cells, although some of them were included in the cells. There were numerous polynuclears and some epithelial cells. The colonies were composed of almost pure pneumococci. This observer calls attention to the fact that the diagnosis of ophthalmia cannot be made upon the time of the appearance of the symptoms nor upon the abundance of the discharge. Although pneumococcic ophthalmia as a rule is not a grave affection, it may nevertheless assume such an aspect.—*Revue Francaise de Médecine et de Chirurgie,* April 25, 1906.

Albumin in the Urine of Tuberculous Patients.—Labbé and Vitry call attention to the practice of forced feeding in the case of tuberculous patients who have reached the stage of cavity formation. The writers have, for the purpose of studying the results of this method, carried out a series of experiments in relation to the albuminoids. They have discovered that the capacity of these patients for assimilation of such food is far inferior to the normal, and decreases regularly in proportion as the quantity of albumin ingested is increased. Whatever may be the quantity ingested, the total amount of nitrogen in the urine which is eliminated remains constant. In each patient there is a limit to the excretion of nitrogen. If this figure is exceeded in the feeding, the result is the overburdening of the digestive apparatus.—*La Presse Médicale,* February 14, 1906.

Puerperal Eclampsia with Fifty Grams of Albumin. Recovery.—Rendu reports this case. The patient was a woman 21 years old. The last menstruation took place between April 9 and 14. On August 8 analysis of the urine showed no albumin, but sugar was present. On August 21 sugar had disappeared. On October 2 there was an eclamptic attack. Examination of the urine showed fifty grams of albumin to the liter. Within three weeks slight traces only could be detected. The writer believes that this condition was quite possibly due to the ingestion by the patient of a large quantity of hare. After eating this meat the patient was distressed with intestinal disturbances. The writer suggests that the eclampsia may have been caused by the retention of the toxins.—*Annales de Gynécologie et D'Obstétrique,* April, 1906.

Treatment of 216 Cases of Diphtheria at the Florence Hospital.—G. Barbensi and A. Barchielli report the treatment of 216 cases of diphtheria in three months at the Hospital in Florence. All were treated with a mixture of equal parts of the bivalent serum of Sclavo-Bandi and the antitoxic serum of Belfanti. The Sclavo-Bandi antibacteric serum was also used locally as an application to the throat and nasal mucous membrane, and to the larynx by the Bayeux syringe. There were 106 pharyngeal and 109 laryngeal cases, with a total mortality of 8.7 per cent. Thirty-five cases required either intubation or tracheotomy. The results, while excellent, are no better than under the use of the Behring serum.—*Revista di Clinica Pediatrica,* April, 1906.

Indications for the Removal of the Adnexa in Hysterectomy.—Giovanni Miranda, after considering the advantages to be derived from the conservation of the ovaries when the uterus is removed, and comparing them with the disadvantages, gives us the following conclusions: Such conservative surgery has only the appearance of conservation and has many disadvantages. Hysterectomy should be accomplished with the least danger to the patient and the greatest simplicity to the operator. The removal of an already diseased ovary makes the operation easier than its conservation. Therefore we should without regret sacrifice organs that present no utility when preserved. The disturbances due to removal of the ovaries seldom become at all alarming, and are not much more serious than those due to a normal climacteric. There is no real proof that there is any internal secretion of the ovary that is of value to the organism. Some of the dangers of the ovary when left behind are pelvic hemorrhage, degeneration of the ovary of a malignant nature, and formation of ovarian fibroids. In addition, the retained menstruation is often painful, and adhesions are also a frequent cause of suffering. On the whole, the disadvantages may be said to counterbalance the advantages, and removal is to be preferred.—*Archivio di Ostetricia e Ginecologia,* February, 1906.

Penetrating Wounds of the Gravid Uterus.—Giuseppe de Grecchio and Luca di Napoli have collected from literature 40 cases of wounds of the abdomen received during pregnancy, and to these add two cases of their own. They find that such wounds always result in interruption of the pregnancy. They have also made experiments on bitches, animals that are very tolerant of operations. These animals received wounds of various nature under aseptic precautions, and all recovered from them without any inflammation. In all these cases abortion took place soon after the wounds were received. The uteri of these animals, all of whom were afterward killed, showed healed wounds of the uterus, and the manner of healing seemed to present nothing abnormal. A large amount of amniotic fluid entered the peritoneal cavity in several instances and had no unfavorable effect on the healing of the wounds, causing no peritonitis.—*Giornale della Associazione Napoletana di Medici e Naturalisti,* January-February, 1906.

Book Reviews.

THE TREATMENT OF GONORRHEA IN THE MALE. By CHARLES LEEDHAM-GREEN, M.B., F.R.C.S., Senior Surgeon to Out-Patients, Queens Hospital, Birmingham; Surgeon to the Birmingham and Midlands Hospital for Children. New York: William Wood & Co., 1906.

THE author has presented the treatment of gonorrhea strictly from the modern viewpoint, especially as typified by the writings and teachings of Kollman, Oberlaender, Wossidlow, etc. This is, to our knowledge, the first attempt at a brief treatise on gonorrhea considered from this ultra-modern aspect. As may be expected, prominence is given to the treatment of acute urethritis with the newer silver salts, and of chronic urethritis by means of dilatation, copious irrigation, endoscopic applications, etc. The Janet method of irrigation does not find as much favor in the author's eyes as does Diday's method of irrigation with the aid of a catheter. Janet's method, however, is recommended in the more chronic forms. The author has evidently drawn freely upon the recent book of Oberlaender and Kollmann, "Die chronische Gonorrhoe der männlichen Harnröhre," and gives these authors due credit. The book is written in a clear, concise and systematic manner, and includes a brief consideration of the commoner complications of gonorrhea, with the exception of stricture and of conjunctivitis. The material entering into the make-up of the volume has evidently been thoroughly digested and presented with the conservatism which the treatment of such a subject as gonorrhea properly requires.

A TEXTBOOK ON PRESCRIPTION-WRITING AND PHARMACY, with Practice in Prescription-Writing, Laboratory Exercises in Pharmacy, and a Reference List of the Official Drugs, especially designed for Medical Students. By BERNARD FANTUS, M.D., Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons of Chicago, the College of Medicine of the University of Illinois; also Professor of Materia Medica and Therapeutics, Jenner Medical College of Chicago. Second Edition, thoroughly revised and adapted to the eighth (1905) edition of the United States Pharmacopeia. Chicago: Chicago Medical Book Co., 1906.

THIS book represents an attempt to teach the medical student prescription writing and pharmacy. As such it forms a useful supplement to the average textbooks on materia medica and therapeutics. The author expressly states that he has no intention of making the student an expert apothecary; so there need be no fear on the part of the future physician that he will be called upon to learn anything unnecessary. The volume consists of three parts: the first deals with prescription writing, and contains chapters on the form and language of prescriptions, the determination of quantities, the composition of prescriptions, and prescription ethics. At the same time ample practice in prescription writing is furnished by the numerous problems inserted throughout the work. The second part takes up the subject of pharmacy, treated from the standpoint of the prescriber rather than the pharmacist. The laboratory work included in this part offers the student an opportunity to prepare a typical specimen of each of the important forms of medicine. The book concludes with a reference list, which furnishes in a concise form all the information required for the prescribing of the official drugs. In each case there will be found the Latin name of the drug, its pronunciation and its genitive, a brief description, the solubility and composition, the incompatibles, the uses, the dose and official preparations with their doses, and the most suitable form of administration. The volume is well printed, of handy size, and should prove of value to teachers, practioners, and students.

SAUNDERS' QUESTION COMPENDS. ESSENTIALS OF GENITO-URINARY AND VENEREAL DISEASES: arranged in the form of questions and answers, prepared especially for Students of Medicine. By STARLING S. WILCOX, M.D., Professor of Genitourinary Diseases and Syphilology, Starling Medical College, Columbus, Ohio; one time First Assistant Surgeon National Home for Disabled Volunteer Soldiers, Central Branch Hospital; and Contract Surgeon in the U. S. Army in the Philippines. Illustrated. Philadelphia and London: W. B. Saunders Company, 1906.

THIS little book will supply the medical student with all that he is likely to need on the subject of genitourinary and venereal diseases. The general plan of the work is similar to that of the other volumes of this series; and both questions and answers are simple, direct, and easily understood.

A MANUAL OF PHARMACOLOGY. By WALTER E. DIXON, M.A. (Cantab), M.D., B.S., B.Sc. (Lond.), D.P.H. (Camb.), etc. Assistant to the Downing Professor of Medicine in the University of Cambridge, etc. Illustrated. London: Edward Arnold; New York: Longmans, Green & Co., 1906.

THIS new book on pharmacology considers the action of drugs from the experimental viewpoint, although it does not profess to be strictly a laboratory handbook. The classification of drugs is the usual one, substances with a similar action being considered together. A feature of the book is its thoroughly modern makeup as attested by the inclusion of such substances as adrenalin and other animal extracts, antitoxins and the newer drugs, such as veronal. In treating of the action of salts, acids, alkalies, halogens, etc., the theory of *ions* which now plays such a prominent rôle in pharmacodynamics, is entered into at some length. But little attention is purposely paid to materia medica, although at the end of each chapter a list of the drugs considered, and their preparations, is given. For this reason the book can very readily be used by American students without the confusion which necessarily arises on this side of the water when reading of pharmaceutical preparations made up according to the British Pharmacopeia. All that is necessary to make the book available here, is to pay no attention to these lists of preparations at the end of each chapter.

Pharmacology is a science that stands midway between materia medica, the branch dealing with the material used in healing, and therapeutics, the art of applying this material in disease. Nothing of therapeutics will be found in Dixon's book, as he very properly confines himself to his own field, although in the selection of his subject-matter he is guided by the importance of the various drugs in the treatment of disease.

The book will undoubtedly prove useful to the student of drug-action who desires a thorough knowledge of the subject without wading through a great deal of cumbersome material.

THE TREATMENT OF SYPHILIS. By E. J. LAMBKIN, Lieut.-Col., R.A.M.C., Specialist at the Army Headquarters, India. London: Ballière, Tindall & Cox, 1905.

LAMBKIN'S little monograph deals with a form of treatment for syphilis by subcutaneous, intramuscular, etc., injections of metallic mercury in the form of a cream prepared with lanolin and oil. The prescription which Lambkin uses consists of one part of mercury, four parts of lanolin, and five parts of carbolized oil, the maximum dose being ten drops once a week. The author is an advocate of the insoluble compounds of mercury for injections, as contrasted with the soluble compounds which are nowadays preferred by the majority of syphilographers. The methods of administering mercury by the mouth, by inunctions, etc., are also mentioned briefly in the book, but the injections are given the preference by the author.

CLINICAL APPLIED ANATOMY, or The Anatomy of Medicine and Surgery. By CHARLES R. BOX, M.D., B.S., B.Sc. (Lond.), F.R.C.S. (Eng.), Physician to out-patients, St. Thomas's Hospital, and Assistant Physician to the London Fever Hospital, Lecturer on Applied Anatomy and Demonstrator of Morbid Anatomy, St. Thomas's Hospital; and W. MCADAM ECCLES, M.S. (Lond.), F.R.C.S. (Eng.), Assistant Surgeon, Joint Lecturer on Anatomy, and Demonstrator of Operative Surgery, St. Bartholomew's Hospital, Examiner in Anatomy for the Fellowship of the Royal College of Surgeons, England, and Examiner in Surgery for the Society of Apothecaries. Philadelphia: P. Blakiston's Son & Company, 1906.

THIS excellent work is one of the most practical and applicable to the needs of the medical practitioner or senior student which has yet appeared on the subject of applied anatomy. The plan pursued by the authors in this book has been to treat the subject entirely from a clinical point of view rather than that of the anatomist, with the result of making the work delightfully readable. Any author who can accomplish this with an anatomical subject, and without detracting from the technical value of his work, deserves and is bound to receive great credit, and this Doctor Box and Mr. Eccles have certainly accomplished in their book.

The opening chapters, on "Inflammation," "Tuberculosis and Syphilis," and "Specific Fevers," are typical in manner of handling of those which follow. The illustrations are fairly good. The diagrams, many of which are borrowed from standard works on anatomy, are instructive and clear. The practitioner in any branch of medicine will find in this work a valuable addition to his library.

NURSING IN THE ACUTE INFECTIOUS FEVERS. By GEORGE P. PAUL, M.D., Assistant Visiting Physician and Adjunct Radiographer to the Samaritan Hospital at Troy, New York. Illustrated. Philadelphia and London: W. B. Saunders Company, 1906.

THIS book is intended for the nurse and not for the practitioner; and is divided into three parts. The first part treats of fever in general, with chapters on hygiene, diet, alleviation of symptoms, and detection of complications. The second part discusses each of the acute infectious fevers as to their cause, signs and symptoms, course, prognosis, care, and management. The third part deals with practical procedures and information necessary to the management of these diseases.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Annual Meeting, Held in Washington, May 15 and 16, 1906.

DR. FRANK BILLINGS OF CHICAGO IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

FIRST DAY—TUESDAY, MAY 15, 1906.

THE twenty-first annual meeting of this association was opened at the New Willard, Washington, D. C., by the president. A cablegram was read expressing greetings and best wishes from Prof. William Osler, formerly of Baltimore.

The President's Address.—Dr. FRANK BILLINGS of Chicago delivered this address, in which he asked that oral abstracts of papers be prepared beforehand to facilitate delivery, and that hereafter no paper be read in full before the Association.

Mechanism of the Blood Pressure Changes in Mitral Insufficiency.—Dr. W. J. MACCALLUM of Baltimore read this paper, which related entirely to experimental mitral insufficiency, leaving out any changes in the left ventricle. He considered the causes of hypertrophy of the right ventricle and told of the extensive amount of work involved in driving the blood along in this condition. The result of the experimental formation of mitral insufficiency with regard to blood pressure from various parts of the circulation was demonstrated. There was a stagnation of blood in the auricles and a greater or less amount of blood stagnant in the pulmonary circulation. He said that what Gerhardt had pointed out, that there was no great obstruction to the outflow of blood, was not true. In all cases of mitral insufficiency there was a constant stagnation of blood, or an overfilling at the end of systole in the pulmonary circulation.

Experiments on Venous Blood Pressure and Its Relation to Arterial Pressure in Man.—Dr. HENRY SEWELL of Denver said that the venous system was divided naturally into two departments, the superficial and the central. The veins of the first were peculiarly subjected to various forms of external stimuli, and they might be used to deduce conclusions as to the state of the circulation in all other parts of the vascular circuit. Of the internal veins those of the splanchnic system formed a homogeneous group which, from its great capacity and special relation to arterial blood pressure through the depressor nerve of the heart and the vasomotor center, made it necessary to consider the splanchnic circulation in every estimate of arterial blood pressure. He demonstrated his own blood pressure gauge from measurement of venous blood pressure. He said the blood pressure in the superficial veins depended upon the ratio of input to outflow, and that the former was greatly increased by muscular exercise and somewhat by heat. The latter was decreased by cold, causing contraction of the veins, and by obstruction to the entrance of blood into the heart. In some persons the venous pressure fell, in others arose, during digestion. The digestive rise in pressure was probably due to obstructive elevation of pressure in the right auricle. The movements of respiration, aside from their aspirating effect on the venous blood, had fundamental importance as an aid to the transfer of blood from arteries to veins. With deep inspiration the peripheral veins swelled and the pressure within them increased. This was often evident with ordinary inspiration, and could be demonstrated by means of a strip of paper, gummed on one side, and stuck by the side of a vein of the hand or forearm and resting across the vessel as a lever. It could be shown that both cardiac and respiratory variations of arterial blood pressure were frequently transmitted through the capillaries. He then considered the relation of venous to arterial pressure in diseased conditions, and told of the characteristically high venous pressure to be observed in gout and lithemia. He referred to the low venous pressure in arteriosclerosis or arterial spasm, and the rise of that pressure when cardiac circulation was impaired.

Rupture of Thoracic Aneurysm into the Superior Vena Cava.—Dr. W. HOWARD RUSSELL of Philadelphia reported the case of a man, 54 years old, a weaver, who was perfectly well until October 17 last, when he noticed a sudden swelling of face and arms, accompanied by cough and dyspnea which prevented him from lying down. He had no pain. Two days later he was admitted to St. Mary's Hospital. He then suffered from orthopnea, his face, both arms, neck, and upper chest were swollen to twice the natural size, were edematous, and markedly cyanosed. All the superficial veins were greatly enlarged. The superficial veins over the left abdominal wall were slightly increased in size. Hands, legs, and genitals were not swollen. The apex beat was difficult to palpate and was quite irregular. The sounds at the aortic cartilage were clear and the second was accentuated. There was a distinct "crunch" at the xyphoid. There were no murmurs in the vessels or at the root of the neck. There was marked dullness over the first piece of the sternum. There was no tracheal tug. An *x*-ray examination was negative. On October 25 the laryngeal examination showed venous engorgement of the mucous membrane but no signs of pressure. On October 31 the apex was far to the left of the nipple line and there were signs of pleural effusion in both chests and about one pint of liquid was removed from the right side. On November 12 there was marked distention of the abdominal veins. The patient suddenly died on November 27. At autopsy it was shown that at a distance of 5.5 cm. from the aortic ring there was a sacculated dilatation of the ascending part of the arch of the aorta, measuring 3.5 cm. in diameter. This sac, which protruded from the aorta on the right and slightly posterior, measured 3 cm. in depth and was narrower than the greatest diameter of the sac itself. The vena cava was constricted near the center where there was a small aperture about 3 cm. in diameter and with a smooth edge, so that there was a direct communication between the ascending aorta and the superior vena cava. The aneurysmal sac distended the aorta at the origin of the innominate but the aorta was apparently normal at the origin of the left carotid artery.

A Case of Varicose Aneurysm of the Aorta and Superior Vena Cava.—Dr. CHARLES CARY of Buffalo presented this paper, which was read by Dr. Williams. The patient, a man, was engaged in the hardest kind of labor, when he was suddenly seized with the classic symptoms of rupture of the aorta into the vena cava. Death followed on the fifth day. The patient was of the blue-black color. The aneurysm was about the size of a large fist. The superior vena cava was occluded, the intima of the two sides being adherent. Into the opening could be passed a No. 10 catheter; this passed into the aneurysmal sac.

Dr. JOHN H. MUSSER of Philadelphia presented a specimen of interest. An aneurysm had pressed upon the esophagus and the left bronchus resulting in the production of a fistula. The patient was 33 years old and had signs of an aneurysm to the right of the sternum, which gradually disappeared; with its disappearance pressure symptoms upon the esophagus developed. Death was sudden. The specimen was presented.

Dr. J. P. CROZIER GRIFFITH of Philadelphia also presented a specimen removed from a Chinaman, who had a condition like that described by Dr. Russell. It was an aneurysm of the superior vena cava and the two characteristic symptoms were the suddenness of the onset and characteristic continuous murmur.

Experimental Study of Cardiac Murmurs.—Drs. W. S. THAYER and W. G. MACCALLUM of Baltimore presented this communication, which consisted of some studies on the heart sounds and of cardiac murmurs, by direct auscultation, with a specially devised instrument, of the exposed dog's heart, with considerations concerning the application of the results obtained to the auscultation of the human heart. With the greatest ease a systolic murmur could be

produced by the slightest pressure upon the conus arteriosus; it gave the same soft blowing systolic sound in every instance. Nothing analogous to mitral stenosis in the human being could be produced, although a presystolic murmur that was analogous was produced in one instance. In conclusion he said that he was impressed with the great value this would have in teaching auscultation of the heart.

Dr. W. G. MacCallum of Baltimore explained the methods used. This, he said, was a part of the work they were doing in attempting to teach pathology and clinical medicine from the point of view of experimental pathology. He demonstrated by means of specially devised instruments how injuries to the heart valves were made.

Dr. E. G. Janeway of New York alluded to the different kinds of murmurs and said that on forced expiration instead of a soft blowing murmur there would often be heard a harsh one, and with a thrill. These murmurs were often mistaken for organic disease. He had seen two such cases in one family. He thought they were due to pressure caused by forced expiration, the pressure being upon the pulmonary artery.

Dr. Henry Sewell of Denver said that the use of salt solution caused relatively more cases of high venous than arterial pressure, the increase being from behind from the venous side and being due to diastolic intracardial blood pressure and not to a systolic intracardial blood pressure.

Dr. L. F. Barker of Baltimore said that the pathological physiology that was now being developed would do more good than pathological anatomy, and he hoped that more work of this sort might be undertaken.

Dr. S. J. Meltzer of New York said that the lung of the animal should be blown up and the trachea clamped while the lung was distended in order properly to recognize the cardiorespiratory murmurs.

Intravenous Injections of Nicotine, With Special Reference to Experimental Arteriosclerosis.—Dr. I. Adler and Dr. O. Hensel of New York presented this report. Intravenous injections of pure nicotine produced lesions in the aorta of rabbits almost identical with those caused by adrenalin and digitalis. The speaker entered upon a brief discussion of these results, especially as to their bearing upon the pathology of human arteriosclerosis. In every instance violent convulsions followed the injections and they were not able to find that tolerance would be produced, even though in some instances over 100 injections were given. The convulsions did not seem to affect the health of the animals. Characteristic lesions were usually found after eighteen injections had been given, yet one rabbit received seventy-seven without showing the slightest signs of any affection of the aorta. These lesions were similar to those found after giving adrenalin and the effect seemed to be upon the muscle cells of the media. The longitudinal layers were never affected; only the circular ones. The place of the muscle cells was taken up by calcareous deposits. Two types of degeneration were noted, viz., a diffuse type in which a large portion of the walls of the vessel were affected with deposits of calcareous matter, and, secondly, that type in which only small patches were affected and deposits of calcareous matter noted. Microphotographs were shown. He said it had frequently been stated by those who worked with adrenalin that the process was comparable to the process found in atheroma. He said that primarily in arteriosclerosis there was a degenerative process in the depths of the vessel wall, the exact location of which had not yet been determined, but it probably was in the intima.

Clinical Observations on Arteriosclerosis from Alimentary Toxins.—Dr. C. S. Bond of Richmond, Ind., read a paper giving twenty years' observation among private patients with arteriosclerosis from alimentary toxins. In these patients all other possible causes, such as senility, lead poisoning, alcohol, and syphilis, were excluded.

Dr. Joseph L. Miller of Chicago referred to some interesting work done a year ago by an Italian experimenter, who produced arterial changes by giving rabbits solutions of tobacco by the mouth through a stomach tube. After three or four weeks he found the same changes as described by Dr. Adler. It seemed to him that evidence so far produced pointed rather more to toxic than to the high pressure element as producing these changes. The changes were in the intima and not in the media.

Dr. Joseph Collins of New York called attention to the experimental work that had been done by Dr. Harlow Brooks and himself during the past two years, producing certain changes by causing the animal to inhale tobacco smoke. A large number of rabbits were taken and kept for fifteen minutes in a chamber in which tobacco was burning. They showed no toxic manifestations, convulsions, or other symptoms as described. There was no initial rise of blood pressure.

Dr. H. A. Hare of Philadelphia said that the action of the nicotine was very fleeting in his experience, so much so that one would hardly expect this agent to affect the aorta.

Report of Cases of Tricuspid Insufficiency in the Course of Pernicious Anemia.—Dr. Robert B. Preble of Chicago made a brief report of cases of pernicious anemia, with insufficiency of the tricuspid valves, pointing out certain features in which these cases of insufficiency differed from those resulting from commoner causes. Insufficiency on the right side was far more common than generally supposed.

Typhoid Spine with Definite Deposits of Bone along the Vertebræ; Relations of the Whole Group of Infections to the Production of Spondylitis.—Dr. Thomas McCrae of Baltimore read this paper. The first case reported was that of a patient with typhoid fever, and the usual clinical features of typhoid spine. Definite bony changes were found in the vertebræ. In a second patient, with a paratyphoid infection, the same changes resulted, although a previous gonococcus infection might have played a part in their production. The relation of various infections of an acute nature to changes in the vertebræ were considered and their possible association with the lesion of osteoarthritis was discussed.

Dr. James B. Herrick of Chicago told of one case in which there was nothing in the general behavior of the patient to make one think of such a condition being present. In a second case the patient had convulsions, the pain was localized, and the swelling could be distinctly made out. The process was definitely an organic one, but he did not know what parts were involved.

Dr. W. S. Thayer of Baltimore spoke of the curiously indifferent nature of the pain the patients complained of.

Dr. Joseph Collins of New York spoke of the relation of gonorrheal spondylitis to the general subject of spondylitis. He said that he recently had a case that had been diagnosed as Marie's *spondylose rhizomyélique*. The patient had had a stiff spine for three years and was practically cured by Dr. Eugene Fuller, by splitting the seminal vesicles and employing drainage.

Dr. James Tyson of Philadelphia told of a case of spondylitis affecting the cervical region in which the *x*-ray showed organic deposits.

Dr. John K. Mitchell of Philadelphia said that such cases of spondylitis might be so slight as not to be discovered until after months, and he reported one case in which it was only after months of careful study and examination that he could account for the truly extraordinary amount of pain complained of throughout the whole back and one side. He then got a history of an injury to the back by a wrench and the pain was relieved only by the removal of two or three fragments from the lateral vertebral processes of one of the lower middle vertebræ.

Dr. S. Solis-Cohen of Philadelphia believed that when such intense pain in typhoid fever was complained of there was something more than a spondylitis.

Dr. Thomas McCrae of Baltimore said that the term typhoid spine should be applied to something that was definite and not to all cases in which pain occurred during the course of typhoid fever. There seemed to be no asso-

ciation between the amount of pain and the amount of change.

Perinephritis as a Cause of Symptoms Simulating Stone in the Kidney.— Dr. James Tyson of Philadelphia gave his experience with a number of cases simulating nephrolithiasis, in which operation failed to discover stone in the kidney or adjacent tracts; this led him to look for other possible causal conditions, and this resulted in the discovery that certain of these cases were associated with tough adhesions of the perirenal fat and capsule and sometimes with the substance of the organ and with cicatricial like markings on the capsule, which might be the results of inflammation which for convenience was named perinephritis. The paper, he said, was suggested by a discussion on a like subject at the meeting of the Association of Physicians in 1905, in which Dr. Forchheimer reported similar experiences. By perinephritis Dr. Tyson meant an inflammation of the capsule and other tissues surrounding the kidney of such a nature as to produce contraction or cicatricial markings in the capsule, whence also the cortex of the kidney might be more or less invaded. The term "perinephritis" was not new, but was used by Rayer in his book on Diseases of the Kidneys, published in 1839. He applied the term to an allied condition including suppurative processes. Three cases were reported in this paper which went to justify the conclusions reached.

Disseminated Sclerosis: An Inquiry into its Alleged Infrequency in this Country, and Its Clinical Manifestations.—Dr. Joseph Collins of New York said that the belief that this disease was of extreme infrequency in this country was unjustified. It had been diagnosed eighty times in the examination of 10,000 cases of nervous diseases, functional and organic. Some of these had been verified by autopsy. Many others, atypical in the beginning, had become most typical while under observation.

Dr. B. Sachs of New York said that during the past two years he had had the opportunity of studying 220 cases of organic nervous disease, and of these there were 15 cases in which a diagnosis of disseminated insular sclerosis was made without a doubt and five in which it was doubtful. In a certain proportion of cases this diagnosis may be made with absolute certainty. There was some difficulty in discriminating between syphilis of the spinal cord and disseminated sclerosis. He thought that absence of abdominal reflexes was so common in cases in which the deep reflexes were exaggerated that one should not attach great importance to it as a diagnostic feature.

Mental Disorders Associated with Acute Chorea.— Dr. B. Sachs of New York said that, while recognizing the existence of a form known as chorea insaniens, a number of clinical experiences would be reported showing the varying character of mental disturbances associated with acute chorea, and proving the simultaneous development of mental and choreic disturbances in the course of, and following upon, toxic and infectious processes. Fatal cases of acute chorea, he said, were at times associated with marked acute endocarditis, with some rheumatic involvement. The name chorea implied a generic group of cases and might be the expression of a general septic or toxic condition.

On Recurrent Acute Pulmonary Edema.—Dr. David Riesman of Philadelphia said that the principal forms of edema described in text-books were (*a*) the acute inflammatory edema accompanying lobar pneumonia and other acute inflammations of the lungs and (*b*) a passive edema occurring usually as a terminal condition in heart disease, Bright's disease, and at times in pneumonia. There were, however, several other forms which, though rare, were nevertheless of much clinical interest. He called attention to the edema that recurred from time to time, and in each attack seemed to place the patient in imminent danger of dissolution. The onset was acute. The lungs and air passages rapidly filled up with fluid, which gushed from the mouth and nose. The fluid was serous, frothy, sometimes blood-tinged, so as to resemble raspberry vinegar. The dyspnea was intense and the patient was ashen pale or deeply cyanosed, and gasping for breath. Over the chest the characteristic râles of edema were to be heard. The pulse was full and bounding, or imperceptible at the wrist. At the height of the attack, the patient appeared to be at the point of suffocation. Like angina pectoris, the first attack of such an acute edema might kill, but more often the condition recurred. Acute pulmonary edema of this type had been met with by Dr. Riesman in association with (*a*) chronic interstitial nephritis, (*b*) arteriosclerosis, (*c*) angina pectoris, and (*d*) asthma. A peculiar edema that in the acuteness of its onset and the gravity of its symptoms resembled the one under consideration, was that sometimes following paracentesis thoracis, of which, under the head of albûminous expectoration, he had recorded an example. The pathogenesis was obscure. In some there was a derangement of the vasomotor mechanism through toxins, while in others there was a sudden weakening of the left ventricle. When there was much cyanosis and a high tension pulse venesection was employed. Dry cupping, atropine, diffusible stimulants, treatment of the underlying conditions during the intervals between attacks, etc., might be resorted to.

Dr. Francis B. Kinnicutt of New York said that the pathogenesis of this condition was certainly a varied one, and his conception of the sudden pulmonary edema occurring in arteriosclerosis was different from that described. In cases of arteriosclerosis there was a condition of hypertonicity of these vessels, and when sudden pulmonary edema appeared there must be some impairment in the integrity of the myocardium. There might be some vasomotor spasm, but not a paralysis. There was a rapid and sudden dilatation of the left ventricle.

Dr. E. G. Janeway of New York said that there were other eliminants than the serum which was going into the pulmonic area in these cases.

Dr. Shattuck of Boston reported a case of pulmonary edema of large extent which rapidly cleared up under the use of nitroglycerin.

Dr. Francis B. Kinnicutt asked if any present had used adrenalin in cases of pulmonary edema, and he reported a case in which the condition cleared up remarkably under its use.

Dr. S. J. Meltzer of New York said it was dangerous to use adrenalin in pulmonary edema.

Dr. Forchheimer of Cincinnati had had the same results with adrenalin as Dr. Kinnicutt had.

Dr. Joseph L. Miller of Chicago said that it was a common experience when working with animals to have them die suddenly from pulmonary edema when adrenalin was used.

Dr. W. S. Thayer of Baltimore said that in giving adrenalin to animals the blood pressure in the greater circulation arose enormously while that in the lesser rose but very little if at all.

Dr. S. Solis-Cohen of Philadelphia said that adrenalin applied locally was good in the treatment of vasomotor edema of the larynx; but on the other hand he had seen edema of the larynx caused by the incautious use of adrenalin applied in this way.

Dr. Richard C. Cabot of Boston said that the trouble with therapeutics to-day was that we did not treat patients without drugs in order to give a basis for observation. The last case of pulmonary edema he saw recovered without any treatment whatever.

Dr. W. G. MacCallum of Baltimore said that with a cannula in the pulmonary vein the injection of various drugs into the circulation did not affect either the pulmonary pulsation or pressure, and possibly the effect of adrenalin was in stirring up the left ventricle, thus pumping away from the lungs the stagnant blood.

The President said that the cases of pulmonary edema that he had seen certainly stirred one's blood because of the intense suffering shown, fluid flowing from mouth and nose. In one case the patient was not breath-

ing rapidly, but was covered with cold sweat, and the urine was passing in large amounts. The remedy that gave him the best results was morphine used in connection with nitroglycerin. One patient had five attacks, and strychnine and digitalis were used without any effect, but a dose of morphine and then nitroglycerin acted promptly for the better. He reported two other cases that recovered rapidly under the same treatment.

Dr. Babcock of Chicago asked if any had used atropine in these cases. He recalled a case of acute pulmonary edema in which 1-50th of a grain of atropine was followed by rapid recovery.

Dr. John H. Musser of Philadelphia called attention to the element of shock in those cases in which there was pallor, sweating, and other symptoms of shock. Morphine in such cases was of great value. He also relied upon nitroglycerin. One should be careful to make the differential diagnosis between this condition and dilatation of the heart, because the treatment of each was diametrically opposed.

Dr. James Tyson of Philadelphia said he never wanted a more satisfactory remedy than atropine in cases of acute pulmonary edema.

Dr. William H. Thompson of New York said that he had received letters from Adami and Osler in which they stated that the pathogenesis of edema or stagnation of the circulation was unknown.

Dr. H. A. Hare of Philadelphia said that one should bear in mind the fact that pulmonary edema was not an entity and that when there was high arterial tension adrenalin would do harm, and that it would do good if there was a low arterial tension.

(To be continued.)

THE AMERICAN THERAPEUTIC SOCIETY.

Seventh Annual Meeting, Held in New York, May 3, 4, and 5, 1906.

Carl Beck, M.D., President, in the Chair.

(Special Report to the Medical Record.)

FIRST DAY—THURSDAY, MAY 3.

Presidential Address.—Dr. Carl Beck of New York took "Gallstone Disease" as the subject of his presidential address. He thought it unfortunate that some well-known surgeons were at present making the attempt to draw analogous lines between appendicitis and cholelithiasis; for appendix and gall-bladder, in the anatomical, physiological, and clinical sense, were two entirely different organs. In cholelithiasis the essential feature was a foreign body, the stone, and this was not the case in appendicitis. Such conditions as cause a stagnation of bile favored the formation of gallstones, and the bacterium was now acknowledged to play a leading part in such formation. There must, however, be a third agent, not yet definitely known, which, acting in conjunction with the other two factors, favored the process. It seemed to him that tissue changes must be prominent in this action, and that this point ought to be determined in the laboratory. Especially did the matter of hereditary predisposition speak for such an assumption. If we summed up the main etiological factors, we found that in general the gall-bladder was the shop for the manufacture of gallstones, not merely a receptacle, as in the case of the urinary bladder. To Naunyn was due the credit of establishing the differentiation between a regular and an irregular cholelithiasis. He had classified the first as among those processes which do not complicate themselves with noteworthy signs of inflammation, while he regarded the irregular cholelithiasis as a condition manifesting itself by the additional appearance of inflammatory signs. The recognition of these two distinct forms, Dr. Beck thought, afforded the solution to the question as to whether in any given case medical or surgical therapy was to be employed. He then considered briefly the medical and dietetic treatment, and, having remarked that the surgery of the bile passages had existed only since the genius of Langenbeck, in 1882, found the means of removing the stone-bearing gall-bladder, took up some points of technique in the operations performed for the relief of cholelithiasis. Later he stated that in a large number of gallstone operations performed in hospital and private practice, he himself had only exceptionally found it necessary to extirpate the bladder, and that while some surgeons now recommended ectomy as the normal procedure in cholelithiasis, he was unable to see, in the majority of instances, the reasons for so radical a measure.

Sarcoma of the Orbit and Temporal Region Successfully Treated by a Combination of Operation and X-Rays.—Dr. Carl Beck presented a patient, the wife of a physician, whom he had brought before the Society three years ago. The sarcoma from which she suffered had been treated by a combination of operation and *x*-rays, and he had been astonished at the result. The eyeball had been enucleated by Dr. Roosa, and soon afterward a large tumor appeared, extending over the temporal region. This was operated upon by Dr. Beck more than four years ago, and then treated, somewhat timidly, he had to confess, with the *x*-rays. Three months afterward there was a recurrence, and now the *x*-rays were administered more powerfully and at shorter intervals, producing a burn of the third degree. After this the whole sarcomatous growth disappeared, and it had never again recurred. The patient had had *x*-ray treatment from time to time, and at present she was suffering from a small burn resulting from it, which was gradually healing. The sarcoma now appeared to be cured, and the general health of the patient was very good. Dr. Beck said that from a scientific point of view this seemed to be very satisfactory, but he thought it necessary to add a word of warning—not to generalize from this case. He certainly did not feel justified in claiming that the *x*-ray was a cure for sarcoma. Unfortunately, there were many cases of the disease in which this agent had no effect whatever. The employment of the *x*-ray here was merely empirical.

Therapeutic Effect of Sound Waves, or Mechanotherapeutics of the Ear.—Dr. C. J. Blake of Boston read this paper. His object, he said, was to show that the application to the organ of hearing of that mode of motion which it is especially constructed to transmit, and to perceive, of course, justifiably, under the head of mechanotherapeutics, and that this claim was demonstrably determinable. In the course of his remarks he stated that, in view of the fact that a secondary muscular contraction is best overcome by prolonged and gentle traction in the opposite direction, the desired release could be best effected, through utilization of absorption of air by the skin, by stopping the external auditory canal by means of a cotton and waxen plug, after the method of Politzer. If at the time when the case came under observation the posterior segment of the drum-head had already become relaxed, the stretched portion might, advisedly, be reinforced by the application of collodion before the plugging process was resorted to, and in all cases it was well to supplement the grosser mechanical treatment by the motive application of sound waves. This might be done by means of various sound sources, but most conveniently by means of the human voice concentrated upon the ear through the medium of a speaking tube; a convenient instrument being the ordinary paper mailing-tube, two inches in diameter, its lumen partly closed, midway of its length, by a ball of loosely rolled wool, serving to decrease the resonance of the tube in its reinforcement of the sharp upper tones of the voice. Dr. Blake's conclusions were: That application of sound waves to the ear for therapeutic purposes is the application of a form of massage commensurably proportionate to the delicacy of the sound-transmitting structures of the middle ear and labyrinth; that the prolonged use of tones of excessive amplitude and very low or very high pitch, whatever their beneficial mobilizing effect upon the

sound-transmitting apparatus of the middle ear may be, is open to the objection of their prejudicial effect upon the organ of perception; that mechanical reproductions of speech are open to the objection of their accentuation of over-tones and their presentation of a distortion of a familiar sound picture, that of the normal voice; that the natural voice, concentrated upon the ear, is, both in its range and its volume, as well as in the more general exercise afforded by its complexly compounded sound waves and the readiness with which it may be uniformly applied, the safest and, in the end, the best, form of sound source for phonomassage of the ear.

The Underlying Principles of Tuberculin Therapy.—Dr. F. M. Pottinger of Monrovia, California, read this paper. Tuberculin, he said, had now been subjected to the test of time. It had been in continuous use for fifteen years. It had been employed in many experiments upon animals, and its virtues had been tested on human beings. In spite of this laboratory and clinical experience there seemed to be a very hazy idea as to what tuberculin is, how it acts, and what it is expected to do. The speaker discussed, first, nature's method of cure in specific diseases, as it appeared in the light of recent researches; second, conditions which militate against tuberculosis curing itself, and, third, the manner in which specific inoculations with tuberculin aid in the cure of tuberculosis. Nature's method of cure consisted in the production by the organism of defensive bodies in response to stimulation from toxins engendered by the specific microbe causing the disease. In tuberculosis, owing to the character of both the bacillus and the tubercle, this specific toxin failed to gain access to the blood in proper quantities, and at the proper intervals, to be effective. It was plain, therefore, that here there was a failure on the part of nature to bring about a cure. In this connection it was well to remember, however, that too great stimulation was harmful, and would defeat nature's purpose, just the same as a failure of stimulation. That in tuberculosis the blood was deficient in protective substances was shown by the measurement of its opsonic power. This, as a rule, was below the normal standard. That the opsonic index in patients with tuberculosis can be raised by the injection of tuberculin had been established by Lawson and Stewart, Wright, Bullock, and others. Their observations were in harmony with those of Koch, Moeller, and others in regard to the increase of the agglutinating power of the blood after the administration of tuberculin. This increase in the agglutinating and opsonic power of the blood meant that the natural defenses of the organism had been increased. The opsonic power was that power of the blood serum which prepared the bacilli to be destroyed by the leucocytes. In an instructive series of cases tabulated by Lawson and Stewart the leucocytes of patients treated by ordinary sanatorium methods were able to destroy only 75 per cent. of the number of tubercle bacilli that a normal person's blood should destroy; while the leucocytes of the same patients, after treatment by tuberculin, were able to destroy 19 per cent. more than the leucocytes of a normal individual. The value of this increase in the natural defenses of the organism was evident. The one reason why tuberculosis killed was because of its tendency to spread to new tissues, either adjacent or distant, and it had long been claimed by those familiar with tuberculin therapy that the disease shows much less tendency to spread in those cases treated with tuberculin than in those treated by ordinary methods. In the light of these new discoveries in immunity and immunizing treatment the beneficial effect of tuberculin was readily explained. This immunizing action of tuberculin was not, however, its only method of aiding in bringing about a cure. Tuberculous areas were naturally very slow in healing. Tuberculin, when administered in proper doses and at proper intervals, furnished a stimulation for these areas which hastened healing by stimulating the formation of fibroid tissue. Theoretically, then, tuberculin had a firm foundation on which to stand.

Turning now to its clinical workings, Dr. Pottinger found that these confirmed the theory. The real test of tuberculin, he said, was in pure tuberculosis. After destruction of tissue had taken place, after other organisms had entered the field, after the general constitution had become undermined, after consumption had supervened, then we should not demand a cure by tuberculin. Nothing short of the elixir of life would be a specific for such a condition. While he believed that tuberculin was of great value in chronic non-febrile cases of tuberculosis, yet it was in early cases that we should expect the most brilliant results. In a former paper he had collected data of 1,200 first-stage cases of tuberculosis. Of these, 611 were treated in sanatoria, with ordinary open-air treatment, with a result of 391, or 64 per cent., being apparently cured. Five hundred and eighty-nine, most of whom were treated outside of sanatoria, were treated with tuberculin, with a result of 496, or 84.2 per cent., being apparently cured. This showed 20.2 per cent. more apparent cures with the tuberculin than without. Another test of the value of tuberculin was the permanency of results. Although the comparative results of very few observers had been recorded, the general experience was in accord with that of Trudeau and Turban, and it was generally accepted that cases treated by it showed less tendency to relapse. In harmony with this was the observation of Bulloch upon the opsonic condition of patients who had been treated for tuberculosis. He examined the blood of fourteen well-to-do patients who had undergone sanatorium treatment with so-called satisfactory results. In every case but one the opsonic index was low. In at least one, which was called a perfect cure, the disease had relapsed within a year. This was also in harmony with the experience of Spengles, who stated that a patient whose agglutinating power is low stands a much greater risk of relapse than one whose agglutinating power is high. Another clinical proof of the value of tuberculin was its action upon local visible tuberculosis, such as is found in the larynx. Most observers were of the opinion that tuberculous laryngitis is almost absolutely fatal. Such a prognosis was not justifiable if the disease were treated in the proper way. Here no remedy offered so much hope as tuberculin. The dosage could be absolutely controlled, and with patience and perseverance a cure could be obtained in a large percentage of cases, even after ulceration had occurred; although the lesser infiltrations were easier to treat and offered better chances of a cure. Among fifteen cases recently reported by the speaker to the National Association for the Study and Prevention of Tuberculosis, the lesions healed, so that there was no further reaction to tuberculin, in eleven instances. These results were not obtained quickly, the treatment extending over several months, and in one or two instances over many months. Having quoted some results by other observers, he went on to say that recent reports from Wright and Bullock showed that tuberculin could be used to advantage also in other forms of tuberculosis, such as ulcerations of the subcutaneous tissue and bone, invasion of the lymph glands, and infections of the genitourinary system. With the mass of evidence before us, he said in conclusion, we must admit that tuberculin therapy was in accord with the modern ideas of immunity, that theoretically tuberculin was capable of increasing the natural defenses of the organism, when given in the proper manner, and that clinical experience warranted a more general use of it in combating tuberculous infection.

The Therapeutic Value of Ergot.—Dr. O. T. Osborne of New Haven, Conn., read this paper. He regarded the fluid extract as by far the most efficient preparation of the drug, and recommended its hypodermatic use in the majority of instances. He advocated the administration of ergot in a considerably larger number of affections than it is commonly employed for. He had found it especially serviceable in hysterical conditions and in diabetes insipidus. He believed it to be useful also in cerebrospinal men-

ingitis and in overcoming the intestinal paralysis often resulting from abdominal operations in which there is much handling of the bowels. He furthermore expressed the opinion that ergot has a distinct effect in intensifying the action of morphine.

The Medical Treatment of Gallstone Disease.—Dr. R. W. Wilcox of New York read this paper. He said that, voluminous as was now the surgical literature upon the subject of gallstones, a careful consideration of the matter led him to place surgery as adapted only to stones of gall-bladder origin, and then only under conditions demanding mechanical relief. The field of surgery here was very limited, though surgery was of great importance when indicated. In other words, the treatment of gallstone disease was practically entirely medical, while that of gallstones themselves was generally surgical. If this distinction were kept clearly in mind, more would be expected of the internalist, and fewer disappointments laid at the door of the surgeon. Gallstones were either hepatic in source or were formed in the gall-bladder; the former being by far the most common. Having referred to the microbic origin of gallstones, he said that the treatment of microbic causes of the stones was the treatment of the infection itself, and the limitation of the opportunities for entrance of the infectious agent. He then spoke of the mechanical causes. Among these was chronic venous congestion of the portal system, the great underlying cause of the gallstone disease. As to extraneous causes, anything which reduced the vitality of the individual was predisposing. Stating that the causes thus far mentioned called for treatment which was chiefly prophylactic and practically medical, he referred next to some of the results of gallstone disease, such as diabetes, pancreatitis, and the so-called intermittent hepatic fever. In regard to surgical procedures it was to be borne in mind that the diagnosis must be established by the physician and that the surgeon should be held responsible only for the relief of mechanical conditions. As to medical treatment in general, the Spa treatment appealed to many. Success was based upon the fact that there the patients' diet and habits of life were regulated and the salines diminished congestions and inflammations in the portal area. Equally good results, he thought, could be obtained at home. Exercise in the open air and a properly regulated diet were very important. As to medicines, salicylic acid was an excellent cholagogue and phenolphthalein a safe and prompt curative, whose antiseptic effects were prolonged through the whole length of the alimentary tract. The following combination pill Dr. Wilcox found most serviceable, increasing peristalsis, allaying nausea, and acting as a carminative as well as an intestinal antiseptic: Salicylic acid and acid oleate of sodium, each 1½ grains; phenolphthalein, 1 grain; menthol, ¼ grain. Four to eight pills were given in a full glass of hot water once or twice daily. The salicylic acid should be obtained from natural sources, and the acid oleate of sodium carefully prepared. The latter, like salicylic acid, was excreted by the epithelium of the bile ducts to assist in disinfection. Both bile as a whole and its salts were uncertain in action. Sodium glycocholate was the best of the salts. Having given the details of two illustrative cases, he said that the conclusion we should reach was that gallstone disease is not purely a disease due to a foreign body, but is primarily a hepatic disorder. The removal of these stones had but little to do with the cure of the patient, for when the end result, the removal of the gallstones, had been accomplished by the surgeon, the patient was but at the commencement of his treatment to remove the cause of the disease, which was entirely within the province of the physician. It was the congestions and inflammation in the domain of the portal system, the infectious catarrhs of the bile ducts and bladder, and the faulty bile formation in the liver, that required attention, and the problems thus presented were purely medical. The elimination of gallstones of the hepatic variety was generally rapid. That they might be painless was best accomplished by the administration of amyl valerate, 15 minims in capsule, two hours before breakfast and after supper.

Duties and Responsibilities of Medical Practitioners in Their Relation to the Border-Line Diseases.—Dr. T. E. Satterthwaite of New York read this paper. He thought it very unfortunate that the text-books of medicine paid so little attention to the management of diseases on the border-line between medicine and surgery. It was quite exceptional to find such affections considered in a judicial way from the dual standpoint of the physician and the surgeon. For example, in one of the most recent works on practice appendicitis was regarded as so preeminently a surgical disease that it was held to be proper for the physician, immediately on the recognition of this trouble, to turn the patient over to the surgeon. It was stated that there was no medical treatment for appendicitis, the author entirely overlooking the fact that medical treatment is by no means synonymous with medicinal treatment. Such an attitude placed the physician in a false position, where he not only jeopardized the prospects of his patient, but rendered himself liable to adverse criticism. The same criticism might be directed against the medical practitioner when he was called upon for a professional opinion in the treatment of the twenty and more other diseases on the border-line between medicine and surgery. In all these there were times when the physician might very properly ask himself the question, Is this an operative or a non-operative case? The affections referred to were abdominal and pelvic tumors, cirrhosis of the liver, pancreatic diseases, morbid collections in the kidney, chronic Bright's disease, cholelithiasis, intestinal hemorrhages, obstruction or traumatism, enlarged prostate, pleurisy or pericarditis with effusion, acute or chronic mastoid disease, diseases of the accessory sinuses, malignant tumors in general, epilepsy, hemorrhoids, and even habitual constipation. The present relation between medicine and surgery made it obligatory on the part of the conscientious practitioner to keep himself thoroughly informed as to the comparative advantages of all the methods of treatment in vogue, not only as applicable to any given case, but to the various phases of it; so that he might be prepared at all times to give his patients the benefit of that treatment which presented the best possible prospect of relief. To this end he should be familiar with all the latest improvements in the treatment of disease, whether they were medical, surgical, mechanical, hydriatic, dietetic, or even psychic; and particularly should he be able to form and give intelligent opinions as to the question of operative or non-operative measures in any of the affections mentioned. The physician would thus be prepared to enter the consulting room armed with definite data, from which to draw intelligent conclusions, perhaps in the light of other facts elicited by the surgeon or brought to his notice by the patient or his friends. The average physician undoubtedly excelled the average surgeon in diagnostic ability, and surgeons were now disposed to admit that their increasing success was chiefly dependent on closer attention to diagnosis, including not only a more thorough study of their patients' histories and symptoms, but also the use of aids the physicians more especially recognized, such as pathological and laboratory teachings and the newer methods of physical examination. Of course, such surgical success was to some extent attributable to improvements in technique, but this was only a minor element in the result. If, therefore, the physician excelled the surgeon in the matter of diagnosis, what could conduce more to the successful issue of a case than that each should contribute his quantum of information and experience in these border-line diseases? Under certain circumstances a surgeon might urgently need both the counsel and the cooperation of the physician. If, for example, the chances of life were going to be slightly improved by an operation, but the surgeon hesitated, perhaps because his personal experience had been unfortunate in this particular line of affections and he dreaded the idea of adding another to his list of failures, it would then become the imperative duty

of the physician to urge the operation, as holding out the best prospects for a successful issue. The speaker said that while he was perfectly willing to admit that in appendicitis the surgical operation had saved many lives which would have been lost under non-operative treatment, this was very far from saying that all cases of the disease should go to the surgeon. He then discussed very fully the indications calling for operative interference in appendicitis and the circumstances in which this should be withheld. Having paid considerable attention also to pyelitis and peritonitis, he went on to say that in nearly all the border-line affections he had enumerated (the exceptions being possibly diseases of the pancreas and certainly pyothorax and certain suppurative diseases of the abdominal cavity, such as of the liver and spleen), nonoperative treatment, and certainly prophylaxis, on the part of the medical attendant, was of recognized utility. His contention in this paper, however, was this: In all the affections referred to he would have the physician fully informed as to the best methods of treatment, whether medical or surgical, the proper time to call for surgical advice, and the chances of the patient's recovery under surgical, as against medical, treatment. More than this, he would have the physician qualify himself to make the diagnosis in all these cases, and be ready to sustain the surgeon should an operation be deemed advisable. Finally, he would urge that future text-books of medicine should contain not only the latest diagnostic data in these border-line diseases, but the most recent statistics of successful treatment, whether by medical, surgical, or any other means.

(*To be continued.*)

SOCIETY OF MEDICAL JURISPRUDENCE.

196th Regular Meeting, Held at the Academy of Medicine, New York City, March 12, 1906.

The President, Dr. Carl Beck, in the Chair.

Medicine and Law in Relation to the Alcohol, Venereal Disease, and Tuberculosis Problems.—Dr. S. A. Knopf read this paper (see page 857).

Mr. Robert Hunter said that it was interesting to note a physician becoming a sociologist, as Dr. Knopf evidently had, but he could not say that he, Mr. Hunter, a sociologist, would ever become a physician, although he might end as one. It was difficult to discover any reform for the many difficulties which were shown to exist by Dr. Knopf, who took only a small part of the social problem, and it showed the necessity of immediately getting at the questions which all physicians met with. He supposed that all physicians took a broad view of the problems; if they did they would all in the end become sociologists. Mr. Hunter said that it seemed to him that the problem of drink, although statistics might be against him on this point, never seemed so bad in this country as in others. For instance, in England, Liverpool, etc., hopeless drunkards were met with, and, in this country, we were relatively free from that evil. In Russia, especially in Moscow, one saw thousands of men in the great public squares drunk; the same condition was met with in various other cities of Russia where it was less serious than in some other countries. However that might be, there was no reason why some of the remedies Dr. Knopf had spoken of should not be applied in this country. The work of saving ourselves or the people from becoming so degraded, utterly and hopelessly degraded, as they were found in some other cities, should be continued. The economic laws are forced upon settlement workers among the poor more powerfully than upon anyone else, except, possibly, the physicians. The misery and wretchedness met with had caused the sociologist to take a deeper interest in the medical side of the question, to see if preventative measures could not be effective in stamping out these evils. But so many economic laws were involved with so many other things that he wondered if it was possible to make any definite generalizations upon the matter. For instance, after ten or twelve years' study, he said he could not tell just how much drink was responsible for poverty, or poverty responsible for drink. Starting with the feeling that most poverty was due to drink, he had come at last to the conclusion that poverty itself produced drunkenness. For instance, he had known many cases in which men had not been drinkers until they had suffered some financial loss; when they had heard their children crying for bread they had gone out and gotten drunk. Some drank themselves into insensibility; some, when they became discouraged with life, went down quickly. He had seen these cases so often that he now believed that the influence of drink in producing poverty had been overestimated. The same thing he believed to be true with regard to tuberculosis. Unquestionably there were many men brought to poverty through tuberculosis. Tuberculosis was a long disease. When a man acquired tuberculosis he went home sick, and his illness continued over a period of one or two years. During this time his wages were cut off and he came to poverty. On the other hand there were many people who lived in poverty and who acquired tuberculosis; here it was not the cause, but the result of poverty. Our biggest death rate was from tuberculosis among the very poor. When one went up the social scale the death rate from tuberculosis declined. This was true also of inebriety. On the East Side, among the Americans, the Irish, etc., drunkenness was found almost universally, and tuberculosis almost universally as well. In other words, when one tried to get at the cause of poverty, the worst social evil, one was baffled, and no definite generalizations upon it were possible. We did know that social conditions did produce an enormous amount of poverty, and that poverty, tuberculosis, and inebriety were the results of bad industrial conditions. The bad wages paid to shop girls in department stores produced prostitution. After referring to Henry's article in *McClure's Magazine* he said that girls in the city wanted joy and happiness in their lives, and prostitution was the only way for them to get pleasure; with the wages they were getting they could not afford it otherwise.

If one got back to economic conditions one got back to the conditions which produced tuberculosis as well. Mr. Hunter said that he was particularly interested in having the subject brought before the public,—the whole social question. He said that he had helped Dr. Knopf in getting started the Tuberculosis Commission in New York City. Before that he had gotten such commissions started in Chicago and elsewhere. Mr. Hunter did this because he wanted the social problem brought up. He wanted the people in New York to know the social conditions that were present, and that were producing the frightful mortality from tuberculosis. He also wished to show them that social conditions were producing inebriety. He said he was convinced that the present social system was at fault in producing despair, discontent, and finally drunkenness. That also obtained in regard to prostitution and the results of prostitution. In other words, he said that while he was amazed at the reforms Dr. Knopf had suggested, because of his very fertile mind, yet he believed we must get back more and more to fundamental social conditions. He wondered if they could get at the problems presented until better wages, better hours, and proper tenements were provided. In every home some girl had gone wrong, the husband had become a drunkard, or some member had been lost from tuberculosis, the result of the miserable state of hopeless, wretched poverty. When one got above this lower scale of life, things were better. Among the skilled workers the wages were better, the tenements were better, and all was better. Their children were growing up, and were going to be a credit to the State. The further up one went in the scale, the better were the conditions met with.

Dr. T. D. Crothers said, in part, that consumption and alcoholism were very closely associated. In clinical experience one followed the other very frequently. The subsidence of one was marked by the appearance of the other. The problems of their relations had been scarcely studied,

and a very interesting field awaited the explorer in this direction. The problems of alcoholism in practical life were coming into greater prominence daily. In medical circles diseases associated with this factor were more serious and destructive, and the knowledge of this altered materially the question of diagnosis and treatment. In legal circles the problems were also increasing, and becoming more and more imperative, demanding solution. Thus crimes of all kinds committed by persons evidently poisoned by alcohol at the time of the commission of the act, raised innumerable questions of responsibility. Wills written by persons under the influence of spirits, important contracts made and signed in this condition, and criminal acts and conduct in which the persons were using spirits, all brought out the question of what could be done, and where the proper rational means for the prevention should be sought. Such cases were constantly coming into court. The counsel turned to the physician for help. There was some abnormality in each instance. The acts were without the pale of reason, and the continuous use of spirits clearly disturbed the natural common-sense line of conduct of the person. The lawyer turned to the rulings of judges in similar or allied cases, and the physician to text-books of medicine and medical jurisprudence. Both failed; while the lawyer found rulings that apparently applied to such cases, he was conscious that they did not comprehend or recognize the real facts at issue. The more closely he studied these facts, the wider seemed the discrepancy between them and the theories of the law. The judge recognized this inconsistency, but was forced to follow lines of previous rulings, and only along certain narrow limits dared he venture to express opinions at variance with others. The legal theories of these cases were the outgrowth or the moral teachings of past centuries. Such teachings showed that inebriety was moral depravity innate in every life, always ready to grow and develop, and particularly from willful neglect and gratification of the lower animal instincts. Also that inebriety was always a phase of savagery, an inborn tendency to lawlessness, and giving up of restraint and control; indulging the passions, regardless of society or the interests of others. The remedy was punishment, suffering, pain, and in this way building up the moral power to control the lower animal.

Lord Coke's rulings, three centuries ago, that inebriety always aggravated the offense, and should be followed by increased punishment, had been accepted and acted upon as the central truth since that time. The physician who was called into court to assist in reaching equitable decisions in such cases found little or no help from the text-books. Dogmatic statements that were obviously unsound and in conflict with the facts comprised the largest part of the so-called authorities on this subject. The physician turned to a study of the cases and sought to find out the facts as they were presented in real life. Here a new world of truth confronted him. The teachings of modern science opened up a new world of facts that indicated clearly the physiologic nature of all brain activities—facts that showed the influence of heredity, of injuries, of disease, of strains, of drains, of failures, of diet, of surroundings, of culture, of ignorance, and all the vast ranges of influences and forces which entered into the acts and character of each one; facts that showed a march downward, and progressive degeneration, or development and evolution. It was from this evidence that the questions of responsibility and capacity to act sanely at any time and under any circumstances should be studied. No legal responsibility could be solved in inebriety from any other point of view, or from any theories. It was a pure question of facts, not theories of the law, or rulings of judges. What was the history of the man and act in question? If these were clearly ascertained the problem would be solved. If one had failed to do this, confusion, injustice, and wrongs followed. The legal responsibility of inebriety as administered by courts to-day was a farce. A new jurisprudence was demanded, a new scientific study and recognition of these subjects and their disabilities was called for. This demand was felt in every court of justice by clear, thoughtful men.

Judge Alfred E. Ommen said he would consider the question of alcoholism as he met with it; not as it was found in law books or discovered in sociology, but as it came before him day after day in the courts where he was a magistrate. Here he met with a great number of these people who were called "regulars." When one of them appeared, the officer on the bridge would call out "regular." It meant that the man or woman had been before the magistrate before for drunkenness. One could not speak of punishment of these people. If sent up to the island for two, four, or six months, when they came out they would go on another drunk. These people would spend ten or eleven months of every year on the island and punishment would have no more effect than gin on a negro. Then, again, there were many people who came in occasionally—fine, intelligent men, college graduates, men of wide knowledge and experience—they occasionally came into the magistrate's court. To such men it was only necessary to say, "Come on and behave yourself." The former class of people one could not educate nor treat. To state that one could was simply theory, and not fact. This was a very serious proposition, and these men could not be gotten hold of in the way proposed. Their moral nature was gone. Blackwell's Island was for them. Drink was all the fun they got; they got gloriously drunk and were sent back to the island. Some of the medical profession would, no doubt, like to squirt some gold into them, but it would do no good. This was a very serious proposition to solve. Alcoholism caused a great deal of crime and a great deal of distress in this city; but he had his own remedy, which worked very well in many cases. Frequently he had seen fine fellows come before him, accompanied by wife and children; the wife had pleaded with him, stating that he was a good man, husband, and father so long as he kept away from rum. He asked what good would come from sending such a fellow to the island; it would not do the wife any good, and frequently he tried, and successfully, to scare him by saying that he was thinking of sending him to the island for six months, but that if he would promise to behave himself and take the pledge before him as witness he would give him another chance. The man would promise, would sign a pledge, promising not to drink again, it would be properly witnessed, and then it would be handed to the wife, with the statement that if he again got drunk, the broken pledge would be handed to the magistrate and the six months' sentence would be imposed. He said he had had half a dozen wives at least return at the end of six months and state that their husbands had not drank since; that the children now had shoes; that they had new carpets on the floor, etc. That was the way to treat alcoholism as met with in every-day life.

It seemed to him that the basis of a cure of all these conditions was founded upon *home life*. That was the strength of this country—home life. We were getting away from it to-day, and tuberculosis and venereal disease would not be cured until one bettered the home life. There was no doubt about the truth of this statement in his mind. The scientific treatment must be gotten by moral force. Teach the neighbor that it is a disgrace to be drunk or drinking; make this suggestion to him face to face, and probably the fellow would behave himself. There was more drinking by women to-day than at any time before in this city. At the Waldorf-Astoria one could see every day intelligent, respectable women drinking highballs and cocktails. They came from the twenty-story apartment houses, where they lived in furnished apartments, eating in restaurants, with the children not having a decent place to play in, an apartment with two or three rooms and bath, where 2,000 or 3,000 people live in one building, like the Ansonia; this he believed was what was ruining the social fabric of the family. The splendor, the dazzling, the wine, the song, the life of to-day was injuring the social fabric of the

city. Fifteen years ago one took a lady to the theater and, when the play was over, she would be asked to have ice cream or lemon soda, and that was the limit; but now nothing was said after the play; the man would take her to a restaurant, sit down, and immediately say to the waiter, "Bring two Manhattans." Then he would say to her, "Now what?" That was the condition that existed to-day.

He did not think one could do anything by making more laws, as suggested. He was opposed to the proposition to open the saloons on Sundays. The less opportunity for the poor man to get rum, the better city we would have. He studied the problems as he met them. He believed in bettering the home life spirit, and instilling into men that moral life was a gain and gave better results than would be possible from any scientific conversation.

Mr. John C. West said that he regretted that Judge Ommen had failed to say anything on the advisability of forming a temperance society among the lawyers, and that he would be glad to have the judge's opinion on the subject.

Dr. L. Duncan Bulkley said it was entirely excusable and proper that the society should have had this paper read, because it opened the eyes of many to very important thoughts. Some ten years ago he had read a paper on this same subject before this society and made a plea for a legal control of syphilis and venereal diseases. A discussion followed, and, as a result, a committee was appointed, who held several sessions for one year, the two professions being combined in their efforts to learn of one step to control this "great black plague." He said that tuberculosis was called the great white plague. Nothing ever came from the combined efforts of these two professions.

He called attention to the fact that at Brussels two or three international congresses had been held and a national society formed in New York, this latter one being called "The Society of Sanitary and Moral Prophylaxis." He said the Charity Organization Society had taken up this subject, and Mr. Devine had started the opening wedge in venereal disease, by publishing in *Charities* an aritcle emanating from the new society, and he hoped the Society of Medical Jurisprudence would get into this society, a small fee of only two dollars a year being required. Dr. Bulkley said he stood solely and entirely as a defender of the innocent, and referred to his work of twenty years ago, when he began his study of syphilis in the innocent. He started this study with physicians and nurses, and then extended it greatly. He spoke of one Russian town with 30,000 people with syphilis contracted innocently. He said it was not only the physician's duty, but the lawyer's duty as well, to take up the task of enlightening the people. He asked that all present buy the last issue of the paper issued by the *Charities* people, which contained important addresses on the topic under discussion—the subject of protecting innocent people from these diseases. They were as right in attempting to protect people from these diseases as they were in protecting them from tuberculosis. Dr. Bulkley had published over 200 cases where innocent syphilis was contracted from shaving, kissing, bites on the ear, etc. One lady he recalled was infected innocently by the use of sticking plaster, a friend licking it and then applying it, resulting in the production of a chancre. He emphasized the great importance of protecting the innocent from syphilis. Dr. Knopf had said that 15,000 out of 50,000 blind people were blind because of gonorrhea, but the speaker believed that 50 per cent. of them were blind from gonorrheal infection. An enormous percentage of women had abdominal operations performed for pus tubes, often with fatal results, that were due to gonococcic infection. This was a subject that was very important, and one that the Society of Medical Jurisprudence should take up. Dr. Bulkley said that he hoped to live long enough to see entered upon the statute books the opening wedge, *i. e.* that anyone who willingly and wittingly communicated venereal disease should be subjected to punishment. That would place the matter in the hands of the Board of Health. He claimed that women of the streets would report these cases, because they had no character to lose and everything to gain. As a result, a man could not go to any house if he was infected. Why? Because the proprietor could be punished. He believed that if this opening wedge was once made, the people themselves would do the rest.

Dr. E. L. Keyes, Jr., indorsed all that Dr. Bulkley had said regarding the Society on Sanitary and Moral Prophylaxis, a society in which he was most interested, among the members of which were a large number of Y.M.C.A. men, men who worked in the settlements, and who looked more on the sociological side of the question. It seemed to him that the universal opinion was that something could be done toward the prevention of venereal diseases by education, especially the education of young persons, regarding matters sexual, so far as they were capable of accepting them soberly. Just what can be told these young men, for instance, a boy of ten or fifteen years, is a matter which can only be decided by the physician himself in charge of that boy. This was a subject that must be handled judiciously, and knowledge must come from a source which would bear weight and personal influence. This was the side of the work that the Society on Sanitary and Moral Prophylaxis was trying to work up. The prevention of venereal disease by education of the young men, particularly of the working classes, was aimed at by this society, showing them the risks they ran, etc., if heed was given to their advice. The moral side of the question of venereal disease did not arise when tuberculosis was considered. Again, many wanted to get drunk, but none wanted to contract tuberculosis. Many were indifferent whether they ran any risk of venereal disease or not. In his own experience everybody considered himself immune to venereal disease until he was caught. The point of innocent infection with venereal disease was one that could be applied very broadly not only to the lady who had a court plaster applied and caught chancre, but also to the young man who had not been given proper education in sexual matters by his father. This was innocence. This young man was not properly prepared to battle with life as he should have been, and, therefore, when he acquired the disease it was innocently acquired. This was the important matter the Society on Sanitary and Moral Prophylaxis was attacking.

Dr. Ludwig Weiss said in part that inasmuch as prostitution was the fountain head of venereal diseases, and in itself an outgrowth of our socio-economic conditions, the suppression or eradication of which was at present beyond our skill, the entering wedge of our interference should come into action as soon as the damage was done. To sterilize the ever-threatening sources of venereal infection, plentiful hospital and dispensary facilities, the latter with evening classes, should be at the disposal of the affected. In endeavoring to hospitalize, isolate, and treat gratuitously we should get as near their inception as possible, and he found the best means was in education, this being the greatest factor in diminishing the spread of venereal diseases. He said that utopian moralists who had the delusive hope of changing human nature in one generation opposed such humane efforts, forgetting the presence of yet viable perennial aberrant cell formation of primeval origin in some brains with their attendant polygamic and polyandric tendencies; their ultimate redemption would surely come about in time. But, meanwhile as the evil consequences of venereal sins do not stop with the transgressor, but spend their loathsome imprint on the innocent, such measures as prophylaxis by treatment are the most rational ones. In the northern countries of Europe where physicians are told to turn in weekly anonymous reports, and treatment is made free and obligatory, venereal diseases have diminished 34 per cent. of late. As to the status of venereal diseases in the United States, according to information gathered by Dr. Weiss, there was not a State, excepting Michigan, that had any laws beside the sanitary police

regulations pertaining to the spread of venereal diseases, making punishable the marriage of persons afflicted with gonorrhea or syphilis that had not been cured. Physicians were compelled to testify. Among continental countries, Hungary had a punitive law against wittingly communicating venereal disease, forbade the treatment of diseased prostitutes as out-patients, made hospital treatment compulsory, and had the wise law of not collecting expenses accruing from such treatment from the place the patient hailed from. The facilities New York extended to venereal patients were shamefully poor, and not one in 5,000 could get hospital treatment. He closed with a strong appeal for more facilities in this respect as the only available means to check venereal diseases.

Mr. Livingston Ferrand said that, after hearing the various speeches made following Dr. Knopf's able presentation of the subject, there were two phases of the subject at issue, one the educational side, the necessity for securing a sound public sentiment, teaching the masses of the people the subject of sociology, and simple facts regarding prevention and cure. The second phase of the question was the necessity for adequate provision for the care of all cases found in our midst. Dr. Knopf mentioned the establishment of sanatoria. Mr. Ferrand believed that if anything was to be done on the preventive side in stamping out tuberculosis, sufficient sanatorium facilities should be provided. A very difficult problem related to the relation of the tuberculosis cause to the State. As yet no sociologist, economist, medical expert, or other had made clear what should be the relation of the State to the establishment of sanatoria. With regard to State aid for private sanatoria, he did not believe in the use of public funds for this purpose. What he did plead for was the establishment of several sanatoria for the treatment of the incipient cases of tuberculosis as well as the establishment of sanatoria for the advanced cases of the disease. He said it was the incurable cases that spread the infection, and if those were taken care of then we would be, in his opinion, able to stamp out tuberculosis.

Dr. S. A. Knopf in closing thanked the distinguished gentlemen for participating in the discussion and expressed his gratitude to the audience for listening so patiently to what he considered after all not such a very delightful subject to treat. In reply to Judge Ommen's severe criticism at his suggestion to have saloons opened a few hours on Sunday, Dr. Knopf said he, too, believed in the religious observance of Sunday; but he could not see why this religious observance, if it had to be enforced, should not be the same for the rich man as the poor. If the selling of liquors on Sundays is not permitted in the saloon even for a few hours, but is permitted through the entire day, even during the hours of church services, at the club, the law is evidently unjust to the poor man. He said, as already stated in his paper, that the saloon is the poor man's club, and it should be just as painful to the gentleman or lady coming from church to see men with their hats on sitting at the windows of the club drinking cocktails as to see the poor man taking a drink in the saloon.

What the honorable judge said of the ever-decreasing home-life in our own metropolis and other large American cities, Dr. Knopf indorsed most heartily; but he could not agree with the pessimistic views expressed by the speaker when he said that all the drunkards sent to Blackwell's Island were hopelessly gone. He was convinced that quite a number of these cases, if they were medically, morally, and sociologically treated, could be cured, and lastingly so.

Dr. Knopf said that he could not add anything to the admirable presentation of the sociological aspect of alcoholism, tuberculosis, and syphilis as presented by Mr. Robert Hunter. There is but one point on which he would venture slightly to disagree with him; that in which Mr. Hunter thought the suggested reforms and changes in law and customs ineffective. When we are confronted in medicine with a disease for which we have as yet no specific remedy, we treat it symptomatically. The specific for treating all these three diseases discussed this evening, may be, as Mr. Hunter thinks, a total change of our social conditions; but as to what kind of a change none of us are quite clear. For this reason the doctor strongly believes in treating these three social diseases by the reforms suggested; in other words, symptomatically until we have a specificum.

Dr. Crother's views, that many alcoholics are born with a defective brain and nervous system because their ancestors were inebriates, and that alcoholism should be treated as disease, had his most hearty indorsement. Concerning the combat of venereal disease Dr. Knopf did not think that his views differed in the essential from either those of Drs. Bulkley, Keyes, or Weiss. Not being an expert on syphilis or gonorrhea, he would gladly leave the medical management of these subjects to others. Prophylactically, he believed that common sense was essential in venereal diseases as it is in tuberculosis. To his mind Koch's bacillus of tuberculosis had no greater enemy than good common sense.

Dr. Weiss had given a hopeful report regarding the venereal disease problem in the Scandinavian countries. Equally hopeful and gratifying are the reports from there concerning the reduction of alcoholism and tuberculosis. The reduction of the former had doubtlessly been due to the inauguration of the Gothenburger System, and the reduction of tuberculosis to compulsory registration and the taking care of all tuberculous patients; for it must not be forgotten that Norway is the only country and New York the only city where the law permits the removal of the careless consumptive, who is a menace to his neighbor, into a detention hospital. Dr. Knopf said it was his privilege to be one of the attending physicians at the North Brother Island Sanatorium for consumptives where this class of patients are treated. It was surprising that, although most of his patients were sent there against their will, their usual rapid physical improvement under improved hygienic conditions soon made of them docile, obedient, and even grateful patients.

Prof. Livingston Ferrand, the Secretary of our National Tuberculosis Association, had given an admirable presentation of the tuberculosis situation concerning the doubts as to what should be the true relation of the State. Dr. Knopf decidedly believed in a State sanatorium for the poor and for those of moderate means. He thought that Prof. Ferrand inadvertently made a slight error in saying that the greatest danger came from the advanced cases. It was, on the contrary, Dr. Knopf's firm belief, based on many years' experience, that a consumptive up and about doing odd jobs or following his regular occupation, but carelessly expectorating everywhere, was the greatest source of danger to his fellowmen. The advanced case confined within four walls is usually taken care of and watched, and even if he should in unguarded moments be careless, the infection is limited to one room.

Dr. Knopf said that all three problems must be treated prophylactically and symptomatically, and it is then immaterial whether alcoholism is treated as a vice or a disease. The venereal patient should be considered as a criminal only when he willingly and knowingly gives his disease to others. In all other instances he should be pitied rather than censured, and always treated expediently and scientifically. With equal kindness and even greater compassion the tuberculous patient should be treated, who, when conscientious, is never a menace to his fellow-men and can be a most useful member of society. In short, all three, alcohol, venereal disease, and tuberculosis problems are not beyond solution. What is required to combat these three diseases successfully is the combined action of a wise government, well-trained physicians, practical philanthropists, and an intelligent people.

The following resolutions were suggested by Dr. Bulkley and referred to the Board of Trustees for approval and further action:

Resolved, That the Society of Medical Jurisprudence place on record its conviction that legal measures looking toward the protection of innocent persons from venereal diseases are eminently desirable.

It was then moved that a vote of thanks should be extended to Dr. Knopf for his highly interesting paper. The motion was carried.

Philadelphia Pediatric Society.

At a stated meeting held April 10, Dr. James K. Young exhibited a girl, ten years old, suffering from "Hydrocephalus Associated with Premature Development." The head was enormous in size, while the breasts were large and the mons veneris was covered with a generous growth of hair. Dr. D. J. Milton Miller exhibited the photograph of a girl, eight and a half years old, suffering from congenital spasmodic right hemiplegia of central origin, and also presenting remarkable development of the breasts and a growth of hair on the mons veneris. Dr. Samuel McC. Hamill presented a series of cases illustrating "Functional and Venous Murmurs in Children." He dwelt especially upon a murmur heard in the pulmonic area toward the close of the systole, inconstant in its presence and best audible in the recumbent posture. He thought the phenomenon due to increase in the diminution of vascular tension common in children. It is at times present in apparently healthy children, and even in cases in which anemia is present this is thought not to be the causative factor. Dr. Hamill also demonstrated "An Abnormal Area of Dullness in the Chest" which is not described in the textbooks. This is present behind the inner third of the clavicle, and is thought to be due to some peculiarity in the disposition of the apex of the lung associated developmentally with infancy and childhood. Dr. H. Lowenburg exhibited "Two Boys with Enuresis Exhibiting Tolerance to Large Doses of Belladonna." The patients were brothers, ten and eight years old, respectively. In one the condition had been of six or seven years' standing, while in the other it had existed from birth. In treatment tincture of belladonna was first administered, the initial dose being five drops thrice daily. This was gradually increased until sixty drops was administered thrice daily. Notable physiological effects being wanting and the activity of the drug being questioned, an equivalent dose of atropine was administered, namely 1-80 grain thrice daily. This was increased to 1-40 grain thrice daily. In both cases the enuresis was controlled, but there was no undue dryness of the skin or mucous membranes or cutaneous exanthem or mental perturbation, although the pupils were distinctly dilated. Dr. D. J. Milton Miller reported "A Case of Pneumonia in an Infant of Seven Months in which Physical Signs were Absent During the Entire Course of the Disease." The temperature was elevated, respiration accelerated and pulse increased in frequency. Cough and expiration were present, and the illness terminated by crisis. There was no opportunity for bacteriologic examination of the sputum or a study of the blood.

New Instruments.

A DEVICE FOR ANESTHESIA IN RESECTION OF THE JAW.

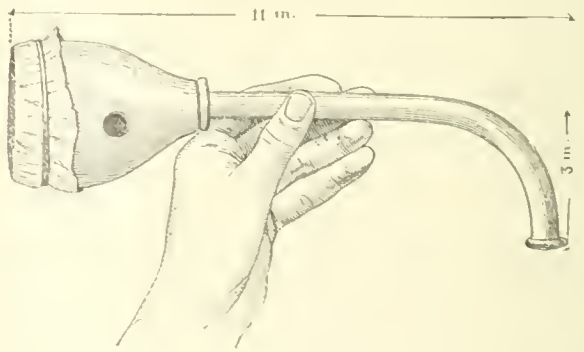
By A. E. Rockey, M.D.,
Portland, Oregon.

Breath and flowing blood, the one every moment necessary to life, and the other, an inevitable consequence interfering with this necessity, combine to make anesthesia in operations on the jaw troublesome, unsatisfactory, and sometimes dangerous. Partial anesthesia in a sitting position, rapid sponging, tracheotomy, intubation with long tube attachment or Junker's apparatus, are means in use. They are only measurably satisfactory, and all open to more or less serious objection.

Several months ago, while assembling my instruments for a total resection of the chin and jaw for cancer, and, no doubt, subconsciously reviewing the steps of the operation, I chanced to see an old and never-used Haegar's ovarian trocar on a lower shelf in the instrument case. Instantly the question of anesthesia in this operation was solved, and in less than five minutes a satisfactory instrument was completed. A few turns of adhesive plaster around the beveled end of the cannula, an old politzer bulb with the top cut off and two air holes at the side, a fold of gauze, and a rubber band, and the device was finished.

To use it, anesthesia should first be induced in the ordinary way. The curved end of the tube tube is then passed back into the throat and the tongue drawn well forward by a stitch passed through it, or by the tongue forceps. The mouth is then packed full of gauze, which compels breathing through the tube and prevents the entrance of blood. Chloroform or any volatile anesthetic is then dropped on the gauze and the air supply controlled by the thumb and finger through the holes in the side of the bulb.

The performance of this simple apparatus has been perfect from the first. The original patient, with a resection extending back of the angles and including the lower lip and chin, is now following his former occupation as director of athletics in a Western college. A recent case in which one side of the jaw and a portion of the cheek were removed, has made a speedy recovery. In both of these operations the lymphatic and submaxillary salivary glands were all removed, as well as extensive portions of the face. The defects were at once closed by plastic flaps. The gauze in the mouth did not require change during the operation and there was no interference with respiration. Profound anesthesia was maintained with ease. The operator and anesthetist are well out of each other's way.



Apparatus for Anesthesia in Operations on the Jaw.

This simple instrument is offered to surgeons and instrument makers for use or improvement. The rubber bulb might well be replaced with a metallic funnel, but I would recommend that the present form and size, both of bulb and tube, be quite closely adhered to. The flange at the end of the tube may be made a little larger, to prevent the gauze from slipping over it and to permit closer packing at the bottom. The accompanying illustration is carefully marked to show the dimensions of the original instrument. The internal diameter of the tube is one-half inch, which is ample for respiration. For me it has served the purpose so well that I shall continue to use the model.

526 Marquam Building.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DIE KOSMETISCHE UND THERAPEUTISCHE BEDEUTUNG DER SIEFE. Second Edition of Book VI. of Dr. JESSNER'S "Dermatologische Vortrage fur Praktiker. 8vo, 58 pages, paper. A. Stuber's Verlag (C. Kabitzsch), Wurzburg. Price, 90 pfennig.

DIE ORTHODIAGRAPHIE. Von Dr. KARL FRANCKE. 8vo, 102 pages, illustrated, paper. J. F. Lehmann's Verlag, Munchen. Price, 4 marks.

THE JUNGLE. By UPTON SINCLAIR. 8vo, 413 pages, muslin. Doubleday, Page & Co., New York. Price, $1.50.

ANNALES DE MÉDECINE ET CHIRURGIE INFANTILES. By Dr. E. PERIER. Vol. X., Nos. 1, 2, and 3. Each 8vo, 36 pages, paper. Redaction et Administration, Paris.

REVUE MENSUELLE DES MALADIES DE L'ENFANCE. Redacteurs en chef Drs. A. BROCA and L. GUINON. Vol. XXIV. January and February Issue. 8vo, 48 pages, illustrated, paper (each). G. Steinheil, Editeur, Paris.

TRANSACTIONS OF THE LUZERNE COUNTY MEDICAL SOCIETY FOR THE YEAR ENDING DECEMBER 31, 1905. Vol. XIII. 8vo, 278 pages, paper. The E. B. Vordy Co., Wilkes-Barre, Pa.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. XXIII. 1905. Edited by RICHARD H. HARTE, M.D. 8vo, 392 pages, illustrated, muslin. William J. Dornan, Philadelphia.

NOTES ON SURGERY FOR NURSES. By JOSEPH BELL, M.D., F.R.C.S., Edin. Sixth Edition. 12mo, 187 pages, muslin. Oliver & Boyd, Edinburgh. Price, 2s. 6d.

BEITRAGE ZUR KLINIK DER TUBERCULOSE. Herausgegeben von Dr. LUDOLP BRAUER. Vol. V., No. 1. 4to, 81 pages, paper. A. Stuber's Verlag (C. Kabitzsch), Wurzburg. Price, 3.50 marks.

DIE BEHANDLUNG DER KRANKHEITEN DER NASE UND DES NASENRACHENS. By Drs. A. ONODI and A. ROSENBERG. 8vo, 468 pages, illustrated, paper. Oscar Coblentz, Berlin. Price 8.50 marks.

OUTLINES OF MEDICAL DIAGNOSIS. 1906. Fourth Edition. 12mo, 33 pages, flexible muslin. F. H. Thomas Co., Boston.

URIC ACID, WITH A DISCUSSION OF THE METABOLISM IN GOUT. By FRANCIS H. MCCRUDDEN. 8vo, 318 pages, paper. Paul B. Hoeber, New York. Price, paper, $2.50; cloth, $3 net.

THE TREATMENT OF SYPHILIS. By F. J. LAMBKIN, R.A.M.C. 12mo, 60 pages, muslin. Bailliere, Tindall & Cox, London, Eng.

THE REAL TRIUMPH OF JAPAN. By LOUIS LIVINGSTON SEAMAN, M.D., LL.D. 12mo, 291 pages, illustrated, muslin. D. Appleton & Co., New York. Price, $1.50 net; postage additional.

A TEXT-BOOK ON PRESCRIPTION WRITING AND PHARMACY. By Dr. BERNARD FANTUS. Second Edition. 8vo, 404 pages, muslin. Chicago Medical Book Co., Chicago. Price $3 net.

PERSONAL HYGIENE. Designed for Undergraduates. By A. A. Woodhull, A.M., M.D., LL.D. 12mo, 221 pages, muslin. John Wiley & Sons, New York. Price, $1 net.

FOOD AND THE PRINCIPLES OF DIETETICS. By ROBERT HUTCHINSON, M.D., F.R.C.P. Revised Edition. 8vo, 582 pages, illustrated, muslin. William Wood & Co., New York. Price, $3 net.

Etiology of Summer Diarrhea in Infants.—G. Volpino has isolated from the stools of eighteen infants affected by severe forms of summer diarrhea a germ that he calls *Bacillus enteritidis infantum*, whose characteristics are half way between those of *Bacillus coli* and *Bacillus typhosus*. The bacillus was not found in the feces of healthy suckling babies, but was found in those of artificially fed babies, whose stools may be always considered somewhat abnormal. The germ was much more virulent to animals than the *Bacillus coli communis*. Its constant presence, its pathogenic characteristics, and its agglutinability with serum of babies sick with acute gastrointestinal disorders all go to show that it is an etiological factor in the production of summer diarrhea.—*Archivio per le Scienze Mediche.*

Therapeutic Hints.

Leg Ulcers.—

℞ Ol. eucalypt. glob..... 1.
Spt. vini dilut..... 4.
Aq. dest.....200.

M. ft. sol. S. Use once daily as an application and to cleanse the ulcer.

Or:

℞ Ol. eucalypt. glob..... 2.
Talci. venet..... 15.

M. S. Apply to the ulcer once daily.—MICHAILOWSKY, in *Russische medizinische Rundschau.*

Hordeolum.—

℞ Hydragyr. oxidi. rubr..... 0.75
petrolati,
Ung. aquæ rosæ.....aa. 15.00

Apply morning and night after thorough cleansing with hot boric solution.—*Mercks Archives.*

Acute Bronchitis.—

℞ Vini ipecac.
Tinct. scillæ.....aa. ♏ x.
Spts. etheris nit.....ʒ ss.
Aq. chloroformi.....ʒ i

M. Sig. At one dose and repeat every four hours.—*Canadian Practitioner and Review.*

Depilatory.—Take two parts of freshly slaked lime, from which all the gritty particles have been removed, and mix with three parts of water. Through this mixture pass a stream of sulphuretted hydrogen; a pasty mixture of bluish-green color is obtained, having a slight odor of sulphuretted hydrogen; it is not in the least caustic, and may be handled without fear. It should be kept in wide-mouthed, brown glass bottles, well corked, as the carbon dioxide of the air decomposes it readily. Apply by spreading a thin layer with a spatula or spoon handle. If the hair is very long it may be clipped off with the scissors first. The paste is left on for five minutes, and then with tepid water and a towel it is removed by gentle friction. The skin will be found completely free from any trace of hair and better shaved than by the sharpest razor. The paste is devoid of irritating properties. It should not be touched with hands wet with bichloride, as the hands will get black from the formation of the black mercuric sulphide.—*The Medico-Pharmaceutical Critic and Guide.*

Bronchial Asthma.—During the asthmatic attack a little chloroform should be inhaled. Hypodermic injections of morphine with cocaine, or morphine (one-third of a grain) and atropine (1-100 of a grain) will bring about the same effect, but this remedy should be reserved for severe paroxysms. Stramonium cigarettes may also be used. A dram of a powder consisting of powdered belladonna, stramonium, and hyoscyamus leaves with some potassium nitrate, burnt and the fumes inhaled, will often bring about relief. Relief may also be obtained by the inhalation of three to five minims of nitrite of amyl from a crushed capsule. Between the attacks the following may be given:

℞ Potassi iodidii.....gr. x.
Tincturæ lobeliæ.....ʒ ss.
Vini ipecacuanhæ.....♏ xii.
Aquæ chloroformi.....ad. ʒ i.

M. ft. mist. S. Two tablespoonfuls to be taken three times daily after food.

The following is a formula recommended by Dr. Burney Yeo:

℞ Potassii iodidi.....gr.xii.
Extracti stramonii.....gr. 1-6.
Spiritus chloroformi.....♏ xx.
Spiritus ammonii aromatici.....♏ xx.
Aquæ.....ad. ʒ ss.

M. ft. haust. S. The draught to be taken just before going to bed.—*Maritime Medical News.*

Goutiness.—

℞ Potass. iodid.....gr. x.
Potass. citrat.....ʒ ss.
Inf. buchu, ad.....ʒ i.

M. S. Ter in die.

If, as is not altogether infrequent, the patient be anemic, five to ten grains of the potassio tartrate of iron may suitably be added to this mixture, which should be taken immediately after the three principal meals of the day.

Or:

℞ Potass. citrat.....ʒ ss.
Spts. æth. nitros.....ʒ i.
Liq. ammon. acetat.....ʒ ss.
Aq. ad.....ʒ ii.

M. S. In a tumblerful of water three times a day.

In connection with spirit of nitrous ether it is important to remember that it must *not* be combined with iodide of potassium, as the result is an explosive mixture.—WILLIAMS in *The Clinical Journal.*

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

The National Confederation of State Medical Examining and Licensing Boards will hold its annual meeting in Boston, on June 4, 1906; the president is Dr. Henry Beates, Jr, of Philadelphia.

New York and Michigan now reciprocate. The *Journal of the Michigan State Medical Society* for May, 1906, says: At a meeting held in Pittsburg on March 18 representatives of the New York Regents and the Michigan Board of Registration made a critical and comparative examination of the New York and Michigan medical acts, and the standards of preliminary and medical education in Michigan, and decided that a license of indorsement should be offered by either State to those who had won a license, by examination, in the other."

Louisiana.—An act is before the legislature of this State to amend the present medical practice act, and to make more suitable regulations for the practice of medicine. Provision is made for examinations as heretofore; and the board is to be empowered, "at its discretion, to waive said examination in favor of any applicant who shall present to the Board a satisfactory certificate of examination from a Board of Medical Examiners of another State, provided, however, that said Board created under this Act shall have found that said Board of Medical Examiners of another State has a standard of requirements satisfactory to the Board created under this Act; the said Board created under this Act to be the sole judge as to the sufficiency of the standard required and of the certificate issued by said Board of another State."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 26, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	404	184
Diphtheria	378	46
Measles	1,111	35
Scarlet Fever	219	31
Smallpox	2	.....
Varicella	111	.....
Typhoid Fever	37	9
Whooping Cough	38	7
Cerebrospinal Meningitis	35	23
Malarial Fever	.....	.....
Totals	2,335	335

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending May 26, 1906:

CIRCUMCISION.

NOTE OF AN UNORTHODOX OPERATION, WITH SOME HISTORIC AND ETHNOGRAPHIC OBSERVATIONS ON THE (NON-SURGICAL) PRACTICE.

By JOHN KNOTT, A.M., M.D., Ch.B. & D.P.H. (Univ. Dub.), M.R.C.P.I., M.R.I.A., etc.

DUBLIN, IRELAND.

One of the by-products of ethnic enlightenment which has been derived from the exploration of the Dark Continent during recent years, is the additional knowledge gleaned therein regarding the cosmopolitan diffusion of the practice of circumcision—at least within the warmer climates. The observations of exploring travelers in sundry remote regions of the world have, during the past half century, added an enormous amount of details to our store of accumulating facts regarding this operation, as practised by the islanders of the remote archipelagoes and the continental savage tribes which had previously succeeded in secluding themselves from the detested encroachments of European civilization. The recent perusal of some very interesting items dealing with this subject in the pages of the *Journal of the Anthropological Institute* brought vividly before my recollection the details of an operation of this nature which I performed some years ago, when spending a holiday retreat in a remote part of the country—under conditions which tended to render the history of the case (and the operation) somewhat primitive in type, as contemplated under either head, and from both aspects. Accordingly, it had the consecutive effect of inducing me to exhume the notes which I had made at the time, and also of awakening the hope that a summary of the same, with some added historical observations on the subject of this operation, might not prove uninteresting to the average professional reader; as they, very obviously, never do to the special students of anthropology and folk-lore.

Circumcision is a proceeding essentially surgical—in its first presentable aspect. By the unrivaled antiquity of its origin, the equally unrivaled extent of its adoption, and the wholly unique characters of its national, racial, and religious associations, it has come to occupy a position which cannot definitely be either compared to, or contrasted with, any other known professional operation. As Dr. Buisson truly and tersely puts it, "Elle a pris place parmi les rites religieux. Sa valeur pratique s'efface devant le symbolisme dont elle est l'expression."

At the date of the operation which forms the subject of the text of the present communication, I was, as I have already mentioned, taking a country holiday. The student (non-medical) who was the subject thereof had imported with him, from Dublin, to the same vicinity, a specimen of gonorrhea, which was just then passing into the subacute stage, and was complicated with left epididymitis. Under those very unfavorable conditions he had, to my surprise as well as disgust, been using the affected organ with the worst results, and indeed under peculiarly nauseating circumstances. After being made acquainted with the facts, I met him at the house of a relative with whom he was staying; and, as he was the subject of a very unusually tight phimosis, I made the—under the conditions extremely heterodox—suggestion of his submitting to circumcision. I was provided with a surgical pocket-case, a supply of iodoform, some absorbent cotton, a roll of rubber adhesive plaster, and a few *et ceteras*. I had full faith in the efficacy of iodoform in the prevention of infection, and felt that the operation would have the very desirable *moral* effect of preventing further inoculation—for a time. I was very much gratified by his acquiescence. The dining room on that occasion was occupied by the host, the patient, and myself. It was an occasion of true Hibernian hospitality. So I procured some boiling water, got our host to hold the patient's hands behind his back, after getting him to swallow a rather large dose of "John Jameson's best"—undiluted; and having exposed the affected organ as he stood in the erect position, I passed a grooved director under the prepuce till arrested by the fornix, and rapidly slit it up with a Syme's bistoury which I had rinsed in the hot water. I then grasped, in succession, each of the two resulting flaps, and removed it close along the line of reflection. I believe that the operation—I suppose I should interject, parenthetically, "although I say it, who shouldn't"—has never been more rapidly carried out. I encouraged the bleeding for a time, by bathing with warm water; as I believed that it would have a beneficial effect on the adjacent inflamed surfaces. After an interval of about ten minutes, I used compression with pads of the absorbent cotton, and, when the oozing had pretty completely ceased, I dusted the cut surface copiously with iodoform powder, wound several layers of fresh cotton round the organ, and secured them in position by strips of plaster, which were anchored laterally on the thighs. There were no further details to be registered; the dressings were renewed on alternate days; no infection whatever of the cut surface followed; the gonorrheal discharge and epididymitis steadily subsided during the treatment; and the wound was closely healed after a period of eleven days. The use of an astringent injection of a solution of zinc sulphate (gr. ij.—℥i.) was then prescribed. When I saw the patient, six weeks later, the urethral discharge had completely disappeared; a barely perceptible, and completely uniform, cicatricial line marked the junction of skin and pseudomucous membrane behind the cervix; and the only ascertainable pathological condition present was some remaining enlargement of the epididymis—with distinct thickening of the emerging vas deferens, which did not wholly disappear till it nearly reached the external abdominal ring. I then prescribed potassium iodide in 5 gr. doses three times a day. I did not see him—professionally—again; but he wrote at the end of a month, and told me that all seemed so well that he had given up taking the medicine. Within a

year after he married. There has been no family. Such are the prominent facts and features of a peculiar case, and an operation carried out in opposition to several of the most important tenets of *secundum artem* procedure. It bears testimony, however, to the antiseptic powers of iodoform, and illustrates the fact that the conservative effects of contraction of newly-formed tissue may leave a cicatrix quite as narrow when not even a single suture has been employed. Since the date of the experience above detailed, I have in a few cases, where there existed a morbid fear of anesthetics, carried out the procedure on similar lines, and always with a correspondingly favorable result.

The statement has been made—and on apparently good grounds—that circumcision is the most ancient of all the surgical operations. Indeed the truth of the affirmation seems to be now generally admitted by experts in the arcana of anthropological and antiquarian lore, as well as by those best acquainted with the history of primitive surgery. The locus of its origin has not been so definitely agreed upon; and, indeed, in the nature of things, the question of its fixation hardly admits the prospect of a satisfactory settlement. It has, however, been very extensively discussed. Various writers have, from time to time, tried to locate its earliest appearance in a single tribe or territory; from which central position the practice radiated through surrounding districts, and so extended to the remoter regions of the earth. The strongest claims hitherto advanced would appear to be those made in favor of Jewish and Egyptian origins. Till within very recent times, of course, the vast majority of the members of the "well-read," and even "learned," circles of Western civilization, unquestioningly attributed the earliest appearance of circumcision to the Mosaic introduction of the practice among the "chosen people"—as a distinctive and sacred rite. But this view was shaken to its foundations by the publication of the results of the researches of Welcke, who found a true specimen of circumcision in the person of the mummified Amen-en-hab, who lived between the years 1614 and 1555 B. C.; and has been even more hopelessly demolished by the discovery of the widespread existence of the practice among the aborigines of the Australian Continent and of the Malayan Archipelago. Philostorgius has left on record his testimony to the existence of the practice among the Arabs as early as 342 B. C. At the present day, circumcision reigns over part of the (now so troubled) Balkan regions; and over Asia Minor, Persia, and a great part of India. It has been truly remarked that the practice is so approximately universal among native African tribes that it would be far easier to enumerate those who do *not* use it than those who do. Its complete prevalence all over Northern Africa has been attributed by some writers to the influence of the example of the Mohammedans; but this view is hopelessly discounted by the fact that it is as diligently observed by aboriginal tribes which have no contact with Islam. An attempt has, indeed, been made by Zobirowski to give some further probability to the Islamic, or at least Oriental, source of the prevalence of circumcision in the Northern Zone of the Dark Continent, by an endeavor to show that it is practised only by the tribes which also possess plants of Eastern origin—such as millet, rice, or sorgho (boura); this fact, if duly substantiated, would favor the writer's view that the custom gradually radiated through Africa from an Egyptian focus. The conclusion has, however, been definitely rejected by some of the most competent critics on the questions connected with this discussion; and the historic (non-) sequence and (ill-connected) induction of the facts and views which that writer displays for the conviction of his readers will not bear critical scrutiny.

The very remarkable prevalence of circumcision over so large a proportion of the area of the African Continent is also shown in its employment by the Christian Abyssinians, as well as by the Bogos and the Copts. It has been suggested that the first of those bodies probably adopted the practice originally from their Jewish neighbors. It is an interesting association of the conservatism of the operation—or ritual observance—that Ludolphus, in his very fascinating historic and descriptive account of Abyssinia, mentions the employment of stone knives by the Alnajas of that country in circumcising; as is the present practice of the aboriginal Australians and the North American Indians, and was the ancient practice of the Jews and the Egyptians. We are told by recent explorers that the Marolongs of South Africa always operated with a "fire-stone" (meteorite) till their routine of life was disturbed by the encroachments of European civilization. Now they circumcise with an assegai! Mussel-shells are still employed in parts of Polynesia. Schudt refers to an instance of the employment of a stone knife by Jews in circumcision as late as 1726.

As might be anticipated in a period of virulent doctrinal controversy, Celsus (the antagonist of Origen) and Julian (the Imperial "Apostate") objected to the account of the Abrahamic origin of the practice of circumcision, the fact of his having come from Ur of the Chaldees. They argue that he found the practice established in Egypt; and, after having left the latter country, adopted it for his own household. This view has been resuscitated in modern times by Chevalier Marsham and M. Leclerc, who base their advocacy on the testimony of Herodotus and of Diodorus Siculus, both of whom state that circumcision was gradually adopted by the neighboring tribes and nations from the practice which originated with the Egyptian priesthood. That the custom existed in the mysterious land of the Nile from time immemorial is an historical fact now thoroughly well established, although the testimony of the uninitiated Herodotus and Diodorus be ruled out—as was, indeed, done in the case of the former by Manetho himself. And it is highly significant, as well as highly interesting, to remember that Egyptian circumcision was not for the *profanum vulgus*. We have the testimony of Josephus, which is corroborated by that of Origen, of St. Ambrose, and of St. Epiphanius, that it was the distinctive physical stamp of the elect and the learned: Priests, geometers, astronomers, astrologers, and the skilled scribes of the hieroglyphic symbols. Indeed, we find St. Clement of Alexandria referring to the efforts made by Pythagoras (in his tireless pilgrimage in search of truth and knowledge) to be circumcised on his arrival in Egypt, as the subjects of that operation could alone be admitted to the privilege of initiation into the special "mysteries" and esoteric doctrines of that inspired circle of priest-philosophers. The fact that the reproachful term "uncircumcised" is applied to the Egyptians by the Jewish prophets Ezekiel and Jeremiah proves that the application of the epithet was not meant to be taken in the literal sense. It corresponded pretty accurately to the "barbarians" of the Greeks, as used by the latter people in the centuries of their self-satisfied superiority. On the subject of the general adoption by the Jewish people, and its origin from that chosen race, statements so diametrically divergent may be found as that of Artapanus, who is cited by Eusebius to prove that Moses originally communicated the practice of circum-

cision to the Egyptian priests, and those of others who believe that the rite was adopted by the Jewish people only in the reign of King Solomon—one of the very numerous importations of that polygamous monarch! There appears to be no doubt that the ritual operation of circumcision in the palmy days of the Pharaohs indicated admission of the boy who had just reached the age of puberty into the "pure" order of priesthood. And in Genesis we find the Hebrew coincident recognition of heirship, and conferring of a new name.

A still more striking testimony to the almost limitless distribution of the practice of circumcision is to be found in its prevalence among the aboriginal natives of America. The Caribs of the Orinoco and the Tacunas of the Amazon use it. Petitot found it regularly practiced by the Athapascans, and McKenzie by the Dog river Indians. Las Casas reported its existence among the Aztecs; and others have found corresponding ceremonial practices to prevail among the Mayas of Yucatan, the Automecos, the Salivas, and the Guemos. It is specially interesting, too, to note that the latter perform it on the eighth day—which appears to be the earliest recorded date of the practice among savage tribes. An analogous custom was found by Squier to prevail among the inhabitants of Nicaragua, of which the most essential item appears to consist in the dipping of corn in the blood drawn from the organ, and then sowing the latter. We are informed by Garcia de Palacio (1576) that a similar practice was found by Cortez among the native Mexicans; but in their ceremonial the blood drawn was offered upon the altar in way of sacrifice. Herrera, indeed, states that the practice which was carried out by the aborigines of Mexico was that of removal of the pendent part of the prepuce, and the correspondingly flexible—pendent—margins of the lobes of the ears.

There was certainly no definite prescription given to the ancient Jews regarding either operator or instrument. The rite could be carried out by the father, or any other relative (mother, as in the instance of Zipporah, Moses' wife), or by the priest. A sharpened stone was the instrument of primitive usage, as it was with the Egyptians (and also employed by the latter in the process of embalming), and as it, or a broken potsherd, was the weapon employed by the Galli (priests of Cybele) in the distantly (blood-) related operation of self-mutilation. That the absence of the prepuce was in after ages discovered by Jewish women to cause a deficiency of sensual gratification during coition is hinted at by Sir Thomas Browne, who, among many characteristically interesting items of information regarding the relations and contrasts of Jews and Christians, mentions that: "Nor are fornications unfrequent between them both, there commonly passing opinions of invitement, that their women desire copulation with them, rather than their own nation, and affect Christian carnality above circumcised venery."

The cosmopolitan distribution of this first and most frequent of all surgical operations has, very naturally, given rise to a great deal of speculation and inquiry regarding the source of its origin and the intimate nature of the practice. The rather numerous theories which have been advanced by various investigators may be classified under the headings of utilitarian, tribal, and sacrificial.

Among the *utilitarian* motives which may have promoted the adoption of the practice, those connected with the cleanliness and hygiene of the person appear to have a very strong claim. We know how soon the preputial smegma becomes offensive when retained—and, more especially so, of necessity, in hot climates. And, where congenital phimosis exists, the subject of this condition, if a tropical resident, must almost inevitably suffer from a persistent balanoposthitis, if the retropreputial *cul-de-sac* is not regularly and carefully syringed out. The reflex irritation produced by this condition in children gives rise to varieties of trouble, as is well known to all medical practitioners. Among these may be mentioned dysuria, enuresis, hernia, hydrocele, prolapsus recti, vesical calculus, epileptiform convulsions, and even reflex paralysis—superadded to the irritation which is so likely to induce the practice of masturbation. And the fact that epithelioma of the glans is most likely to appear, in advanced life, among the subjects of congenital phimosis, has been generally recognized since the publication of "Observations in Surgery," by William Hey of Leeds. Even Philo, the contemporary of Christ, mentions cleanliness as one of the motives for the original Biblical injunction on the chosen people; and late writers of high authority, such as Claparède (1861) and Rosenzweig (1878), have recommended the universal adoption of circumcision on these grounds. The apparently fatal objection to the hypothesis that the original adoption of circumcision by so many primitive tribes and nations was due to motives of personal cleanliness and hygiene, is found in the fact that it is at the present day practised most scrupulously by many tribes in various parts of the world who do not possess, or carry out in practice, the most elementary ideas of cleanliness in any other direction.

Another suggestion toward the utilitarian motive of the original practice of circumcision was advanced by the late Sir Richard Burton, the very accomplished and (probably most) experienced traveler. He advocated the view that the operation was introduced for the promotion of fertility. The fact that in Celebes it is performed only on the persons of princes who have no children would seem to furnish at least one item of evidence in support of the theory, but the practices of the great majority seem to be decidedly against this view. In some other regions, also, it would seem to have been cultivated as one of the distinctive privileges of the upper classes. It appears to have been so regarded in Mexico; and we are told that in Rook Island it is performed on the persons of the wealthy only. There would seem to be a good deal of probability in the view that utilitarian ideas had a certain amount of influence toward its adoption as a preparation for marriage in some instances. A long, narrow prepuce, even if not originally in a state of actual phimosis, was liable to become so at any time—from the occurrence of even slight inflammation. Its presence, in case of negligent persons, was always productive of local uncleanliness. And, on the occasion of sexual intercourse, the sensitive glandular surface was necessarily excluded from direct contact with that of the vagina—a very objectionable condition from the sensualist's point of view. Also, a very long prepuce, by folding or creasing, might cause misdirection of the ejaculated semen. And, furthermore, the chronic phimosis was liable, on the occasion of the consummation of the marriage rite, to become converted into an acute paraphimosis, of which all practitioners have necessarily met with examples. The establishment of this condition always produces great alarm, as well as local pain and uneasiness, and causes the afflicted individual to seek advice and relief whenever procurable. In this connection, I cannot pass from the subject without calling attention to the curious pathological error which universally prevailed in the surgical text-books of my student days, and contin-

ues to reappear in the pages of their successors even in the twentieth century. An item of orthodox surgical faith which was invariably taught, and (necessarily) universally received, was that the tight paraphimotic constriction—if not artificially relieved—must necessarily lead to sloughing of the glans from the interruption of the circulation in the latter. Yet the surgical and pathological truth is that such a consummation never occurs, and never can occur from this cause alone—in the case of a previously healthy organ. The cause of the prognostic error is that the constricting band which temporarily interrupts—or retards—the circulation is formed by the retroflexed—previously free—margin of the prepuce, and is therefore a portion of the living tissues of the affected part. It is also the particular portion of the whole structure in which the circulation is most affected by the mechanical obstruction. The necessary consequence is that if the constriction be not relieved, the surface of the tightest portion of the constricting band undergoes ulceration—the Gordian knot is cut, and the circulation in the glans is restored. Accordingly, every acute paraphimosis, alarming as the condition looks, tends to a spontaneous cure.

The Mohammedans do not carry out the operation of circumcision with the exacting scrupulosity of the Jews: they merely detach the overhanging foreskin, but do not think it necessary to expose the surface of the glans. We are told that in India the operator introduces a wooden probe between the prepuce and glans, and passes it round and round, in order to make sure that no unnatural adhesions exist. Some primitive tribes paid very special attentions to the detached piece of foreskin. The Marolongs buried it with scrupulous care; the Zulus received it in a cup nearly filled with ashes, which they interred with it; among the natives of Madagascar a relative of the child operated on seized the detached prepuce and—swallowed it!

The suggestion of the practice of circumcision as a *tribal* distinction has been defended by the argument derived from the fact that the age at which many African tribes perform the operation is identical with that which some of their neighbors confer their own special tribal "hall-marks." For instance, the Hereros of Africa knock out the front teeth of their boys on the arrival of the latter at the age of puberty; the same date at which so many of the circumcised tribes of the same continent perform their distinctive rite. Although the adoption as a solely tribal distinction may have been true in a (very) limited number of instances, I think that everything known of the history of circumcision argues, in the vast majority of cases, against the reception of that view. This remark, I venture to state, applies with special weight in the case of the Jewish race—notwithstanding the bigoted antipathy with which they regarded their uncircumcised contemporaries. Racial and collateral antipathies led to the development of such expressions of odium; but there can be no doubt of the religious—sacrificial or symbolic—origin of the adoption of the practice in their case. Indeed, as Gerland has pointed out, it would be difficult to fancy the employment of circumcision as a distinctive tribal mark, having regard to the fact that the organ is almost invariably hidden. Nevertheless, it is instructive to remember that as an example of the universal diffusion of the contradictory instincts and opinions of the representatives of learning and wisdom, we find the Roman historian Tacitus refer to circumcision as the distinctive racial stamp of the Jewish people: "Genitalia circumcidere instituêre, ut diversitate noscantur." And this view was deeply impressed upon Christendom by the great authority of St. Jerome: "Ne soboles dilecti Abraham ceteris nationibus misceretur, et paulatim familia ejus fieret incerta gregem Israeliticum quodam circumcisionis cauterio annotavit."

The *sacrificial* theory of the origin of the practice of circumcision—national and tribal—or, better, perhaps, the combination of a sacrificial and an initiatory ceremony would seem, I incline to think, to furnish the most acceptable account of this widely-spread practice—in accordance with all the available evidence. It may take the aspect of a quasi-sacramental token of initiation into a religious sect, as it has done for the Jewish and Mohammedan proselyte—which goes to show the intimate nature of the native view of the ceremony, as performed upon themselves at an earlier period of life. It has been suggested—and with some show of probability—that the transfer of the date of the operation from that of initiation into the religious brotherhood, simultaneously with induction into the fraternal equality of mature life, was made from considerations of convenience and diminution of amount of pain inflicted. The age varies greatly in different races and regions of the world. The Jews, as is, of course, well known, have always adopted the eighth day—according to the Mosaic injunction. And the influence of initiation on the fixing of the date is well shown by the fact that in Yemen, where Jewish influence was much felt, the Arabs circumcised their children on the eighth day. The Mohammedan laws recommend circumcision between the ages of seven and twelve years; but its performance seven days after birth is allowed. We are told by Josephus that the Arabs circumcised after the completion of the age of thirteen, because Ishmael, the founder of their nation, was circumcised at that age. Other various ages have been assigned by Ibn al-Athir and many other Arabic authorities. Mohammed himself, for whatever reason, does not appear to have thought it necessary to make any mention of circumcision in the Koran. Abulfeda, indeed, in his "Historia Ante-Islamitica," reckons circumcision among the rites of pagan Arabia, whose continued practice was sanctioned by Islam; and Ibn al-Athir, in discussing the annals of that period, attributes to the prophet of Islam the aphoristic statement that: "Circumcision is an ordinance for men, and honorable for women." Hurairah, the great authority on the traditional history and doctrines of the Moslem faith, attributes to Mohammed the ruling that circumcision is an observance of *fitrah* (natural impulsion), and, accordingly, possesses no special religious character. But, whatever may have been the original opinion and teaching of the founder of Islam on this head, there is no question of the fact that the practice was soon established among his followers as a religious obligation which was imposed upon all the faithful. The time at which the rite was performed hardly seems to have been definitely limited; it would appear that each locality fixed its own period. I have already alluded to the practice in Yemen, which followed the Jewish eighth-day ceremony. It is lawful to carry it out even on the seventh, but Muslim law *recommends* the period between the seventh and twelfth years (inclusive). A new name is then added to the former one of the individual, and a festival and rejoicings follow.

The age at which the rite is performed has varied very widely among the various tribes who practise circumcision, as the examples already referred to show. The Jewish—eighth-day—operation is the earliest; indeed, the sect of Falashas perform it on the seventh, while the natives of southwestern

Arabia choose the seventh, fourteenth, twenty-first, or twenty-eighth, according to the influence of collateral circumstances. Few savage races of other countries circumcise their children so early; but we are told that the Susus, near Timbuctoo, and the Guemos of South America perform the operation on the eighth day after birth. The Mazeguas of East Africa choose between the first and second month. The Persian votaries of Islam wait till the third or fourth year, and the Coptic Christians till the sixth, seventh, or eighth. The Fijians and Samoans also circumcise their boys in the seventh year. But there is no doubt that the great majority of circumcising tribes connect this operation with the advent of puberty. The neglect of Moses to circumcise Gershom was, perhaps, in some way associated with the fact of the marriage of the original Hebrew lawgiver with a Midianitish woman.

In all ages of historic time, and among all the tribes and nations who have practised circumcision, the performance of the operation has usually furnished the nucleus of some special ceremonial. Most frequently it is found to form a part in the general process of the initiation of the youth into the mysteries and responsibilities of manhood. Halévy tells us that among the Jauf of Southern Arabia it is regarded—in one aspect, at least—as the application of a test trial of endurance. The native tribes of Australia and of Africa employ elaborate ceremonial observances, from which strangers are jealously excluded. Thus Livingstone was unable to obtain admission to the "boguera" of the Bechuanas. In this relationship Ploss, who is certainly one of the best-informed authorities on the ethnology of *Knaben-Beschneidung,* contends that the fact that circumcision is almost always found forming part of a rite of initiation furnishes the clue to its general adoption. Commenting on this view, the eminent Jewish authority, Joseph Jacobs, observes: "According to the wise custom among savages of initiating their youth into all the duties of the mature life, the elders prepare the lads for their marital life at this time; and circumcision, often of both sexes, is resorted to as part of the preparation. The only ancient legend about Zipporah circumcising Moses (as would seem to be implied by her exclamation, Ex. iv. 25, 26) confirms Ploss's view to some extent; but the exceptionally early age at which Jews perform the rite takes it entirely out of the category of initiation ceremonies among them, and proves it to be of a religious or symbolic nature, as, indeed, is expressly claimed for it."

Some inquirers have arrived at the conclusion that circumcision, like castration, originated among savage tribes as a substitute for human sacrifice. Herbert Spencer has suggested that it began as a sequel of conquest: the victors permitting the vanquished to retain their lives with this permanent stamp of humiliation. Samson's appeal to his father (Judges xiv. 3), and that made by David to Saul and the Israelites, give a certain appearance of plausibility to this theory; but, as Jacobs points out, the fact that its practice is either common to all the members of the tribe, or is reserved for the upper and privileged classes, argues very strongly against the view.

A very suggestive and, probably, enlightening fact in connection with the study of the origin of circumcision is that the Arabic word *hatana* signifies both "to marry" and "to circumcise." It seems to point definitely to an original connection between the two rites. Our eminent contemporary Jewish authority, Kaufmann Kohler, inclines to regard its practice among that primitive people as a consecration of the generative powers, and proceeds to observe that: "At all events the age of puberty is most frequently selected for the rite; and, after weeks of purification, accompanied by tests of courage, the boy is formally graduated into manhood and, bearing a new name, is ushered into the bridal chamber." This writer also refers to the theory advanced by the representatives of the "higher criticism" to account for the non-circumcision of the junior Israelites during their prolonged wanderings in the desert: "The ancient Hebrews followed the more primitive custom of undergoing circumcision at the age of puberty, the circumcision of young warriors at that age signifying the consecration of their manhood to their task as men of the covenant battling against the uncircumcised inhabitants. After the settlement of the Israelites in Palestine, the rite was transferred to the eighth day after birth." The origin of circumcision from hygienic motives, although suggested by the very representative authority of Philo and of Josephus, is regarded by Kohler as a theory which presents no other than a historical value.

The harsh treatment which the Jews were doomed to undergo at the hands of their more powerful neighbors had, as such conditions always have, the effect of increasing their devotion to the national customs. The Romans would seem to have entertained a special dislike to their rite of circumcision; and the terrible persecution which they suffered in the reign of the Emperor Hadrian was specially aimed at its practice. And the gruesome history of the Jewish race in western Europe during the Middle ages served to stamp their adhesion to this item of faith and practice all the more deeply. The biographers of a celebrated rabbi bear records such as the following: "Why did God not make man as he wanted him to be?" asked Tinnius (Tyrannus) Rufus, with biting sarcasm; and Akiba replied, "In order that man should perfect himself by the fulfillment of a divine command." To be born circumcised was the distinguishing mark of the most select saints—including Adam, "who was made in the image of God," Moses, who was chosen to be his lawgiver, and Zerubbabel, who led back the first band of returned exiles.

During the period of the Babylonian exile the strict observance of the Sabbath and the rigid attention to circumcision became the distinctive symbols of Judaism. The national appreciation of the sanctity of the "Seal of the Covenant" appears to have increased with every succeeding exile and persecution. The *Book of Jubilees* informs the reader that: "Whosoever is uncircumcised belongs to 'the sons of Belial,' to 'the children of doom and eternal perdition'; for all the angels of the Presence and of the Glorification have been so from the day of their creation, and God's anger will be kindled against the children of the covenant if they make the members of their body appear like those of the Gentiles, and they will be expelled and exterminated from the earth." (Charles's Version.) Still the Hellenistic movement among the Jews, which emanated from (Alexandrian) contact with Greek life and philosophy, produced a troublesome agitation in this connection. The games of the arena, which had at that date become so popular, exposed to general view the distinctive stamp of the Jewish youth. The public comment must have been decidedly unfavorable, as the affected gymnasts made the troublesome effort to appear like the Greeks by the adoption of "epispasm." Hence the mournful record (I Macchabees, I-16): "They made to themselves prepuces, and revolted from the holie testament, and were ioyned to the nations, and were solde to doe evil." (*Douay* Version, 10, which I quote as being more literal than others.)

An edict prohibiting the practice of circumcision was promulgated by Antiochus Epiphanes, but it was treated with scorn by the nationalist Jews. The Jewish women made an emphatic display of the obstinacy of their (sex and) race by circumcising their own sons, even at the risk of the lives of both. Rabbinical authorities taught with progressively increasing emphasis the inestimable sanctity and importance of the ritual operation. "He who destroys the covenant sign of Abraham (*i.e.* by epispasm) has no portion in the world to come." Esau neglected to practise the operation in his own household; *i.e.* "he despised his birthright." The tribe of Ephraim also failed in the observance; this criminal negligence caused Elijah to swear (I Kings, xvii. 1): "There shall not be dew or rain these years but according to my word." And as it was the hard lot of Elijah to be ever exposed to the persecutions of Jezebel, the Lord of Hosts swore that no *berit milah* (rite of circumcision) should thenceforth be celebrated in Israel without the presence of the great prophet, "the angel of the covenant." Hence the fact that a chair is always reserved for the prophet Elijah during the ceremony, whether in the synagogue or in the home. It was Shem who circumcised Abraham and Ishmael on the "Day of Atonement," and the blood of the covenant then shed is ever before God on that day to serve as an atoning power. Abraham sits at the gate of Gehenna to save his circumcised descendants. All the superhuman merits of Moses could not save him from the danger to which he was exposed by his neglect of this command. It need hardly be added that "the Sign of the Covenant," as well as the phylacteries, possessed unlimited talismanic powers. King David owed one of his innumerable hair-breath escapes to it; hence the inspiration of the XIIth Psalm, with its distinctive superscription, 'Al-ha Sheminit ("Upon the eighth," *i.e.* day). A rabbinical comment upon Jeremiah xxxi. 35 tells us that, "Circumcision is of such importance that heaven and earth are held only by the fulfilment of that covenant."

As proselytism was very actively promoted in opposition to the anti-national Hellenistic movement among the Jews, other aspects of the value of the ritual stamp of circumcision were brought into unwonted prominence, and schismatic difference of opinion was evolved which lasted for centuries. One party would admit a proselyte without other initiation than a purificative bath, the other insisted on the absolute necessity of circumcision. On the subject of a proselyte who had been born without a prepuce, a noisy controversy was maintained between the Shammaites and the Hillelites. The former insisted on drawing a drop of the "blood of the covenant" from a point on (what would have been) the line of normal incision; the latter declared that such procedure was entirely unnecessary. Similarly opposed views were maintained regarding the practice to be adopted on the admission to Judaism of members of other religions—Egyptians, Samaritans, etc.—who had previously undergone ritual circumcision. This question was, of course, frequently ventilated after the origin of Mohammedanism. The Palestinian Jews would only accept uncircumcised converts as "Proselytes of the Gate," and the rigor of the subsequent Roman wars and persecutions had the effect of turning the opinions of the previously Liberal (Hellenistic) members of Judaism towards the same doctrine and practice. Accordingly, we find Flavius Clemens (nephew of the Roman Emperor, Titus) undergoing circumcision on embracing the Jewish faith, for which he suffered the death penalty at the hands of his indignant compatriots. And, in a subsequent period of diminished racial animosity, we find the *Codex Justinianus* prohibiting physicians from carrying out the operation of circumcision on the persons of Roman converts to Judaism.

In the earlier centuries of the practice of Jewish circumcision, performed as it was with a crudely-edged piece of flint, and very often by the hand of the mother, the removal of the prepuce and exposure of the glans were very incompletely accomplished. Indeed, it appears that it was only after their terrible oppression by their Roman governors, and probably subsequent to their final desperate struggle for independence under Bar Kokba, that the rabbis definitely instituted the complete exposure of the glans as an essential part of the operation. Their fully-developed procedure, as is, of course, now well known to all readers, consists of three stages: (1) *milah,* in which the prepuce having been drawn through a narrow slit (with free opening at one end) in a metallic shield applied for the protection of the glans, is removed with a single sweep of the knife; (2) *per'ah,* in which the operating *mohel* seizes the preputial lining which remains in contact with the glans between the index finger and the thumb-nail of each hand, and tears it to an extent which allows the remnant of the prepuce to be rolled back so as to expose the glans freely; and (3) *mezizah,* in which the mohel takes some wine in his mouth and sucks the wound, ejecting the mixed blood and wine into a receptacle specially placed for the purpose; and, having repeated this process several times, thereby completes the operation. The control of hemorrhage and dressing of the wound are addenda. It is also well known that the recent teachings of antiseptic and aseptic surgery, and the unpleasant revelations of syphilitic infection communicated by the mouth of an operating mohel—Glassberg refers to one in Cracow who infected a large number of children in this manner—have led liberal-minded Jews during the past few years to advocate certain modifications, of which the nature is too obvious to call for discussion on the present occasion.

The terrible antagonism of the Jews and their Roman oppressors maintained an increasing horror among the rigidly orthodox of the former at the contemplation of the practice of the *epispasm* which had been induced by the more congenial contact of Alexandrian Greek and Jew. The symbolic significance of the rite must have been recognized many centuries before by the most thoughtful of the children of Israel, for the lawgiver in Deuteronomy (x, 16) directs his brethren in a spiritual sense: "Circumcise the foreskin of your heart," and nowhere prescribes the physical operation throughout the whole of that book; and Jeremiah (ix, 25-6), while pointing out that all the other nations are uncircumcised, mournfully announces that "the house of Israel are uncircumcised in heart." As Kohler points out, the prophetic view of the sacredness of the rite obviously differed from that of the people. The religious and intellectual collisions of Jews and Romans generated a large proportion of the high tidal wave currents of thought which did not cease to rise and flow till they had inundated the principal intellectual centers of the known world. The mutual mental contact and pressure of Jews and Greeks tended at that period to internal confusion among the former, rather than to external violence. The coincident series of successive events had among their manifold consequences that of transmitting the discussion of the religious values and symbolic significance of circumcision, epispasm, and baptism, from Jew and Gentile to the newly awakened Christian. The weapons thus

furnished to hand from the old armories formed some of the most trenchant and effective in the arsenal of St. Paul, who firmly substitutes the "seal of baptism" for the "seal of the covenant."

His principal epistles abound in arguments and statements regarding the value of circumcision. In the Epistle to the Romans we find the following (I quote the Rhemish version of 1582, which, being so exactly literal, conveys the sense of the original Greek far more forcibly than other English versions): "This blessednes then doth it abide in the circumcision, or in the prepuce also? For vve say that vnto Abraham faith vvas reputed to iustice. Hovv vvas it reputed? in circumcision, or in prepuce? Not in circumcision, but in prepuce. And he receiued the signe of circumcision, a seale of the iustice of the faith that is in prepuce: that he might be the father of al that beleeue by the prepuce, that vnto them also it may be reputed to iustice: and might be father of circumcision, not to them only that are of the circumcision, but to them also that followv the steppes of the faith that is in the prepuce of our father Abraham" (Rom. iv, 9-12). And in another epistle he counsels: "Is any man called being circumcised? Let him not procure prepuce." "Is any man called in prepuce? Let him not be circumcised. Circumcision is nothing, and prepuce is nothing; but the obseruation of the commaundements of God" (1 Corinthians, vii, 18-19). Again: "Neither circumcision auaileth ought, nor prepuce; but faith that vvorketh by charitie" (Galatians, v, 6). The general impression of the corresponding significance of the seal of baptism resulted; and St. Augustine definitely states the value of circumcision to infants as cleansing from "original sin": "Ex quò instituta est circumcisio in populo Dei quod erat tunc signaculum justitiæ fidei ad significationem purgationis valebat, et parvulis originalis veterisque peccati" (De Nuptiis et Concupiscentia, Lib. iv, Cap. 11). It is unnecessary to add that this authority carried with it those of a very large proportion of the subsequent luminaries of theology—from some of the most brilliant downwards to those forming the strata of lesser magnitudes. The famous "Magister Sententiarium" writes: "Fuit circumcisionis sacramentum idem conferens remedium contra peccatum, quod nunc baptismus præstat." St. Gregory the Great is an explicit exponent of the teaching of the great Bishop of Hippo on this head: "Quod apud nos valet gratia baptismatis, hoc egit apud veteres vel pro parvulis sola fides, vel pro majoribus virtus sacrificii, vel pro iis qui ex Abrahæ stirpe prodierunt mysterium circumcisionis."

St. Thomas Aquinas regarded it as a sacrament of the ancient law: "Quia in Abraham fides primò habuit quasi notabilem quantitatem, ut propter fidei religionem ab aliis separaretur; ileo ei signaculum, sive sacramentum fidei determinatum fuit, scilicet circumcisio." But he did not admit that it purified the individual from the stain of original sin. The sacramental function of circumcision is, of course, quite irreconcilable with Jewish theology, and is utterly rejected by the rabbinical authorities.

A glance at the various contradictory views which have been maintained by "authorities" of high standing on the subject of the possible physical success of the epispasm reveals an interesting vista in the very tangled forest growth of both physical and theological opinion. The references of St. Paul and of the writer of the Books of the Macchabees seem to show that they regarded the restoration of a prepuce as *un fait accompli*. St. Jerome—who is followed by Rupert and by Haimon—absolutely denies the possibility of obliterating the mark of circumcision. The learned and saintly editor of the "Vulgate" version of the Holy Scriptures adopted the view that the author of the Macchabees referred to the practice of the Jewish parents who did not wish to have their infants subjected to the operation of circumcision, and offered what many have professed to regard as a forced metaphoric explanation of the allusion of St. Paul to the—then obviously familiar—practice. Indeed, the dogmatically emphatic denial by St. Jerome of the possibility of restoration of an amputated prepuce displays a germanic resemblance to the thesis of the same Father, in which he undertakes to prove that it was not in the power of the Omnipotent Creator himself to restore a lost virginity. However, even in the olden times, it was admitted by the Fathers of Medicine, that the uncircumcised condition could be successfully simulated; and, of course, having regard to the almost unlimited extensibility of the skin when exposed to gradual traction, it must now be admitted that the reformation of a prepuce would be merely an expenditure of time and trouble. Celsus, Galen, Paulus Ægineta, and many others recognize the possibility—and very fully discuss the associated questions; in more recent times, Fallopius and Bartholin recognized the successful practice; and—more significant still—the Jewish scholar, Buxtorf the younger, furnished the latter with the most definite affirmative testimony derived from the observations and practice of his Hebrew compatriots. It may be of interest to note in this connection that in those older centuries the (simulated) restoration of a missing virginity was a frequent—and sometimes an exceedingly lucrative—function of the witch, the alchymist, the herbalist, the skilled midwife, and even the surgeon of widest reputation—especially if connected with aristocratic and courtly practice. Readers of Arnaldus de Villanova will remember his very careful instructions for the attainment of that desirable consummation; and that trusted medical adviser of Popes, Emperors, Kings, and other contemporary potentates, was a leading representative of the practice of the members of lesser magnitude and brilliancy who formed the professional host of his day.

The fact that circumcision of females is extensively practised among some of the tribes who habitually amputate the masculine prepuce, even in the present day; and that where both sexes are thus treated, the time of election is the approach of the dawn of puberty, argues strongly in favor of the view that the operation was originally adopted by such people as a part of the general ceremony of preparation for marriage, and for the duties—including the pains and the dangers—of mature life. The practice prevails very extensively within the broad subtropical zone which includes the Red Sea and the adjacent countries, Arabia, Upper Egypt, Abyssinia, Sudan, etc. It is a curious fact in the history of the evolution of theological doctrine that the opinion advanced by St. Augustine of the efficacy of the Jewish circumcision in the removal of original sin was strongly opposed to that of a large proportion of the Christian Fathers, both before and after the enunciation of his views. Tertullian very plainly demands: "Si circumcisio purgat hominem, Deus

Adam incircumcisum cum faceret, cur eum non circumcidit; vel postquam deliquit, si purgat circumcisio?" And a later argument, which was very strongly pressed against the view promulgated by the great Bishop of Hippo, was that: As the original sin was common to both sexes, it would not have been compatible with either the wisdom or the goodness of God to deprive the female sex of the remedy which he had placed within so easy reach of the male. Some of them, therefore, would seem to have not been aware of any extensive adoption of female circumcision, although St. Ambrose refers to the Egyptian custom of circumcising the youth of both sexes—in the fifteenth year. Paulus Jovius, and Munster refer to the practice of such ceremonial operation by the subjects of Prester John (Abysinnia), but state that it was a special stamp of the highest nobility—the privilege only of those who could prove direct descent from Nicaulis, Queen of Sheba, as the fruitful result of her patriotic and purposeful visit to the all-wise monarch of Israel; whose representation in the direct line of male descent is proudly claimed in our own generation by Menelik, the present reigning monarch. With this reference to the oldest, and otherwise most unique, of existing royal pedigrees, I drop the curtain on my crude panoramic sketch of the theory and practice of circumcision.

SOME CLINICAL OBSERVATIONS ON SALPINGITIS AND PARAMETRITIS IN NULLIPARÆ.

By SAMUEL WYLLIS BANDLER, M.D.,
NEW YORK.
ADJUNCT PROFESSOR OF GYNECOLOGY, N. Y. POST-GRADUATE MEDICAL SCHOOL.

Salpingitis is an inflammation of part or all of the Fallopian tube. We distinguish three degrees of salpingitis: (1) A mild form scarcely to be recognized, which involves the ciliated epithelium and to some extent the mucous membrane. (2) Involvement of the mucous membrane. (3) An interstitial form which involves also the muscular wall and which thickens the tube. The third form is generally associated with more or less adhesions having a tendency to close the outer end of the tube. Cases beyond these grades are to be considered as hydrosalpinx or pyosalpinx. The same variations in the degree of inflammation are to be noted in salpingitis as are observed in appendicitis. Restoration to the normal, or so nearly to the normal as to present almost no microscopic evidences, occurs in salpingitis as in appendicitis. Restoration to the normal in salpingitis, however, is a process which takes months or years, as can be readily appreciated when we consider the bacteria which are present in this inflammation.

It is first important to recognize the fact that an injury, even extensive in its nature, may be present in one tube without an involvement of the tube of the other side, or else there may be an involvement of the other side of a much slighter degree, or an involvement which can scarcely be recognized. This association of widely divergent degrees of inflammation may be present even with a pyosalpinx.

The elements of infection may enter the tube through the blood channel (tuberculosis), through the abdominal cavity (tuberculosis, septic parametritis, septic peritonitis, appendicitis), or in the form of an ascending infection from the cervix, either directly through the uterus into the tubes or through the lymphatics of the broad ligament into the tubes. While it is true that the exanthemata produce, far more frequently than is recognized, permanent harmful changes in the ovaries, and either primary or secondary changes in the uterus and tubes, yet the causation in the majority of cases of tubal disease is to be referred to the bacteria generally found in the diseases of the urinary and genital tract.

The bacteria most frequently encountered are the tubercle bacillus, colon bacillus, streptococcus, staphylococcus, anäerobic bacteria, and the gonococcus. Infection may occur in children, in nulliparæ or in multiparæ. The seat of the primary infection is in most cases the cervix, or the cervix and uterus, extending then at various times and in various degrees of severity into one or both tubes, or first into one and then into the other, or into one tube and through the abdominal cavity into the other. The cause of salpingitis in nulliparous women may be infection without or with intrauterine manipulation. With intrauterine manipulation in addition to infection there may be an injury to the tube as a result of intrauterine injections which, not rarely, find their way into the tubal lumen. The cause of salpingitis in nulliparous women without intrauterine manipulation is in most cases a latent unrecognized gonorrhea existing in the form of an endocervicitis or an endometritis.

The generally accepted picture of gonorrheal infection in the female represents a virulent infection of the urethra, a virulent Bartholinitis, a virulent vaginal discharge, a virulent endocervicitis, endometritis, pyosalpinx, or peritonitis in the secretion of which conditions the gonococci can be readily found. To illustrate the peculiarities of such acute inflammations due to virulent gonococci it is only necessary to note the fact that a gonorrheal urethritis does not necessarily mean a complicating Bartholinitis, nor does a Bartholinitis necessarily mean a complicating urethritis or rapid extension into the uterus or tubes or peritoneum. The cervix, or cervix and uterus are the most frequent seats of the acute infections and often, too, without an accompanying urethritis or Bartholinitis. It is marvelous that these internal conditions may exist without accompanying external involvement and vice versa. (Cases I, II, III.) It is this *acute* inflammation, however, which leads, often rather early, to large accumulations of pus in one tube or both; but this involvement of the tubes frequently results only after a fair lapse of time and is favored by injuries due to work, overactivity, intercourse, abortion, curetting, and other disturbances.

When this condition, originally acute, exists in nulliparæ and is continued on into pregnancy, it is then that abortion, labor, or curettings may produce a new development which is acute in all of its manifestations, leading on to virulent accumulations in the tubes, peritoneum, or pelvic connective tissue. On the other hand, these local acute conditions may be cured to all intents and purposes, and months or years afterward an extension upward may take place, which extension is not necessarily acute in its character. The bacteria may have lost their virulence, the patient's tissues have grown somewhat accustomed to the cocci, have become more or less immune, and any new involvement may take on the character and nature of a subacute inflammation. (Case IV.)

Quite another picture is produced by an infection in the female due to a gonorrhea in the male supposedly cured or showing only elements

generally not recognized as infectious because the gonococci are not to be found by the microscope. Such an infection very rarely produces the purulent urethritis, Bartholinitis, endocervicitis, etc., mentioned above. *It produces a catarrhal infection of the cervix with or without erosions.* This infection may remain localized or may extend upward. It produces at first few or slight symptoms aside from the leucorrhea, in which discharge, because of the mucous character and destructive action of the secretion, it is almost impossible to find gonococci by the microscope. This infection may make its way through the cervix into the pelvic cellular connective tissue, producing the condition known as parametritis, especially the form known as posterior parametritis. It may also extend upward into the uterus and then further on into the tubes and into the peritoneum. In nulliparous women so infected we may have, then, either a parametritis, a salpingitis, an oophoritis or a peritonitis, producing in some individuals few symptoms, in others symptoms of a marked character. This, in my opinion, is the etiology of the majority of cases of salpingitis. In these cases of cervical or uterine localization, curetting, pregnancy, abortion, labor, excessive coitus are the elements which favor either an extension upward or subacute recrudescences of the lesions, but they never reach the degree of severity observed after infections by virulent gonococci. The gonococci in these cases are totally different in their behavior from the cocci given off during or soon after acute infection in the male. This etiology explains numerous cases of sterility, abortion, pelvic pain, ectopic gestation, cystic ovaries, etc.

If we concern ourselves now mainly with the question of salpingitis, let us consider the factors on the basis of which we attribute to the gonococcus the etiology of most of these instances, for in the woman who has aborted or in the multiparous woman there is always the implied possibility of infection by other bacteria.

Even in puerperal women free of fever, a certain though small percentage show in the lochia streptococci, staphylococci, gonococci, and bacteria. In 296 puerperal women *with* temperature Krönig found *gonorrheal endometritis* in 31. According to Krönig, examinations of puerperal endometritis shows the relative proportions of the various infecting bacteria to be 2 per cent. staphylococci, 27 per cent. saphrophytes, *27 per cent. gonococci*, and 43 per cent. streptococci. Most of the fatal cases are due to streptococci. The sequelæ, then, of puerperal infections can be easily understood.

Wertheim, among others, proved the gonococcus to be the most frequent cause of purulent salpingitis. In many of his cases of ascending gonorrhea in the female the tubal pus was sterile. In some the staining of sections showed gonococci in the tissues, but the pus and tissues of most cases of pyosalpinx at the time of operation are free of bacteria. Besides, in long-standing cases evidences which tend to distinguish between gonorrheal and septic disease disappear. If in such conditions the bacteria and gonococci are so often not to be found, and when present are so hard to find, how can we expect better or as good results in the way of ocular proof in those cases which from the beginning are less virulent or subacute or unrecognized.

We have in several instances observed the mild further course of an originally acute gonorrheal infection in the female in which the gonococci were readily found. Appropriate treatment produced amelioration of the acute condition, and careful attention has often prevented, so far as observation extended, an acute invasion upward of a virulent nature. At various periods, however, an extension, through the lymphatics or in continuity, of a mild form has been observed affecting the parametrium, the tube on one side or both tubes with or without marked involvement of the peritoneum. When such cases come to operation the gonococcus is not to be found, but the nature of the lesion is quite different from the picture associated with a pyosalpinx. We do not have the accumulation of pus nor the hard dense adhesions, nor the thickening and swelling of the broad ligaments. If, in other cases, like lesions are found in patients in whom personal examination was not made during the acute stage, but who give a history of acute infections, there is no reason why the same etiology should not be considered. (Cases V, VI, VII, VIII, IX.)

When, however, instances of like tubal lesions are found in patients who give no history of an acute infection, it is difficult to expect a general acceptation of the same etiology, though why this should be so it is hard to understand. It is by no means essential that subacute infection of the cervix or uterus should extend into the tubes, for this does not necessarily occur with acute conditions. But, when the tubal lesions resulting from cases of catarrhal endocervicitis or endometritis are like those observed after mild tubal infections subsequent to an originally acute infection, the conclusion is that the etiology is the same. (Cases X, XI, XII, XIII.)

The gonococcus needs no wound or injury in the tissues to aid in the penetration into subepithelial tissues or to aid in an extension in continuity. While a goodly proportion of women acquire the ascending lesions subsequent to operations, labor, abortions, or *curettings*, this extension does occur without these predisposing causes. Only in this way can we explain the etiology of the various forms of salpingitis occurring in nulliparous women, especially in those who have never been curetted. In this way we explain the complicating symptoms and annoyances resulting in many instances in primary sterility. It is surprising how frequently a parametritis is found existing with a tuboovarian or peritoneal lesion, and this condition is an important index to the subacute etiology. These mild infections are responsible for many cases of so-called small or large cystic degenerations of the ovary. It is the cervical and uterine site of this inflammation which explains an extension to a tube or ovary after the other tube or ovary has been removed, for we have no means of definitely deciding at operation whether the infecting cocci have lost their power or have disappeared.

From the cervix at the level of the internal os extend the six ligaments composed of peritoneum and filled with connective tissue, lymphatics, blood-vessels, etc., *i. e.* the two broad ligaments, the uterosacral, and the uterovesical. Infections after labor or abortion frequently invade the broad ligament because of the lateral lacerations of the cervix. They frequently invade the uterosacral ligaments after labor or abortion. After abortion and without this condition pus may accumulate in the posterior parametrium with or without pus tubes. In nulliparæ and multiparæ a chronic, slowly progressive but decided invasion of the uterosacral ligaments, and of the posterior parametrium especially, is quite frequent. I know of no other local pelvic condition which is more frequently overlooked. What is its etiology in nulliparæ? This involvement is often combined with salpingitis. Annoyances of urination depending on

slight or unrecognized urethritis, urethrocystitis, or cystitis are very often combined with these lesions, and in numerous cases the history shows that the leucorrhea, the bladder annoyances, the backache, and the pain came on in close succession, just as they may do with an acute gonorrheal infection.

The examination of the seminal secretion is not always possible, in fact, it is only possible in rare instances. We have to rely for a logical conclusion on the association of symptoms and our knowledge of the fact that gonorrhea even when supposedly cured may still supply cocci capable of infection.

Innumerable cases could be quoted of like conditions occurring in women who have been curetted or have aborted or have gone through labor, but I have mainly selected cases, which I have observed, in whom no abortions or careless curettings could justify the suggestion of an infection by other organisms than the gonococci.

A few words about ectopic gestation. Abel in his "Gynecological Diagnosis" attributes to affections of the mucous membrane the etiology of many cases of ectopic gestation.

In the *Medical News*, March 14, 1903, my views as to the causation are expressed as follows: "I believe that in the so-called sterile period gonorrheal, puerperal, tubercular, and atrophic changes take place. The interval of years between the last labor and the ectopic gestation, the fact that the location is generally in the middle area of the tube, the occurrence of an ectopic gestation on both sides at the same time, and the frequency of external migration, together with the combination of extra- and intrauterine gestation point certainly to an affection of one tube and probably, but to a lesser degree, of the other tube. The frequency with which, according to Kustner, a hemorrhagic tendency of the nonpregnant side occurs, as well as the microscopic discovery of catarrhal conditions, together with the history and the microscopical evidences of the presence of gonococci, point distinctly to a tubal affection. The observation of Dührssen, who found cilia abdominal to the placental site and none median to it, and Veit's observation of the presence of inflammation median to the ovum, as well as the theory of congenital and acquired atrophy of the tube, especially subsequent to labor, lead us at the present day to seek in the microscopical changes of the tubal mucosa, i.e. injury to the cilia, the etiological factor in tubal gestation." Subsequent observation has still more surely confirmed my opinion.

That salpingitis is certainly the etiological factor in the production of some cases of ectopic gestation, I well illustrated by the Cases XIV, XV, XVI.

The purpose of quoting these observations on ectopic gestation is this: There is certainly some obstruction in the tube which prevents the ovum from entering the uterus. This obstruction is either an inactivity on the part of the ciliated epithelium as a result of inflammation, or else adhesions of the tubal mucosa. The ovum is arrested in its progress toward the uterus. Such a salpingitis, whether in an early stage and slight, or in a late stage and nearly healed, must certainly be fairly normal in its outer end to permit the ovum to be taken up into the tube, and yet, to the eye at least, these tubes do not appear markedly affected. When, on the other hand, we find in so many of these cases the other tube affected to the degree mentioned below, it simply represents the same variation in the degree of severity of the affection of the two tubes as are observed in most of the cases of salpingitis and even of pyosalpinx.

Now most cases occur in multiparæ, yet a certain proportion do occur in nulliparæ. I consider uterine or ectopic gestation, after long periods of non-artificial sterility and after conservative operations, in most instances an evidence that restoration to the normal has taken place in the tubes in whole or in part. I consider ectopic gestation as an evidence that either a tube is beginning to be affected or that it is almost restored to the normal.

It is impossible, of course, to make an unanswerable assertion regarding the etiology of salpingitis by gonococci diminished in virulence, when the same cannot be shown by the microscope or by cultures. We can only say that even in undoubted cases of acute gonorrhea, after the lapse of several weeks or months, gonococci can no longer be found in the secretions or pus accumulations. It is not so long ago that the vast majority of cases of pyosalpinx were referred to sepsis (streptococci or staphylococci) post-partum or after abortion or curetting. Though pyosalpinx certainly may be caused by other bacteria, and though probably two per cent of the cases are due to *B. tuberculosis*, it is now quite generally recognized that the majority of these cases are due to gonorrheal infection and yet, in innumerable instances, the gonococci cannot be found. They die easily, are destroyed by their own toxins, especially if in association with other bacteria. It is recognized that the gonococci in pyosalpinx either lose their virulence or disappear after a certain period of time. Yet they have been found in the tube wall when not present in the purulent accumulation. In puerperal cases gonococci are often found in the lochia, when not found before, and readily disappear so far as examination by the microscope is concerned. The fact that they are not to be found is no proof of their absence. The staining for the gonococcus in tissues is not an easy procedure, and a great tax on time, and we have to content ourselves in a study of these cases with a comparison of the ultimate lesions resulting after subacute infections with those found after some of the primarily acute infections, and when the two are alike the conclusion is logical. When, in addition, we find these cases so frequently in nulliparæ, when we find that aseptic curettings are so frequently followed by involvements outside of the uterus, it is difficult to attribute to any other infecting media the etiology of most cases of salpingitis.

The crux of the whole problem is supplied by the studies of gonorrheal infections in the male. We know of the discussions, as yet by no means difinitely settled, regarding the curability or noncurability of this disease when it once involves the posterior urethra of the male. Suffice it to say that not rarely in cases in which the microscope shows nothing, examinations (by cultures, etc.) of the prostatic secretions or of the urine, etc., show that gonococci may be present even when almost no symptoms or signs are to be noted. In this connection I wish to state that we need by no means accept as certain the statement that posterior urethritis in the male cannot be cured; I am firmly convinced, however, that in a very goodly proportion of cases it is only supposedly cured. I desire in this connection, to refer to the views of Lapowski and Morrow on this question, and to state that since I have paid attention to their opinions on this matter, I have reason to believe even still more firmly and absolutely that the majority of cases of

salpingitis, no matter when they occur, are to be attributed to the gonococcus as the causative factor

The following cases, from a very large number, have been selected as illustrating the varying degrees of infection. In no instance in which the husband could be questioned or examined has the question of etiology failed of confirmation, as the histories of cases VI, VIa, VII, IX, X, XI, and XII show.

Case I.—Mrs M., came to me suffering from metrorrhagia and marked pain in the left side. There was a mass the size of a hen's egg formed by the left tube and the diagnosis rested, between a pyosalpinx and a tubal gestation. There was no Bartholinitis, no urethritis and very little temperature. Operation divulged a left-sided pus tube in which the gonococci were readily found. Bichloride douches were given subsequently, and examination of the cervical secretion three months later showed no gonococci by the microscope. That they were and are present in the cervix and uterus is probably not to be doubted.

Case II.—Mrs. P., forty-five years old, married twenty-five years, the mother of seven children. For the first time, and that just a few weeks before the date of this case, her husband acquired a gonorrhea, of which he was supposedly cured. The wife then complained of pain in the left side, and her physician sent her to me. Examination showed a decidedly inflamed and sensitive left tube twice the diameter of the thumb. The patient was put to bed and subsequently continued her bichloride douches, since which time she has complained of no annoyance whatsoever.

Case III.—Mrs. M., married four years. Her husband two years after marriage acquired an acute gonorrhea, the wife then acquiring an acute urethritis and cystitis, for which she was treated by me for six weeks. Bichloride douches were given and at no time subsequently was I able to find gonococci in the cervical secretion. The patient since then has been operated on vaginally by me for an ovarian dermoid, subsequent to which she went through a normal pregnancy without any evidence of tubal or peritoneal involvement.

Case IV.—Mrs. B. came complaining of a vulvar irritation, and expressed the opinion that she had been infected by her husband who, since their marriage, had acquired "a disease." Examination revealed a left Bartholinitis and a marked vaginal discharge, in both of which gonococci were found. The abscess was opened and drained and bichloride douches were ordered. After a period of six weeks no gonococci could be found in the microscopical examination of the cervical secretion. Four months later the patient appeared with a left-sided salpingitis and markedly tender and infiltrated left broad ligament.

Case V.—Mrs. L., twenty-five years of age, 0-para, married two years. Five weeks after her marriage she was in bed for three months with what she called "an inflammation of the womb." Since then she has been troubled with backache, marked abdominal pain, and leucorrhea. Examination showed a pyosalpinx of the right side and a salpingo-oophoritis of the left side. Operation consisted in a double salpingo-oophorectomy. No gonococci could be found in the tubes.

Have not been able to communicate with her husband.

Case VI.—Mrs. S., twenty years of age, 0-para. Six months after marriage complained of pain on both sides. Examination showed a salpingo-oophoritis of the right and left side with adhesions. Treatment failing to relieve annoying symptoms, patient was operated on by me and two tubes the size of a lead-pencil with both outer ends closed were removed. Examination of the tube-contents by the microscope did not show gonococci. On subsequent inquiry the patient said that she was treated six months after marriage for gonorrheal infection and for gonorrheal vulvar warts. The husband gives the following history:

He suffered from gonorrhea six years ago, the attack lasting five months. He married four years ago and his wife had a child. His wife died shortly after childbirth. In June he had a second attack of gonorrhea, which lasted three months. He married for the second time in November, 1904. He noticed a colorless discharge in the morning of a stringy character which persisted for one month after marriage.

Case VIa.—Mrs. MacF., twenty-four years of age, married two years, one abortion at the second month. Two months later she underwent an abdominal operation. She then "acquired a disease from her husband." Six months after the first operation a second operation was performed. Six months later she came under observation suffering from marked pelvic pain. I removed the inflamed adnexa (cystic ovary of one side and closed thickened tube of the other side) remaining after the previous conservative operations. Her husband's history is as follows:

He is twenty-seven years old. Seven years ago acquired a gonorrhea lasting two months. Two or three years ago he had a second infection lasting, off and on, for one year. In the first attack he suffered from a double orchitis.

Case VII.—Mrs. J., thirty-two years of age, married ten years, 1-para nine years ago. Six months ago complained of pain in the back and decided pain in the left side. She suffered then from a marked bloody discharge for several days, this occurring two weeks before entering the hospital. Diagnosis, salpingo-oophoritis duplex. Operation, double salpingo-oophorectomy. Diagnosis of etiology was gonorrhea but no cocci could be found. Examination after operation showed a persisting posterior parametritis, but the patient feels absolutely well. The husband gave me the following history:

He is thirty-four years old, a veteran of the Spanish-American War. He had gonorrhea twelve years ago, which lasted one year, during which he had an orchitis, and his inguinal glands were incised. He also suffered from inflammation of the bladder and a subsequent persistent stringy mucous discharge. This trouble came back in slight fashion soon after marriage and lasted about three weeks. Five years ago, while serving on one of the battleships, he acquired a new attack of gonorrhea, which lasted two and one-half months. He returned home one year ago with a mucous discharge. Six months ago the symptoms of Mrs. J. began.

Case VIII.—Mrs. R., thirty-two years of age, 1-para fourteen years ago. Patient came complaining of a right-sided pain, and examination showed a salpingo-oophoritis dextra. At operation an adherent and thickened tube and ovary were removed, the other tube and ovary, appearing normal, were left in place.

On questioning the patient subsequent to the operation she stated that she believed herself to have been infected by her husband a short time after the birth of her child, because of which fact she had been separated from him for years. Subsequent to the operation the patient has married

again on securing a divorce from her first husband. Three months after marriage she comes complaining of the same pain on the other side, and examination shows an inflamed tube and ovary of that side.

Case IX.—Mrs. C., twenty-eight years of age, o-para. One year ago complained of pain on the left side, which came on suddenly and was diagnosed by her physician as abscess of the left ovary. She was in bed for ten days with fever. She now has a dull steady pain in the same spot, extremely painful when on her feet or walking. Examination showed a slight erosion of the cervix, the fundus markedly drawn to the right side, a decided parametritis dextra. The right adnexa seemed apparently normal, but those on the left side are prolapsed, sensitive, and adherent. Diagnosis was made of probable gonorrheal infection. This diagnosis was sent to her physician, and he was asked to interview the husband.

Husband states that he had gonorrhea ten years ago; married one year later. One year ago he was treated by a physician for a profuse typical discharge, which date, according to his statement, was about four months after his wife had acquired pelvic inflammation.

Case X.—Ida M., twenty years old, married three years, o-para. One year ago the patient complained of pain on the right side. Examination showed a right-sided salpingo-oophoritis. These enlarged and adherent adnexa were removed by me. Three months after the operation the patient complained of pain on the left side. Both her physician and I now find a left-sided salpingo-oophoritis. Her physician states that the husband was treated by him four years ago for a gonorrhea which lasted eight weeks.

Case XI.—Mrs. J., married three years and sterile. Two and one-half years ago, after some intercurrent illness she developed a mild leucorrhea and acquired marked pain on both sides, particularly on the left. Examination showed a double-sided salpingo-oophoritis with peritoneal adhesions. Examination of the spermatic fluid showed active spermatozoa but a fair number of pus cells.

On interviewing her husband, he stated that subsequent to his marriage he was treated for a newly-acquired gonorrhea of a mild nature.

Case XII.—Mrs. A. L., o-para. Treated for some time for double salpingo-oophoritis. Operation refused. Examination of the spermatic fluid shows inactive spermatozoa and large numbers of pus cells.

Case XIII.—Mrs. F., thirty-two years old, married eight years, o-para. Had a "sore on the womb," and was operated on for this eight months after marriage. Leucorrhea and frequent micturition since marriage. Complains of marked pain on both sides, particularly on the left. Examination shows parametritis dextra and sinistra and salpingo-oophoritis of both sides. Was curetted two years ago. Have been unable to interview her husband.

Case XIV.—Mrs. L., thirty years of age, operated on by me for ectopic gestation of the left side. The right tube was thickened and inflamed and the ovary of that side was cystic. They were also removed.

Case XV.—Mrs. K., forty-four years of age, ectopic gestation of the right side removed by me. Left tube and ovary were markedly involved by adhesions and were also removed.

Case XVI.—Mrs. P., twenty-seven years of age, ectopic tube of the left side removed. The right tube was thickened and swollen, and the outer end closed by adhesions. This tube was also removed.

Conclusions.—(1) Virulent gonorrhea in the female results from infection by an acute or persisting or recent gonorrhea in the male. (2) The majority of pyosalpinges are to be attributed to the gonococcus of this class. (3) Less-virulent gonococci from old cases, in which examinations by microscope show pus cells, etc., but no gonococci, or from supposedly cured gonorrheas, produce a subacute and scarcely recognized infection of the cervix. (4) Reinfection, labor, abortion, pregnancy, *curettings*, produce a recrudescence of the lesions, varying in severity according to the character of the original infecting cocci, and in proportion to the resistance of the tissues. (5) Pregnancy, abortion, labor, *curettings*, favor extension in continuity in many cases of "catarrhal infection" of the cervix and uterus. (6) The majority of cases of chronic non-purulent parametritis and salpingitis are due to gonococci of a less virulent character. (7) Many cases of cystic ovaries tuboovarian cysts, perioophoritis and peritoneal adhesions, are due to such a salpingitis. (8) Numerous cases of pelvic pain, many cases of sterility, and many cases of ectopic gestation are the result of such forms of salpingitis. (9) Milder degrees of salpingitis do not necessarily cause much pain or discomfort. (10) If the tubercle bacillus, non-virulent streptococci and staphylococci, etc., may produce a mild salpingitis, then in nulliparæ the source of the two later forms of cocci may be a urethritis or prostatitis originally gonorrheal. (11) Since the gonococci are in the cervix and uterus, conservative operations always include the possibility of subsequent further invasions of the structures left behind. (12) Since parametritis so often exists alone and so often complicates salpingitis, operations on the adnexa cannot possibly free all patients of their annoying symptoms without due attention to this condition either before or subsequent to operative interference.

While correcting the proofs for this article there were published two papers worthy of close inspection, and bearing directly on the subject matter of this article.

In the Transactions of the New York Obstetrical Society, reported in the February number of the *American Journal of Obstetrics*, Dr. William S. Stone reported seventeen cases, which were studied in the wards of the Lying-In Hospital in 1904, and were collected from 172 cases of pregnancy. Only selected cases were examined for the gonococcus, and in suspicious cases repeated examinations were made until positive or negative results could be obtained. In these seventeen cases gonococci were found. All of these seventeen patients were primiparæ, although a certain number of multiparæ were delivered in the clinic. The tendency of the disease to spread upward and involve the tubes was believed to account for this disproportion. One child sterility was thus caused, as the report states, by gonorrheal disease.

Under the title of "The Sharp Curette Within the Uterus," Byron Robinson expresses the following views in the *New York Medical Journal*, January 20, 1906: "It is cruel because it inflicts untold damage and misery on the genital tract and adjacent pelvic structures as well as causing numerous deaths without accomplishing relative benefit. The endometrium sits directly on the myometrium with no intervening submucosa to check endometrial infectious invasion, hence uterine curettage is practically dangerous, first and foremost because it produces wounds, atria

for infection in a spongy lymph-bed, susceptible to invasion and germ culture. Curettage is the direct cause of vast numbers of subjects possessing chronic metritis, salpingitis, and pelvic peritoneal exudates, necessitating long suffering, sterility, or removal of the uterus or oviduct. Uterine curettage for sterility is irrational as it is unsuccessful and dangerous, for frequently one observes the condition of the patient is worse some months after the operation. The existing pathological conditions are exacerbated. The indiscriminate use of the curette has been the cause of perhaps more misery than any other factor in gynecology, and not a few deaths. In curettage, dilatation of the uterus is generally a preliminary operation, and the dilator produces hundreds of wounds, atria for infection, not only in the endometrium, but also in the myometrium. Few uteri can be dilated without causing laceration, new wounds for infectious invasion. The sharp curette is the most dangerous and cruel of gynecological instruments. It is cruel, because it inflicts untold suffering. It is dangerous, because it inflicts on the adjacent and genital visceral tract acute and chronic disease with sterility and occasional death."

134 West Eighty-seventh Street.

IONIZATION BY MEANS OF THE HIGH FREQUENCY CURRENT IN THE TREATMENT OF TUBERCULOSIS.

By ALFRED GOSS, M.D.,

ADAMS, N. Y.

As an introduction to my description of the plan pursued by me in the treatment of tuberculosis during the past two years, I would like to say that evidence seems conclusive that the disease is of bacterial origin, and the readiness with which these cells lodge and multiply varies greatly. Indeed, the number of instances in which they fail to take root and grow vastly exceeds those in which they do. The cause of the difference in individual susceptibility has an important bearing upon the treatment. In a state of health nature seems to furnish in nonsusceptible cases protective proteids, found in the blood plasma called alexins. Besides these, we find according to the laws of Dalton in regard to the absorption of gases by liquids, "the blood plasma holding oxygen in solution and the hemoglobin which by actual weight makes 90 per cent. of the dried corpuscles entering into partial combination with oxygen. The oxygen in the hemoglobin is in such a loosely combined state that it readily solves its bonds of union and, under the slightest provocation, goes over to other elements, for which it has affinity, as soon as the pressure conditions of the plasma are changed." This affords, together with the phagocytosis taking place upon an invasion of bacteria, all the protection required. This I will refer to later also as an illustration of the union taking place between atoms of matter and electrical units.

In susceptible cases we find the phagocyte unable to cope with its enemy, the bacillus, and after absorption digestion fails to take place. The germs multiplying within the phagocyte, and by overcrowding produce its destruction, thus indicating that in nonsusceptible cases the bacilli are destroyed so far as multiplication is concerned before being absorbed by the phagocyte. This leads to the discussion of the question of the introduction of a substance into the blood plasma having a special affinity for the tubercle bacilli, taking the place of the alexins where they are wanting, thus giving nature a chance through phagocytosis to eradicate the disease. This might be easy if it were not for the fact that the bacillus being an irritant, upon its gaining access the same response occurs to it as to other irritants. The wandering leucocytes flow from the adjacent cells which constitute the bulk of the tubercle, the reticulum of connective tissue is formed just as is connective tissue in ordinary nonspecific inflammation by the fibrillation of the protoplasm of cells and the rarefaction of the resulting matrix, thus making an impenetrable wall beyond which no circulation takes place. If by any means this passage could be cleared and this wall cut down the great obstacles to our success would be overcome. It is on this account that I first attempted through the medium of high frequency currents to effect a penetration of this wall. These currents, possessing as they do qualities of high potential, extreme voltage and rapid interruption make them suitable currents on account of their great penetrating qualities. Acting as they do as a stimulant to the circulation, or perhaps more correctly stated, equalizing circulation, they tend to relieve congestive action, thereby producing rapid absorption and elimination, rapidly stimulating the production of leucocytes as well as the red cells, they would not only furnish an increased army to combat their enemy, but by absorption would rapidly break down the barriers or breastworks of their enemy. Added to this, the current stimulating as it does cell growth, overstimulates the bacilli, and by their overproduction in their narrow quarters they become attenuated both in size and vitality. The current of electricity to be used should under no circumstances be one lacking in pressure, nor should it be allowed to be too general in its action, but should be focused or centralized as much as possible to the infected area. According to Kinraide, and as has been verified by Mr. Wilkinson in recent experimentation, "When electric energy changes from a condition of diffusion to a center of focalization it is passing through its negative phase; when it changes from a condition of focalization to a condition of diffusion it is passing through its positive phase. These two conditions may be correctly termed the anodus—or going in—and the exodus—or going out—of electric energy. Electricity is not a dual force with a dual activity, but a single force with a single line of direction for the sweep of its energy; furthermore, the positive and negative phenomena indicate the one, an accumulation or heaping up of electric energy, the other a corresponding withdrawal." In these treatments the body represents the condensor, and the concentrated or accumulated electricity from the negative side of the machine is discharged into it, and each interrupted discharge produces a certain amount of electric entity, which entity has a birth, a growth, and a death or dispersion. This entity, or union of the positive and negative quantity, has a center or body which is neither positive nor negative in character, and represents the dynamic phase of electricity. It is at this point of each electrical discharge I claim atoms of matter will unite with surplus electrical units, not forming new compounds, but in the same manner that the hemoglobin holds its surplus oxygen. The atoms of matter having polarity in the presence of electrical units that are nonrepelling, lacking either positive or negative force, would tend to attach these units to themselves by a feeble bond and travel together until the atom of matter was brought in contact with a substance for which it had an affinity, when it would

drop its surplus electrical units and form a more stable union.

The form of electrode I think is of great importance. I use a vacuum tube for surface application, and instead of having a flat surface have it concave on the bottom, with a wire extending lengthwise through the tube, and a large disc made concave on the under surface to correspond in shape with the bottom of the glass electrode and suspended about one-half inch from it. By the application of the high frequency current the superficial circulatory apparatus becomes greatly engorged and the patient breaks out in profuse perspiration. This drainage changes the specific gravity of the blood plasma. With this change in specific gravity there should be a rapid absorption of the gases retained under the vacuum electrode. By this means I endeavor to introduce substances into the circulation to take the place of the alexins where they are wanting. To focalize a current when treating the chest, I cover the back with tinfoil connected to a chain which is grounded, and reverse this when treating the back. The machine used is a Van Houten & Ten Broeck static machine connected with a resonator, devised by Dr. William J. Morton and constructed by Mr. Wilkinson of the before-mentioned firm. This gives me a current of from 250 to 500 milliamperes and about a million and one-half volts. The superiority of the current is in its great pressure, and one does not get the irritating effects upon the skin that are found in using coils such as I have tried. The pressure of the current should be such that when it is allowed to discharge before a fluoroscope the sensitive screen on the opposite side of the pasteboard from the discharge and within the fluoroscope will fluoresce.

The question of the penetration of these currents I think it unnecessary to dwell upon, as the facts are too well established to need further comment. The evidence of the penetration of the gases generated by this current is in the fact that the patient detects the taste in what is coughed up and expectorated for from twelve to twenty-four hours following treatment. In evacuations from the bowels it is detected by its odor, when used over the abdomen, and when used over the bladder the urine has the characteristic odor.

By the method described I have treated in the past two years a little over two hundred cases, but on account of failure to keep my records accurately previous to June 1, 1905, I report my cases from that time, and will merely state in regard to the previous cases that I had forty-four cases out of eighty recover within a period of six months. Since June 1 I have one hundred and seventeen cases recorded, with thirty-eight absolute recoveries so far as after repeated examinations no tubercle bacilli showed in the sputum. They regained their weight and ran a normal temperature. They have since been living in various sections of the country and still remain well, performing their usual avocations. There were seventeen that were improved, but from various causes discontinued the treatment and are still remaining comparatively well. One thing of interest to me is the fact that in three instances where people were dismissed improved I have heard through their physicians that there was a complete disappearance of the germs after a few weeks, without further treatment, they living at home and performing their usual work. I have had thirty-seven deaths and twenty-five unimproved. Of the cases improved or recovered I notice the following conditions existing during the first week: there would be an invariable increase in the number of germs present which would be gradually diminished again, so that by the end of the third week the number of germs would correspond with the number first shown. During this time they would be gradually gaining in weight, and from the end of the third week the germs would gradually diminish in number.

In regard to the temperature changes, for the first week a person would get extreme fluctuation, varying from 96° in the morning to 103° in the afternoon, and in exceptional cases dropping even as low as 93°. In these cases before the third week of treatment was finished their temperature would not vary any time within the twenty-four hours to exceed one-half a degree. The physical examination will show, in all these cases within two weeks from the time of commencing treatment, increased breathing capacity and frequently the sputum is slightly stained with blood. This I look upon as a favorable sign. While in the cases that progressed unfavorably one would get a high temperature each afternoon, and although their appetite would generally improve and they would take on a small amount of flesh, this would be of short duration.

The formula which follows generates a gas which is stated by John Glassford, chemist of Cooper Institute, to be Carvocrol, a powerful germicide which I think has a special affinity for the tubercle bacilli. The mixture consists of gum camphor and iodine, each 3 ounces, turpentine, 6 ounces, and sulphuric acid, one dram.

None of these cases were in the incipient stage when admitted, the shortest time any patient had been afflicted with this trouble being one year, and the oldest case eight years. I append a list of favorable cases, giving the temperature, weight, pulse, and bacteriological examination at various times during treatment.

In this list I have selected the cases, giving the results without showing the change each day or the rapid fluctuation in temperature resulting from the first few treatments, more especially to show the general effects from time to time, and I have not spoken of the hygienic or dietary side. It goes without saying that good fresh air, pure food of nutritious kind, and passive exercise is advisable. No forced feeding is given to impair the stomach's functions, and only such medication as from time to time is demanded by individual cases. Climatic conditions are more than compensated for by this treatment, and the surroundings and comforts of our cities and eastern towns. Good nursing, salt and oil baths, passive exercise that takes the attention and promotes cheerfulness is a great factor that should never be lost sight of. All this together covers the plan I pursue.

The first date given is the time of commencing treatment. The patients were dismissed within a week or two after the tubercle bacilli disappeared, and in a few cases as shown, stopped taking treatments and recovered when the disease was not far advanced, performing their usual work with no bad results.

Owing to limitations of space it is necessary to condense considerably the record of the cases, and I will, therefore, to save repetition, give the information in the following order: Case number, age, duration of disease before treatment, duration of treatment, following with results of microscopic examinations and remarks:

Case No. 2.—Fifty years, 23 months, 25 days; began treatment June 8, 1905; June 3, Meader, tubercle bacilli present; July 2, Bingham, no tubercle bacilli; remains well at present time.

Case No. 3.—Thirty-two years, 18 months, 42 days; began treatment June 8, 1905; June 8 tubercle bacilli present, sputum swarming with cocci; July 15, Meader, a few tubercle bacilli; October 5, swarms of cocci, no tubercle bacilli.

Case No. 6.—Twenty years, 1 year, 50 days; began treatment May 17; May 20 tubercle bacilli plentiful; July 15, Meader, 2 to 10 tubercle bacilli in each field; July 25, very few tubercle bacilli; August 5, no tubercle bacilli; remains well at present time. Gained 11 pounds during period of treatment.

Case No. 10.—Thirty-five years, 1 year, 96 days; began treatment May 18; June 3 tubercle bacilli thick; June 16, Bingham, tubercle bacilli present; June 21, Bingham, very few tubercle bacilli; July 7, Meader, few tubercle bacilli; July 31, in 10 fields only 1 tubercle bacilli; August 13, Bingham, 3 tubercle bacilli in 30 fields; September 2, no tubercle bacilli. Gained 35 pounds in weight during treatment.

Case No. 60.—Twenty-three years, 2 years, 124 days; began treatment June 7; June 10 tubercle bacilli present; June 28, Bingham, tubercle bacilli present; July 15, few tubercle bacilli, many pus corpuscles; August 12, Bingham, mixed infection; average number of tubercle bacilli, 2 to the field; September 13, few cocci, 24 tubercle bacilli in 30 fields; October 9, 200 fields show no tubercle bacilli.

Case No. 66.—Forty-eight years, 30 months, 106 days; began treatment June 5, tubercle bacilli present; July 15, 2 to 6 tubercle bacilli in each field; August 7, 16 tubercle bacilli in 10 fields; gained 18 pounds in weight and returned to work and remains well since.

Case No. 81.—Sixteen years, 1 year, 94 days; began treatment June 28; June 27, tubercle bacilli present; July 25, Meader, many tuberculous masses, few bacilli; August 5, 15 fields show 5 tubercle bacilli; August 25, no tubercle bacilli.

Case No. 83.—Twenty years, 18 months, 51 days; began treatment June 15; June 15, tubercle bacilli present; June 28, few tubercle bacilli; August 7, no tubercle bacilli; remains well at present time.

Case No. 89.—Forty-four years, 22 months, 57 days; began treatment June 27; July 7, Meader, tubercle bacilli present; July 25, average 10 tubercle bacilli to a field; August 15, average 14 to a field; Bingham, August 21, average 2 to a field; September 30, no tubercle bacilli present. Gained 12 pounds during treatment.

Case No. 96.—Thirty years, 14 months, 89 days; began treatment July 19; July 25, Meader, average 6 to 10 tubercle bacilli; August 18, Bingham, 6 tubercle bacilli to 15 fields; September 3, no tubercle bacilli.

Case No. 97.—Twenty-three years, 1 year, 100 days; began treatment July 17; July 31, 10 to 11 tubercle bacilli in each field; August 15, 16 to 17 tubercle bacilli in each field; August 30, 3 to 4 tubercle bacilli in a field; October 21, 15 fields contained 12 tubercle bacilli; gained 14 pounds in weight. Went home and has since remained well without further treatment.

Case No. 102.—Forty-one years, 23 months, 56 days; began treatment August 9; August 10, tubercle bacilli 18 to a field; August 23, 16 tubercle bacilli in 45 fields; September 6, average 2 tubercle bacilli; October 5, 45 fields showed 3 tubercle bacilli; October 26, no tubercle bacilli. Gained 18 pounds during treatment.

Case No. 116.—Twenty years, 15 months, 40 days; began treatment October 1, average 16 tubercle bacilli; October 26, 4 tubercle bacilli in 15 fields; November 3, 5 tubercle bacilli in 15 fields; December 26, no tubercle bacilli; January 7, no tubercle bacilli; gained 20 pounds during treatment and remains well at present time.

With reference to the preceding examinations, they were made by Drs. Meader and Bingham, of Watertown, Dr. Jones of Utica, and some by Dr. Williams and Dr. May.

FRESH-AIR HOMES AND MEDICAL WORK IN CONNECTION WITH THEM.*

By LINSLY R. WILLIAMS, A.M., M.D.,

NEW YORK.

ATTENDING PHYSICIAN TO SETON HOSPITAL, FOR CONSUMPTIVES, ASSISTANT PHYSICIAN TO THE CITY HOSPITAL, ATTENDING PHYSICIAN TO THE SEA BREEZE HOSPITAL FOR SURGICAL TUBERCULOSIS IN CHILDREN, ETC.

I need not enter into a detailed description of all the fresh-air homes in Europe and this country, but let me recall to your mind that fresh-air homes and summer vacations go back to the earliest historic times. That during the past century there have been built in Italy numerous summer homes on the Adriatic for convalescents and the sickly, and that France has numerous Ecoles des Vacance, and that similar institutions are numerous in Germany and England.

There are many fresh-air homes in this country, situated, quite naturally, in the neighborhood of the larger cities. These homes have in the main been built in the last two decades, for the needs of the poor in this country, as a result of our large acquisition of wealth and the ever-increasing demand of the general public for fresh air.

In New York City a large part of its population, 36 per cent., lives below Forty-second Street, on Manhattan Island, where, compared to the total park area of the city, that below Forty-second Street amounts to only a few breathing spaces, namely, 5 per cent. There is no advantage to state any arguments as to the demand, the need, and the value of fresh air for the New York tenement-house population.

It does not seem necessary, either, to prove that for laboring men and working mothers and factory boys and girls, a vacation is more of a necessity than it is for the professional classes and the small leisure class who are almost always able to obtain a vacation. The need of giving these 500,000 a vacation if only for a day's outing, has been appreciated for many years, and probably from 20 to 30 per cent of this number obtain a day's outing on river or ocean, or to country or seashore, during the summer. "During the summer of 1903, 116,464 mothers, babies, and elder children received a day's outing These were sent by twenty-four different agencies The New York Association for Improving the Condition of the Poor sending 17,699, while twenty-two different agencies gave stays of a week or more to 33,161, that is, between 5 and 10 per cent. of the number needing a vacation received it." (Allen.†) Of these 33,161, 2,754 were sent by the New York Association for Improving the Condition of the Poor to Coney Island for an average stay of ten days.

The need of this vacation in a fresh-air home is occasioned by sickness, hardship, overwork, or the want of work, overcrowding, and underfeeding. A fresh-air home does more good, in my opinion, in

*The results of two years' experience at Sea Breeze, Coney Island, a Fresh-Air Home conducted by the New York Association for Improving the Condition of the Poor. A paper read before the Society of Internal Medicine, December 20, 1905.

†Allen, Annals of the American Academy of Political and Social Science, May, 1904

a medical and economical way, in a week's time than several months of treatment at a dispensary, for many patients, at least.

Who, then, go to these fresh-air homes? The convalescent and the poor. Applications for the convalescents are made to the various agencies by hospitals, dispensaries, day nurseries, physicians, district nurses, parish workers, etc. For the poor, applications are usually made by visitors of charitable associations, to whom these cases have been referred for relief.

What agencies are there, then, to receive these applications? In Manhattan and Bronx there are sixty-four different agencies noted in the Directory of Charities who give a stay of a week or more to about 50,000 mothers and children. Besides these sixty-four there are numerous smaller agencies in the various churches and in many schools and clubs, but only one home takes men.

The great majority of these agencies are engaged only in fresh-air work, but some are also engaged in other fields of charity. Six societies in Manhattan and Bronx deserve special mention: 1. the Society of St. Vincent de Paul. 2. the Children's Aid Society. 3. St. John's Guild (though it does not call itself a fresh-air charity, but a hospital). 4. the *Tribune* Fresh Air Fund. 5. the New York Association for Improving the Condition of the Poor. 6. the Hebrew Sanatorium for Children.

Three of these agencies are engaged in fresh-air work only, and three of them in other branches of relief also. There is no central application bureau to prevent "overlapping," that is, to prevent one family from taking advantage of the several societies and obtaining more than their share of fresh air. This does happen, but probably not to any great extent except in the day parties. Of eight hundred children sent to the country, during the summer of 1904, for a stay of a week or more, sixty had been to Sea Breeze; and of these sixty only two had been elsewhere. Among the day parties there is doubtless greater "overlapping," due mainly to the ease of procuring invitations, and to the fact that in large parties of five hundred or more, fifty to one hundred more people make little difference..

During the summer of 1904 I was invited to examine, not the applicants for Sea Breeze, but those who had not been invited to Sea Breeze (applicants are always more numerous than those who are invited). The main idea of this examination, was to exclude cases of contagious diseases, and to recommend the length of stay for each person or family. During the three seasons previous, there had been in New York a large number of cases of trachoma so that regular examinations had been necessary, and in those seasons the examining physician reported that 10 per cent. of the children had trachoma. These children were refused Sea Breeze for two reasons, because the glare and sand were both bad for the eyes and because of the infectious nature of the disease. Owing to the efficacious methods of the Department of Health, during the summer of 1904, there were only five cases of trachoma and two of conjunctivitis amongst the invited guests. This, among 1,716 boys and girls, seemed not excessive.

Before the invitations for Sea Breeze are sent out the homes of all the applicants are visited by the so-called Fresh Air visitors in order to learn several important things about the family. Are they able to pay for a vacation? Have any of the family been away at any other home? Has there been or is there any contagious disease in the family? Are the children at school? (Sea Breeze opens before school closes and does not close until after school opens.) Are the children of the proper age? (Girls of all ages, boys under twelve, being admitted to Sea Breeze.)

If all questions are satisfactorily answered, instructions are given as to cleanliness, especially of heads, and for the family to come to 105 East Twenty-second Street at 8:30 on an appointed morning to the Assembly Room, in the United Charities Building. The parties are examined as expeditiously and quietly as possible, and sent in groups of forty to seventy-five to the East Twenty-third Street Ferry, and when all have arrived on the Brooklyn side, they are all, numbering from one hundred and sixty to two hundred, sometimes more, snugly packed into special trolley cars and taken direct to Sea Breeze at West Coney Island, without any change of cars.

The attempt is made to get the party to Sea Breeze in time for dinner between 12 and 1 o'clock, and in these same cars, returns the party of the previous week who have already had their dinner. This method prevents overtiring on the part of the guests, brings them to Coney Island in a good humor and after a glimpse of lawn and flowers, they are seated for dinner. This insures that their first impression is a good one. The returning parties at the same time have lost no time, so a larger number of total days can be given and there is a saving in transportation.

To examine from one hundred and fifty to two hundred and fifty women and children, two-thirds of whom are children, on a hot summer morning and to do it quickly is a trying task and requires patience and good temper to no small extent. The limit of time is from two to two and one-half hours. To get in a word with each mother, to inquire about each child, to send directions to the nurses and to have the supervisor check off each guest to prevent frequent attempts at substituting an uninvited guest, or from suddenly increasing the members of the family, requires quick, pointed questioning and tact.

In the summer of 1904, large numbers of children having "nits" in their hair were excluded in the early parties, and on one particular day, the nits and lice were so numerous, and so many children were infested that over one-third of the party of over two hundred were rejected and their visits postponed. This served as a lesson, for rumor spreads quickly in the tenements, but only after each visitor was told to insist that all heads be free not only from nits but from lice and lice eggs, was there any diminution in the number of cases. After a time the effect was marked, and during the summer of 1905 there were several parties in which it would be hard to find a single nit.

To keep accurate statistics while hurrying through such examinations was impossible, even with two doctors, which was tried for a time; but a partial list was kept, which was as follows (the complete list being in the Sixty-first Report of the New York Association for Improving the Condition of the Poor):

Disease of circulation, 20; respiratory organs, 13; nervous system, 26; eye and ear, 23; convalescent from acute diseases, 38; from operations, 25; from fractures and injuries, 8; disease of alimentary canal, 42; gout, rheumatism, goiter, etc., 17; deformities, 20.

There were altogether no less than 292 women and children convalescent or convalescing, including a few abnormalities. There developed at Sea Breeze one case each of measles, diphtheria, pneumonia, and typhoid fever.

The diagnoses made are snap diagnoses, made from a few statements of the patient and from a glance, and the diagnoses are given as they were in the report to the Association in laymen's language.

This list of diseases is given in detail in order to show the class of patients that can be admitted to a fresh-air home. Of course, none of these patients was, at the time of departure for Coney Island, ill enough to be in bed.

During the winter of 1905 there was considerable thought given to the question of the public school children, and it was found that numerous physical defects existing among them were due to the fact that they went breakfastless to school. This question received much discussion in the public press and in school and philanthropic circles. Various estimates were given by charity workers and school superintendents as to the number of breakfastless children, varying from 50,000 to 200,000.

There was, and is, no means of telling the total number. The Salvation Army offered "free breakfasts for school children," but this was not attended with great success, as the poorest did not get them, and many parents who could well afford to give their children a good breakfast sent them to obtain this free breakfast.

During the spring of 1905, the Department of Health, under the direction of Dr. J. J. Cronin, Chief Inspector of Schools, examined 7,166 schoolboys, and found among them 3,152 needing medical attention; 1,638 had enlarged cervical glands, 133 had evidence of heart disease, 127 of pulmonary disease, 1,946 had defective teeth, 1,273 had defective vision, and so on, through the various organs of the body.*

With the results of these spring examinations in mind, it was decided to attempt to get a physical examination of each child of school age who went to Sea Breeze, and further to get a record of the height, weight, and chest circumference of each child. This naturally meant a more thorough examination than in the previous summer, and an enormous increase in the work.

One thousand four hundred and ninety-two children between the ages of 5 and 14 years went to Sea Breeze. Of these, 955 were examined at Twenty-second Street for the condition of the mouth, teeth, hair, and cervical glands. Time was too short for the examination of eyes and ears and for adenoids, only self-evident defects being noted. One thousand and eleven children were examined at Sea Breeze. This examination was made at bed time on the night of arrival or on second night.

The physical examination and chest measurements were made by myself, with the assistance, on several occasions, of Dr. Charlton Wallace. The chest measurements were taken at the level of the nipple, during easy respiration. The height and weight were taken with a special measuring stick and Fairbanks scale. These were taken by the superintendent or by some member of the nursing staff under her supervision.

The percentage of defects of the Sea Breeze children was a little higher than those of the Department of Health, for the reason that the children were "selected children"; that is, those whose parents were in very poor circumstances, children who have lived in poor surroundings, and who have had very poor and insufficient food. But these Sea Breeze children were school children, and among the 1,087 examined, defects were found that suggest causes lying too deep to be reached by "free school breakfasts."

The height, weight, and chest circumference of the Sea Breeze children were compared with the standards of Bowditch and Porter based upon 7,000 and 15,000 children of American-born parents in Boston and St. Louis. The weights of the latter were reckoned with their clothes on; those of Sea Breeze children with night shirt weighing only a few ounces. Due allowance, however, was made by correcting to net weights, allowing 2½ pounds for children of five years, 3 pounds 5 ounces for children from six to nine, 5 pounds 7 ounces for boys ten to twelve, 4 pounds 5 ounces for girls ten to twelve, and 5 pounds 6 ounces for girls of thirteen, as recommended by Holt.

Of 555 cases 185 were of full American parentage, 90 having one parent American. Few of the children were Italian, Austrian, or Jewish. The great majority were American, then Irish and various strains of English, German, and Scandinavian. The tables also distinguish children according to school—public school, parochial school, industrial school, and those not attending school. There were too few observations among the industrial school children to be of any value. The observations made for different ages show no appreciable difference between the other three classes. As to height in early years, it agrees fairly with the standard, but soon falls below. The weights are much below the standards of Bowditch, and in some instances far below the very low standards ascertained by Porter. It is also interesting to note that all of these tables are far below the standard set by the anthropometric committees of England and the United States, and very far below the measurements by Dr. Dukes* of the boys from the favored classes—*i.e.* 7,855 boys at Rugby. The chest circumference is woefully deficient at all ages for both boys and girls, being nearly an inch at each age.† (Boys, Table 1. Girls, Table 2.) What do these deficiencies mean? Are we growing a smaller race than Boston? If so, why?

Many other evidences of poor surroundings and poor care were observed, notably a frightful condition of the teeth. Teeth were examined in 955 cases and found bad in 290—bad meaning unfilled cavities, generally foul with sore gums, and in nearly every instance swollen glands in the anterior part of the neck. Bad teeth did not include de-

*Up to December 23, 1905, the Department of Health had examined 55,332 children, and in 33,551 treatment was advised. Private conversation with Dr. Cronin.

†The tape was subsequently accurately measured and found to be 1-32 of an inch short to the yard.

fective or crooked teeth. Many of these children with bad teeth had coated tongue, foul breath, and sallow, muddy skins. Naturally, for bad teeth means poorly masticated, poorly digested, and poorly absorbed food. These conditions applied to all ages and were a striking proof of the urgent need for competent, compulsory, free dental clinics for school children.

532	....	....	.....	.....	....	....

These tables were also divided to show the difference (which was so slight that it can be disregarded) between the children of the parochial and the public schools. There were only 29 children of the industrial schools examined, so little comparison can be made with these figures, but they are included in the totals. By comparing the results obtained, it will be seen that they are similar to, or below, the results of Porter, a far lower standard than that of Bowditch.

An incomplete physical record was published in the Sixty-second Annual Report of the New York Association for Improving the Condition of the Poor. This table showed that over 50 per cent. of 955 children had enlarged cervical glands, 30 per cent. had bad teeth, 6 per cent. had heart disease, and 3 per cent. pulmonary disease, including 13 cases of pulmonary tuberculosis. A certain number of cases of contagious diseases developed while at Sea Breeze, several each of measles, whooping-cough, mumps, diphtheria, typhoid fever, and chickenpox. I may state that no case of measles developed until the fifth day, and almost all the contagious cases were in children under five years except the typhoid cases; that is, these diseases occurred in those children who were not so carefully examined.

What cases should we not send to a fresh-air home? Any contagious case or one in which there has been exposure to contagion. Cases of pulmonary tuberculosis and cases that need hospital care rather than that of a convalescent home.

Also, young infants, so-called "feeders," unless there is a resident physician who is competent to care for such cases, and unless one is reasonably sure that such babies will not die en route, or immediately after arrival, for they are so often sent to the seashore, like a dying consumptive to the mountains, as a last chance.

Some of the more important things done for these children at Sea Breeze: Out of doors all day—a daily ocean bath. All windows wide open all night. All children are completely undressed before going to bed.* An attempt is made to teach the children not to hurry in eating. Each child is given a tooth brush and shown how to use it. Face and hands must be washed and hair brushed before coming to breakfast. Mothers are told the physical defects in their children and the nature of treatment needed. Cases of contagious diseases promptly isolated and reported to the Department of Health, are readmitted to Sea Breeze for convalescence. Unvaccinated children are reported to the Department of Health. What can be done to help them at home? Thorough inspection and complete examination of all school children. Compulsory treatment of the teeth of all school children; there should be a suitable number of dental clinics where this treatment can be competently given. More complete inspection of food supplies, more particularly of the milk supply. More thorough inspection of tenements. Instruction in schools of the older children, especially girls, as to the relative value of foods, and methods of preparing it; distribution of leaflets among the poor in their homes stating the kind of food needed and the approximate cost. A larger number of fresh-air homes to be regarded as educational centers where the elementary principles of cleanliness, ventilation, and feeding can be taught by precept and example.

*Many go to bed without undressing. One boy had to be undressed four times the first night.

What can one do to help the poor children and adults who need more fresh air? I think you will all agree that the physician's duty to his patients is to do the best he can to get each patient well, with the least amount of discomfort and suffering, and to prevent him from being ill again, so far as he can.

Yet each summer I urged the chief of one of our larger children clinics to make application for Sea Breeze for the convalescent children under his care; this was also urged upon several of his assistants. And how many children do you think were sent from that clinic? Not one. Probably no child at that clinic needed a change of air. I would ask, therefore, especially of those of you who are engaged in hospital and clinical work in the summer, to see to it in the spring that each hospital and clinic is supplied with a list of all the fresh-air charities, and, further, that this list is not only supplied but used.

If all of us in the clinics and dispensaries referred the suitable cases to the fresh-air charities, the demand would more than exceed the supply. This would be a good thing, for the demand for worthy charity never goes unheeded, and in New York would result in time in the formation of a joint application bureau which would relieve the hospitals and dispensaries of detailed search for fresh air for individual cases, and in the building of more numerous fresh-air homes for the needy and deserving poor.

I express my thanks to Dr. Charlton Wallace for assistance on several occasions at Sea Breeze, and to Dr. Norman E. Ditman for assistance at examinations at Twenty-second Street.

Without the kind and enthusiastic assistance of Miss Thomson, superintendent, and the various members of her staff at Sea Breeze, and without the hearty cooperation of the Association and various members of the staff at the central offices, this work would not have been possible.

A Believer in Nostrums.—An aged woman died at Dover, England, the other day in a room which no one but she had entered for thirteen years. It was found so full of medicine bottles and pill boxes, so stated the veracious reporter, that a clearance had to be made before the corpse could be removed.

RESECTION OF THE STOMACH FOR CARCINOMA.*

By FRANZ TOREK, A.M., M.D.,

NEW YORK.

ATTENDING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL; ADJUNCT PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; ASSISTANT VISITING SURGEON TO THE GERMAN HOSPITAL.

THE dictum that it is useless to attempt a radical operation in carcinoma of the stomach whenever the tumor has attained such size that it can be plainly felt, has been repeated so often that it is believed by many to have the significance of an axiomatic truth. Only recently, at the annual meeting of the New York State Medical Association, some of the speakers reiterated this view. It is for this reason that I present to you a case of resection of the stomach for carcinoma performed fourteen months ago, which, if the above-mentioned policy had been adhered to, would certainly have been treated by palliative procedures, as in this case the large tumor could not only be felt but even distinctly seen protruding the abdominal walls of the emaciated patient and moving up and down with respiration. The patient presented is enjoying the best of health and has gained forty-five pounds. While I admit that most cases with large tumors of the stomach are not amenable to resection, I wish to emphasize that it is wrong and misleading to propound as an apodictic truth the experience gained by a moderate number of observations. The question of resection in carcinoma of the stomach is better stated thus, that while in most cases of large tumors a successful resection is impossible, the procedure in each special case depends upon its own merits. To express it more specifically, we must consider our ability to resect well beyond the limits of the disease; we must examine whether the involvement of the lymphatic ganglia is confined to the immediate vicinity of the tumor or is more diffuse; we must be guided by the presence or absence of involvement of the pancreas or other neighboring organs; and the nature of the adhesions must be considered. To determine the operability merely by the size of the tumor betrays a lack of discrimination, and is unscientific.

The patient, Mrs. H. W., forty-eight years of age, was referred to me by Dr. A. Caillé, in December, 1904. As long as a year ago she had felt pain in the epigastrium, dull in character, intermittent, and not necessarily augmented by taking food. Since that time she had lost fifty-four pounds and had become steadily weaker. For two months past she had vomited almost every day after taking food, even fluid food; sometimes twice daily. On admission to the German Hospital, December 26, 1904, her condition was very poor. She was considerably emaciated and profoundly anemic; her tongue was coated. Abdomen boat-shaped, considerably sunken in. In the umbilical region, a little to the right of the umbilicus, there was seen and felt a tumor, two inches or more in diameter. It was smooth, hard, and sensitive on pressure. It moved with respiration, and could also be moved from side to side. Stomach tympany extended beyond the left mammary line.

On January 2, 1905, the operation was performed. Epimesogastric incision seven or eight inches long, with excision of navel. The omentum was found attached to the pyloric part of the stomach by adhesions which were easily separated. The tumor now appeared to be about one and one-half inches in diameter, situated at the pyloric portion, completely encircling it. Inspection now showed the presence of five or six little glands in the lesser omentum and a very small one in the gastrocolic omentum, all these in close proximity to the tumor, so that they could be removed in connection with it. The duodenum appeared to be movable, and the stomach was dilated to such an extent that it seemed it would be possible after resection to approximate stomach and duodenum without tension; in other words, that Billroth's first method would be feasible, and this method was therefore selected. After applying a chain of ligatures to the gastrocolic and the lesser omentum, these were divided as far as necessary and the tumor with adjoining parts of stomach and duodenum liberated. Now compressors were applied, one to the duodenum an inch and a half below the tumor, and one to the stomach about three to three and a half inches above the tumor. The stomach was then resected two inches above the tumor and the duodenum one inch below it. The stomach was sutured by two rows of silk sutures, except at the lowermost part, which was united with the duodenum by a Murphy button.

After the operation, the patient's temperature reached its highest point, 103.4°, on the fifth day, then declined to the normal. She was kept on fluid food for nine days, then on soft diet till four weeks were up; after that time solid diet was given. On February 5, the button was discharged and the patient left the hospital. The pathologist's report was carcinoma gelatinosum.

Read before the Surgical Section of the New York Academy of Medicine, March 2, 1906.

Sprained Ankle.—Robert Carothers concludes that: No one is exempt from sprained ankle, although some are more prone than others. In severity a sprained ankle will range from a trivial accident to one of extreme severity and permanent. The outer side more often than the inner side of the ankle is the seat of trouble. The diagnosis, which is ordinarily made with ease, is at times made with difficulty, and at times an *x*-ray examination is required to make the diagnosis certain. The treatment by immobilization with a plaster-of-Paris cast is unsatisfactory and at times injurious. The treatment instituted by Cotteral, the so-called adhesive plaser strappings, advising and urging the patient to walk on the injured foot and the early removal of these straps followed by massage, gives the most satisfactory results. The old cases are to be, under anesthesia, converted into acute sprains and treated in the same manner.—*Lancet-Clinic.*

Origin of Simple Cysts of the Ovaries.—Domenico Cesa-Bianchi has made experiments on guinea-pigs, rabbits, cats, dogs, and other mammals to determine the causation of simple cysts of the ovaries. After examining the normal ovaries of many animals he concludes that embryonal remains of the Wolffian bodies may be found in many normal ovaries, which by undergoing congestion and long-continued hyperemia become abnormally developed and form simple cysts. These cysts are not the result of hydrops of the follicles, as has been stated by numerous observers. Experiments were made also by producing aseptic injuries and inflammations of the ovaries and by means of grafts, to produce cysts. The conclusions of the author are that such inflammations have no part in the production of simple cysts of the ovaries.—*Archivio per le Scienze Mediche.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, June 9, 1906.

THE SURGICAL TREATMENT OF EXOPHTHALMIC GOITER.

THERE are a number of diseases in which a controversy is still being carried on regarding the superiority of operative over non-operative treatment without any definite conclusion having yet been agreed upon. One of these is exophthalmic goiter, and here the opposition to surgical intervention has apparently increased, although the results of non-operative measures have not improved very much, despite the use of the highly lauded serums and the Röntgen and radium rays. All of these are still on trial and it is too early to venture an opinion as to the completeness and permanency of the final results. It may be admitted that many cases yield to hygienic and general medical measures where the circumstances permit of the proper treatment being carried out, but in numerous instances the disease is resistant from the very beginning and conservative measures are of no avail.

That surgery should be reserved for severe cases which have resisted medical treatment is the opinion of B. Farquhar Curtis (*Annals of Surgery*, March, 1906), although he does not intend this to mean that it should be considered as a last resort, for experience has shown that the mortality is greater in the bad cases than in those in which the symptoms are less severe and the patient is in better condition. On the other hand, it is not advisable to advocate immediate and early operation in every case, because many recover with medical measures alone, and there is a mortality from operation even in the slight cases, although there is less risk than in the serious ones. Curtis thinks that the only operations which need be considered are partial thyroidectomy and extirpation of the cervical sympathetic nerve and ganglia. Ligature of the thyroid vessels has a palliative effect and is useful as a preliminary to thyroidectomy. Hoping to avoid the acute thyroid poisoning which has made the mortality from the operation so high, Curtis tried sympathectomy in seven cases, but only four of these patients recovered. Of these, however, three remained practically cured, so that the results from this operation may be deemed fairly satisfactory. The operation is much more difficult, however, than thyroidectomy; it cannot readily be done with local anesthesia, and the mortality is fully as high. For these reasons the writer is inclined to favor thyroidectomy. He performed the latter in fourteen cases, with four deaths, all advanced cases, from acute thyroidism. The operation is best done in two stages, a preliminary ligation of the arteries being followed by the partial excision of the gland. During the interval the patient should be kept in bed and general sedative measures employed, including the bromides, ice bag to the heart, etc.

The total number of cases treated by thyroidectomy which have been published now number one hundred and thirty-six, including those of Schulz, Kocher, Mayo, Hartley, and Curtis. The deaths, seventeen in number, were chiefly from acute thyroidism. It has been claimed that the operative successes represent the periods of temporary improvement so often observed in exophthalmic goiter, with or without treatment. Curtis thinks that this explanation does not hold good because many of these patients have been followed for a number of years and continued well without any other form of treatment having been employed. He justly concludes that whatever the danger of operation may ultimately be shown to be, even if the mortality be twelve per cent., there can be no doubt that the survivors will be cured of their symptoms. None of the methods of internal treatment which have thus far been tried has shown results comparable with this in advanced cases of the disease.

ANOTHER POSSIBLE ETIOLOGICAL FACTOR IN MALARIA.

ALTHOUGH the mosquito has been quite universally recognized as the main factor by which malaria is ordinarily transmitted, there are certain phases of the question which are not quite entirely cleared up, for we have well authenticated instances in which the presence of malaria, either in the individual or in a given locality, cannot satisfactorily be accounted for by the activities of this insect. Other modes of transmission have been noted, among them that by the much despised bedbug; and now we have the authority of a Brazilian physician, Dr. Schrwald (*Medizinische Blätter*, No. 10, 1906), for the statement that some of the intestinal worms are also capable of acting as the carriers of the malarial infection. In a large number of cases of this disease which came under his observation, he found that *Ankylostoma duodenale*, or the hook worm, contained malarial parasites in its intestinal canal. It is well known that these parasites subsist by attaching themselves to the interior of the intestines and absorbing the blood from the latter. Schrwald made a number of serial sections of ankylostomata derived from malarial patients and demonstrated that the malarial parasites wander from the intestinal canal of the worm into the mucous glands of the mouth. He was able to demonstrate in these glands the same forms of the malarial organism as were found in the oral glands of *Anopheles*.

It is known that the hook worm secretes a peculiar fluid which serves to prevent the coagulation of the blood of the host at the point where the worm attaches itself. In this way malarial organisms may be transmitted directly from the parasite to the blood of the host. It appears, therefore, that cases of chronic malaria and also

recurrences in regions which are ordinarily free from the disease can thus be explained very readily by the presence of these infected intestinal parasites.

The writer calls attention to the possibility that *Ankylostoma* itself may transmit malaria from the sick to the well by means of its eggs or larvæ. This supposition has not, however, been confirmed by any actual observations. From what has been said it is quite evident that the individual who harbors infected hook worms will not be freed from his malaria by the administration of quinine alone, for as long as these worms remain *in situ* the disease may continue to flourish. In such cases, therefore, it is necessary first to cure the hook worm disease. The writer also found that individuals who, after they had been infected with malaria, became anemic and cachectic, soon regained their health after these intestinal parasites had been gotten rid of. Furthermore, persons who had presented recurrent attacks of malaria every year, remained free; in fact, this became so well known that patients afflicted with malaria tried the "worm cure" before attacking the malaria itself.

These observations are quite interesting, and, taken in connection with the importance which the hook worm disease has lately assumed in our own tropical and subtropical possessions, may prove the means of combating malarial diseases which so often present many difficulties in the way of treatment.

FUNCTIONAL NEUROSES AND DISEASES OF THE FEMALE GENITALS.

The idea that certain disturbances of the nervous system in women are entirely dependent on diseases of the generative organs is very old indeed. The symptoms so graphically described by this class of patients vary greatly and may be characterized by the most improbable features. For want of a better word, the condition is now very wisely—and evasively—termed a genital reflex neurosis, and in many cases a lesion of the uterus and its adnexa has been accepted as the cause without much questioning. Gynecological procedures of varying extent are instituted, and the result is often favorable, but more often otherwise. The condition has, unfortunately, been studied from a limited point of view, for which the gynecologist is, to some extent, to blame, as operation is undertaken to relieve what is apparently a very prominent symptom, without further inquiry into other factors of disease, particularly of a nervous type, which the patient may possess. A study in which the neurological point of view is more strongly brought forward has lately been published by E. Meyer in the *Monatsschrift für Geburtshülfe und Gynäkologie* for January, 1906, in which it is shown quite conclusively that nervous disturbances which are commonly attributed to gynecological lesions are in many cases instances of true hysteria, or hysteroneurasthenia, and associated with other evidences of a general neurosis.

It is an established fact that hysteria, which we are justified in considering a psychic disease, may assert itself as a disturbance of certain organs or regions of the body without any demonstrable lesions being present in the latter, or, if present, no connection can possibly be traced between the two conditions. The psychic processes which form the basis of hysterical phenomena can, moreover, be worked out in these patients without much difficulty. Meyer claims, moreover, that, up to the present time, the theory which ascribes certain neuroses to reflexes or a kind of irradiation has not been sufficiently supported by facts; while it has often been noted that the most extensive diseased conditions of the genitals are rarely accompanied by nervous disturbances of this type.

Opinions as to the etiological significance of genital lesions in the production of hysteria vary greatly even among those who acknowledge this possibility, and the claim has been made by one prominent observer that the presence of a chronic atrophic parametritis alone is of any consequence in this connection. As noted above, it has been found, unfortunately, only too often that much vaunted gynecological procedures directed primarily against the adnexa failed to produce the desired improvement in the nervous symptoms complained of by the patient, while a much better result would have been accomplished by measures of a very different character familiar to all neurologists in the treatment of hysteria and allied states.

Although the older ideas regarding the influence exerted by genital lesions in the production of hysteria must now be modified, or at least restricted, in order to agree with the weight of latter-day evidence, there can be no doubt that derangement of the female sexual apparatus may play an important part in the character and development of hysteria and similar neuroses; but the presence of an actual localized pathological process is not essential. The diagnosis of hysteria should not be based on any one symptom; it must depend on the general psychic and nervous condition of the organism, and, in order to ascertain this, it is most essential that the previous history of the patient, hereditary influences, former nervous disturbances or injuries, etc., should always be carefully investigated. General treatment directed to the organism as a whole should be the first indication in any given case, rather than a hasty resort to local operative measures. If pathological processes in the genital organs or elsewhere are present, an operation may, with perfect justice, be undertaken. Castration and other radical procedures should, however, always be avoided, and likewise those lesser gynecological measures, which can only be expressed by the term, "tinkering," for they are more likely to bring about a fresh irritation of the nervous system than to accomplish any useful purpose.

The Case Against the Cat.

Kipling, in one of the most charming of his "Just So" stories, offers a fanciful but altogether delightful account of the way in which, in remote ages, the first cat drove a hard bargain with neolithic man for food and shelter, without binding itself to yield in return any recompense in servitude, as did the less astute horse and cow and dog. "I am the cat that walks by himself, and all places are alike to me," was the oft-reiterated

platform from which this sagacious progenitor of the feline race refused to budge in spite of all the blandishments of our own prototype; and, true enough, from that day to this, *Felis domestica* has never deserved its specific appellation, for, though tamed, the cat has never become domesticated in the true sense. It is this refusal to submit to restraint or to abandon its natural predatory habits that has of late so exercised the brotherhood of bird lovers. At the annual meeting last November of the National Association of Audubon Societies a resolution was adopted, in the interest of the feathered world, officially expressing disapprobation of the ornithophagous propensities of grimalkin; but, though well intentioned, these resolutions will hardly, we fear, appreciably reduce avian mortality from this cause. The sanitarian has, however, still more cogent grounds for discouraging the perpetuation of the cat as a household pet, and it would be the part of wisdom for the family practitioner, even at the risk of falling in the estimation of the youthful members of his clientèle, to utter a serious word of warning anent the very real possibility of disease transmission through the house cat. The enumeration of scarlatina, influenza, whooping-cough, measles, diphtheria, and ringworm probably does not exhaust the list of diseases whose communication has been or might be ascribed to this intermediary. Even the proudest and sleekest tabby yields readily to atavistic calls; and prowlings in unseemly places, refections in strange garbage cans, and midnight conclaves with the mangy outcasts of the gutter afford ready opportunities for the acquisition of contagious materials. Practically all cats have worms, most of them suffer from catarrhal conditions of the nasal passages, and the feline method of ablution is not such as to command the respect of the hygienically inclined; while no one who has witnessed the enthusiasm with which children caress their pets can fail to realize the magnificent opportunities for infection that are afforded in this way. Cats and fleas are nearly always associated, and the importance of suctorial insects as inoculating agents has been so much emphasized of late that the possibility of danger in this direction also is not altogether remote. At any rate, it appears that the doctor, like the dog—that other "friend of man"—must in the interest of public health set his face against the "fireside sphynx" and warn parents of its possibilities for harm. He should at least see to it that no cat is allowed to enter a sick room. For the physician who finds his own arguments insufficient to convince some obdurate cat-lover, we recommend an article entitled "The Case Against the Cat," appearing in the April number of *Good Housekeeping*, as eminently suitable for lay perusal in this connection.

Alleged Danger in Stamp Licking.

While the practice of moistening the gum on postage stamps, envelopes, etc., with the tongue is certainly not a commendable one under any circumstances, though the perils it involves must be regarded as excessively remote, the *Lancet* has pointed out that the English three-penny stamps are colored with a yellow dye containing chromate of lead, and that one-fifth of a grain of the salt is contained in fourteen stamps. This is regarded as an added argument against what is called "the very common, dirty practice of licking postage stamps." As the three-penny stamp is used only in exceptional cases for postage, and probably not more frequently for revenue purposes, and as the gummed side only is licked, lapping of the printed side being an occupation of idiots and young children, the danger of lead poisoning from this source to the average Briton does not yet appear imminent.

The Obstetrical Fee for Triplets.

The question of whether a physician who agrees to conduct a confinement for a specified sum is entitled to increase his charge if the delivery is a multiple one, was recently made the subject of judicial decision in a Long Island court. In the case in question triplets were born, but the father refused to pay more than the honorarium originally agreed on. The court denied the right of the obstetrician to augment his fee on this account, but decided that an additional sum should be paid to compensate for the greater quantity of dressings, etc., consumed.

News of the Week.

Memorial Tablet to Dr. Fowler.—On May 28 a tablet in memory of the late Dr. George Ryerson Fowler was unveiled in the library of the Kings County Medical Society, 1313 Bedford avenue, Brooklyn. The tablet was designed and executed by the Tiffany studios and has a bronze bust of Dr. Fowler in the center. The presentation speech was made by Dr. Lewis S. Pilcher. Dr. William F. Campbell received the memorial on behalf of the society.

New Dispensaries Proposed.—Applications have been made to the State Board of Charities for a license for a dispensary at the new Swedish Hospital in Brooklyn, and charters for the Manhattan Odontological Society and the Hebrew Memorial Dispensary. The Swedish dispensary is planned for 126 Rogers avenue, Brooklyn, and is intended to serve the large Swedish population of that district. The Hebrew Memorial Dispensary is to be located in the region below Fourteenth street and east of Third avenue. Objections were made to these petitions on the ground that new dispensaries were not needed in the neighborhoods in question.

St. John's Guild Seaside Hospital.—The seaside hospital of this organization at New Dorp, Staten Island, was opened on June 4, two weeks earlier than usual. Until the Guild's floating hospital begins its daily trips at the usual time—about July 1—the patients for the seaside hospital will be conveyed thence by the Staten Island ferry and trains, on boats leaving the foot of Whitehall street at 10 A.M. and 2 P.M. An inspector from the Department of Health will be at the ferryhouse fifteen minutes in advance of these hours, to examine the patients and countersign their tickets, and a nurse and orderly will meet the patients in the ferryhouse on the New York side and will conduct them to the hospital. The fares of the patients will be paid by the guild.

Uniform Hospital Accounting.—The committee on hospital needs and hospital finances, which was organized a year ago last March to devise some uniform method of hospital accounting and to make suggestions concerning more adequate hospital economies and financial management, has completed its work and filed its final report with the managing boards of the several hospitals of the city. The committee strongly recommends the adoption of a sys-

tem of uniform accounting, which shall be adapted to the varying conditions in different hospitals, but still permit of satisfactory comparison and classification. It is stated that four of the largest general hospitals of the city, the New York, the Presbyterian, Roosevelt, and St. Luke's hospitals, have perfected a system of uniform accounting for themselves, and the committee recommends that the system of the four hospitals mentioned be adopted as the model for all hospitals in the city, with such modifications as may be necessary. An increase in the city's per diem allowance to the hospitals already receiving municipal aid is suggested after the uniform system of accounting is adopted.

To Aid St. Vincent's Hospital. — The annual lawn festival in aid of the destitute sick of St. Vincent's Hospital was held on June 4, 5, 6, and 7, in the hospital grounds, from 3 until 6 and from 7 until 9 P.M.

Bequests to the Montefiore Home and Other Charities.—Henrietta Blumenstock, by her will, filed for probate on May 30, bequeathed $5,000 each to the Hebrew Sheltering Guardian Society, the Montefiore Home for Chronic Invalids, and the Montefiore Home for Consumptives.

Tuberculosis in Germany. — According to the figures published at the National Tuberculosis Congress recently held in Berlin, there has been a decrease of 38 per cent. in the number of deaths from tuberculosis in Germany since 1875. Sanatoria have restored to health and work 34 per cent. of the patients treated. During 1905 26,621 persons coming under the Workmen's Insurance act were treated at sanatoria. The results attained at dispensaries were also excellent. Thus in 1905 15,161 persons were examined in Berlin and 8,200 apartments inspected and modified so that infected persons could be isolated. The insurance companies of Germany from 1901 to 1905 spent £1,900,000 in fighting tuberculosis. The outlay included the establishment of twenty-six sanatoria with 2,111 beds for women and ten sanatoria with 541 beds for children.

The Free Alcohol Bill Passed.—The Free Alcohol bill was reported favorably to the Senate by the Finance Committee on May 23, and the next day the measure was passed without division. The bill has already been passed by the House, but it has been amended so that the time for its provisions to become effective has been postponed to January 1, 1907, instead of three months after passage, as was fixed by the House. The change was made by the Finance Committee both in order to give the Internal Revenue Department time to organize its service and also to afford the wood alcohol manufacturers an opportunity of disposing of their surplus stock. The bill provides that after January 1 next, domestic alcohol of such degree of proof as may be prescribed by the Commissioner of Internal Revenue may be withdrawn from bond without payment of internal revenue tax for use in the arts and industries and for fuel, light, and power; provided said alcohol shall have been mixed in the presence and under the direction of an authorized Government officer, with denaturizing material, which destroys its character as a beverage and renders it unfit for medicinal purposes. The law requires the keeping of books subject to the regulations of the internal revenue bureau. Penalties are prescribed for persons who withdraw alcohol or use it after its having been so withdrawn and conceal it to avoid the process of denaturing, with a view of making improper use of it.

Typhus Fever in Mexico.—The increasing prevalence of this disease in Mexico has stimulated research into its etiology and mode of transmission. Several announcements regarding the discovery of a specific organism have been made, and the Government has offered prizes aggregating $50,000 for the discovery of the germ and means of prophylaxis and treatment.

Unlawful Practitioners in Trouble. — A registered physician was sentenced to three months' imprisonment at a recent session of the Court of Special Sessions for furnishing prescriptions with an illegal object to women. The agents of the County Medical Society have also secured the arraignment of a man whose specialty was "electric milk" for the complexion, it being charged that he practised medicine without a license.

Patent Medicines in Minnesota.—The Minnesota Dairy and Food Department has announced that it is about to make a careful examination and analysis of all patent medicines on the market. The contents of each preparation will be published in a weekly bulletin to be issued by the department and have wide circulation. If the medicines contain opiates or alcohol the fact will be published, together with the quantity.

An Authors' Clinic.—During the meeting of the Illinois State Medical Society, held in Springfield, May 15, 16, and 17, a unique entertainment was given to those members interested in the eye, ear, nose, and throat. It was called an authors' clinic, and lasted three days, commencing Tuesday morning at the David Prince Sanitarium, Wednesday morning at the St. John's Hospital, and later at the Springfield Hospital. The clinical material was assigned to the hospitals, and the individual operator was notified of the time and place of his demonstration. When possible, operations were conducted in adjoining rooms, and on two occasions three operations were conducted simultaneously. About forty-five operations were performed during the meeting. Authors of operations who were invited were: Dr. Otto Freer, window resection of septum; Dr. Frank Allport, ptosis; Dr. Casey Wood, excision of the tarsus for intractable trachoma; Dr. B. L. Ballinger, enucleation of tonsil in its capsule; Dr. Charles Robertson, tonsil excision; Dr. F. C. Hotz, entropion; Dr. Wilder, symblepharon; Dr. Baird, advancement of the rectus; Dr. E. Fletcher Ingals, intranasal method for frontal sinusitis; Dr. Ostrum, septum deflection; Dr. A. E. Prince, strabismus and nasal obstruction. Dr. Prince also demonstrated his advancement operation, excision of the rectus for paralytic squint, and exercised a general management of the clinic.

Wood Alcohol Poisoning. — Two men were killed, another is seriously ill, and a fourth is almost totally blind as the result of a wood alcohol drinking bout held in the neighborhood of Northport, L. I., last week. The alcohol was obtained from the local druggist on the pretense that it was to be used for local application.

Suit Against a Surgeon.—Suit for $20,000 damages has been brought against a surgeon of Lincoln, Neb., by a patient who alleges that not until the completion of the operation did she know that it was to be performed in the presence of students. It is also alleged that the operation was performed in an unsuitable operating room and that it was carelessly done, so that she has suffered permanent injury.

Christian Science Healer Held. — The English healer under whose care Major Whyte recently died has been committed for trial on a charge of manslaughter, the total bail required being $10,000.

American Dermatological Association.—At the thirtieth annual meeting of this association, held in Cleveland, Ohio, May 31 and June 1 and 2, 1906, the following officers were elected for the ensuing year: *President,* Dr. Arthur Van Harlingen of Philadelphia; *Vice-President,* Dr. William A. Pusey of Chicago; *Secretary and Treasurer,* Dr. Grover W. Wende of Buffalo.

Association of Surgeons of the Southern Railway.—At the eleventh annual convention of this organization, held on May 24, Washington was chosen as the next place of meeting. The officers elected are as follows: *President,* Dr. R. S. Toombs of Greenville, Miss.; *First Vice-President,* Dr. M. F. Coomes of Louisville, Ky.; *Second Vice-President,* Dr. B. B. Simmes of Talladegra, Ala.; *Secretary and Treasurer,* Dr. J. U. Ray of Woodstock, Ala.

North Carolina State Medical Society.—At the annual session of this society, held at Charlotte on May 30, Morehead City was selected as the next place of meeting. Officers were elected as follows: *President,* Dr. S. D. Booth of Oxford; *First Vice-President,* C. M. Strong of Charlotte; *Second Vice-President,* Dr. J. E. McLaughlin of Statesville; *Third Vice-President,* Dr. W. T. Hargrove of Kinston; *Secretary,* Dr. D. A. Stanton of High Point; *Treasurer,* Dr. H. M. Tucker of Raleigh.

Michigan State Medical Society. — The forty-first annual meeting of this society was held at Jackson, May 23 to 25, 1906. New work was taken up relating to medical education and the study and prevention of tuberculosis, standing committees being appointed for research in both of these subjects. The society appropriated $500 from its funds for the benefit of the physicians of California, the sum to be sent through the American Medical Association. The following are the officers for 1906: *President,* Dr. C. B. Stockwell, Port Huron; *Vice-Presidents,* Dr. William Fuller, Grand Rapids; Dr. E. T. Abrams, Dollar Bay; Dr. D. E. Robinson, Jackson, and Dr. A. R. Stealey, Charlotte; *Secretary-Editor,* Dr. B. R. Schenck, Detroit; *Treasurer,* Dr. G. W. Moran, Detroit. The next annual session will be held in Saginaw in May, 1907.

Wayne County (Michigan) Medical Society.—At the meeting of this society recently held, officers were elected as follows: *President,* Dr. J. H. Carstens; *Vice-President,* Dr. W. F. Metcalf; *Secretary-Treasurer,* Dr. Walter D. Ford.

Massachusetts Association of City and Town Physicians.—At the annual meeting of this association, held in Boston, the following officers were elected: *President,* Dr. Edwin P. Gleason of Brockton; *Vice-President,* Dr. C. C. Crane of Norwood; *Secretary,* Dr. W. G. McFee of Haverhill; *Treasurer,* Dr. Daniel Rose of Stoughton.

Connecticut River Valley Medical Association.—Officers were elected as follows at the annual meeting, held in Bellows Falls on May 22: *President,* Dr. J. Sutcliffe Hill of Bellows Falls; *Vice-President,* Dr. A. L. Dinsmore of Keene; *Treasurer,* Dr. E. H. Campbell of Bellows Falls; *Secretary,* Dr. A. L. Miner of Bellows Falls.

Iowa State Medical Society.—Cedar Rapids was selected as the next place of meeting for this society at its recent session in Des Moines, and the following officers were elected: *President,* Dr. E. W. Clark of Grinnell; *Vice-Presidents,* Drs. H. A. Leipziger of Burlington and M. J. Kennedy of Algona. The secretary, Dr. Treynor, was elected for five years and is still in office.

Missouri State Medical Society.—The election of officers of this association at the meeting held in Jefferson City on May 17, resulted as follows: *President,* Dr. C. H. Wallace, of St. Joseph; *Vice-Presidents,* Drs. F. W. Allen of Callao, W. G. Carow of Sedalia, C. J. Orr of St. Louis, E. H. Thrailkill of Kansas City, and H. L. Reid of Charleston; *Secretary,* Dr. C. M. Nicholson of St. Louis; *Treasurer,* Dr. J. Franklin Wells of Salisbury.

Dartmouth Medical College Alumni Association.—The following officers were elected at the meeting of this association held in Concord, N. H., on May 17: *President,* Dr. W. A. Megrath of London; *First Vice-President,* Dr. R. V. Baketel of Methuen, Mass.; *Second Vice-President,* Dr. D. R. Goodhue of Springfield, Mass.; *Secretary and Treasurer,* Dr. H. N. Kingsford of Hanover.

New Hampshire State Medical Association.—The one hundred and fifteenth annual meeting of this society was held at Concord on May 17, and the following were elected as officers: *President,* Dr. Ira J. Prouty, Keene; *Vice-President,* Dr. John H. Neal, Rochester; *Secretary,* Dr. D. E. Sullivan, Concord; *Treasurer,* Dr. D. M. Courier, Newport; *Necrologist,* Dr. Eli E. Graves, Penacook. Dr. Granville P. Conn of Concord, the retiring secretary, had held this office since 1869, save for two years when he was successively vice-president and president of the society.

New Hampshire Military Surgeons.—The annual meeting of the New Hampshire Military Surgeon's Society was held at Concord on May 17, and the following officers were elected: *President,* Dr. Ezra Mitchell of Lancaster; *Secretary,* Dr. G. P. Conn of Concord; *Treasurer,* Dr. F. A. Stillings of Concord.

Michigan State Homeopathic Medical Society.—At the meeting of this organization, held in Grand Rapids on May 17, these officers were elected: *President,* Dr. Harold Wilson, Detroit; *Vice-President,* Dr. S. H. Knight, Detroit; *Second Vice-President,* Dr. O. L. Ramsdell, Petoskey; *General Secretary,* Dr. D. W. Myers, Grand Rapids; *Corresponding Secretary,* Dr. J. H. Ball, Bay City; *Treasurer,* Dr. R. M. Richards, Detroit.

San Francisco College of Physicians and Surgeons.—The annual commencement exercises of this college were held on May 17, in the Danish Lutheran Church, and diplomas were awarded to a class of twenty-nine members. Degrees in dentistry and pharmacy were also conferred.

City Seaside Park.—The Board of Estimate on June 1 gave a public hearing on the proposal to establish a municipal seaside park and convalescent home for the city's poor. The new law authorizes the Board of Estimate to spend $2,500,000 on such a project. Several sites have been recommended to the city, among them being Rockaway Park, Long Beach, South and Midland beaches on Staten Island, and Barren Island. A committee composed of President McGowan of the Board of Aldermen, President Cromwell of Richmond, Dr. J. W. Brannan, president of the Bellevue Hospital trustees, and representatives of several charitable organizations has made an inspection of these sites and considers that Rockaway Park offers the most advantageous location.

Obituary Notes.—Dr. Hugh McFatrich of Denver, Col., died on May 27, at the age of eighty-two years. He had practised in Wisconsin, Illinois, and Iowa, but retired in 1897 and since then had lived in Denver.

Dr. George A. Ketchum of Mobile, Ala., died on May 29, at the age of eighty-one years. He was born in New York City and in 1846 was graduated

from the Medical Department of the University of Pennsylvania. In 1859, in conjunction with Dr. J. C. Nott, he organized the Medical College of Alabama at Mobile. He had been professor of Theory and Practice of Medicine from the start, and upon the death of Dr. W. H. Anderson, in 1884, succeeded him as second dean. For many years before the war he was President of the Common Council of Mobile, and was a member of the convention which passed the Alabama ordinance of secession. Upon the outbreak of the war he volunteered as a surgeon. After the fall of the Confederacy he again became President of the Common Council, and was for a while *ex-officio* Mayor of the city. He was an original member of the Board of Health of Mobile, in 1871, and had since been annually elected its president.

Dr. Henry Howland Chase of Rock Island, Ill., died on May 21, at the age of forty-eight years, after an illness of several weeks due to an operation infection. He was graduated from the Chicago Homeopathic Medical College in 1881, and after practising for some time in various other places, went to Rock Island nine years ago.

Dr. S. Wayne Gamble of Kingstree, S. C., died on May 22, after an illness of three days. Dr. Gamble was a member of the Constitutional Convention of 1895 and later served as member of the House of Representatives.

Dr. Darwin D. Eads of Paris, Ky., died at Chicago on May 27. He had practised in Paris forty years and was well known as a botanist.

Dr. Louis A. Weigel of Rochester died on May 31, at the age of fifty-two years. Dr. Weigel's life was sacrificed through his devotion to his profession, for in consequence of long-continued work with the *x*-rays he developed malignant disease of both hands, and this disease, in spite of several amputations, became generalized and killed him.

Dr. William M. Findley died at Altoona, Pa., on June 2, at the age of sixty-four years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1876. He was the Blair county representative on the State Board of Health.

Dr. J. T. B. Foard of Pollard, Ala., died on May 26, at the age of seventy-three years. He had practised in Escambia county since 1868.

Dr. Harry B. Hargis of Klamath Falls, Ore., died of heart disease on May 18, at the age of forty-three years.

Dr. Samuel P. Boardman of Springfield, Ill., died suddenly on June 2. He had suffered from melancholia for some time.

Obituary.

CHARLES WARRENNE ALLEN, M.D.,

New York.

Dr. Charles Warrenne Allen of this city died of typhoid fever in the Colonial Hospital, Gibraltar, on May 30. He sailed from New York the latter part of March to attend the International Medical Congress at Lisbon, to which he was accredited as a delegate from the American Dermatological Association. Although ill at the time, he insisted upon sailing from Genoa on the return voyage on May 17, in order to be home in time to attend the meeting of the Dermatological Association in Cleveland on May 31 and present his report. Before he reached Gibraltar, however, the disease had declared itself as typhoid fever and it was thought safer for the patient to leave the ship there and seek the care of the Colonial Hospital. There he remained for eleven days, and died on the eve of the meeting of the Dermatological Association.

Dr. Allen was born in Flemington, N. J., December 4, 1854. He was educated in Nantes, France, and at the Phillips Academy at Exeter, N. H. He began the study of medicine at Harvard, but later came to New York, obtaining his degree from the College of Physicians and Surgeons with the class of 1878. After post-graduate courses of dermatological study in Paris and Vienna he began practice in this city in 1880. He gradually confined his attention more and more to dermatology, and soon won for himself a reputation as an acute observer and successful practitioner in this specialty. He was a skilled worker in Roentgen-ray therapy, and a little over a year ago wrote a lucid work on the subject, entitled "Radiotherapy, Photography, Radium, and High-Frequency Currents." He was also the author of "The Practitioner's Manual," "The Handy Book of Medical Progress," the chapter on Diseases of the Tongue in the "Reference Handbook of the Medical Sciences," and several chapters on subjects relating to dermatology in the "Twentieth Century Practice of Medicine." He was also a frequent contributor to the periodical literature of dermatology and radiotherapy. For very many years he was a valued member of the editorial staff of the Medical Record, although of late the demands of a large private practice had left him little time for editorial work.

Gregarious in his tastes, genial in disposition, and gifted with humor, Dr. Allen was popular in a wide circle of acquaintances, lay and medical, and warmly loved by those who were so fortunate as to be counted among his friends and intimates. A careful student and a facile speaker, he was naturally a prominent figure at society meetings, ready with original paper or no less original discussion to do his share in the general exchange of ideas. He will be sadly missed, cut off untimely in the prime of his professional life.

Correspondence.

FIFTEENTH INTERNATIONAL MEDICAL CONGRESS.

(From Our Special Correspondent.)

UTERINE RETRODEVIATIONS AND MYOMATA—CESAREAN SECTION—TUBERCULOSIS OF THE EYE—PATHOLOGY OF DIABETES—HIGH FREQUENCY CURRENTS IN SKIN DISEASES.

Lisbon, April 29, 1906.

Richelot of Paris took as his subject the treatment of retrodeviations of the uterus. He said that there were two types of such lesions which must be clearly distinguished. In one of these the uterus was drawn backward by adhesions resulting from diseases of the adnexa, etc., and in the other the uterus appeared perfectly healthy except for its malposition and enlargement. It had been maintained that in the second type no symptoms were produced, and that the complaints of the patients were of nervous origin. Richelot did not consider that this was so, and stated that he had observed eighty cases, of which he had followed forty very carefully. Thirty-nine of these patients had been relieved by operation and many had undergone subsequent pregnancies without mishap. The eighty patients had all been treated according to the excellent method of Doléris.

Tuffier of Paris and Rouville of Montpellier reported their results in the treatment of uterine myomata. They considered that the internal treatment of these growths was purely symptomatic and that palliative procedures were to be avoided as much as possible. The conservative operation was to be preferred, and the vaginal route was to be chosen for tumors projecting into the uterine cavity and for small myomata of the supravaginal portion of the uterus. The abdominal operation was preferable for all other cases. The size of the growth was never a contraindication to the operation, though the great numbers of the tumors or their close proximity to each other might increase the technical difficulties and might in some cases make the conservative

operation impossible. In cases in which any suspicion of carcinoma existed hysterectomy was to be preferred to enucleation. Vaginal hysterectomy was feasible when the uterus was small and freely movable, but could not often be carried out. Total hysterectomy was to be preferred to the supravaginal operation when the cervix was involved or when suppurative foci had been discovered in the organ, making infection of the stump seem likely. The ovaries should be preserved if possible. Pregnancy did not form an indication for operation unless the situation of the tumors was such as to interfere with the development of the fetus.

Palderini of Bologna spoke of the cesarean operation, its indications and technique. He said that the abdominal and the vaginal procedures must be recognized. The mortality of the Porro operation with its numerous variants had been reduced from 15 to 6.8 per cent., and in this connection it was to be remembered that the operation was often done on septic cases and on those in which more conservative attempts had failed. The greatly simplified Saenger's operation was gaining more and more adherents and was particularly suitable for cases with contracted pelves. Vaginal cesarean section was indicated in contraction of the soft parts, but when it was undertaken the possibility of the necessity for resort to total extirpation on account of hemorrhage had always to be kept in mind. If repeated cesarean section became necessary on the same woman sterilization should be considered.

Collins of London read a paper on tuberculosis of the eye and contributed a very detailed review of the subject, beginning with a historical résumé. He then discussed the value of the histological and bacteriological tests for determining the tuberculous nature of the disease. After this he described the exogenous and endogenous tuberculous affections of the eye, and stated that they were much commoner than was usually believed, especially tuberculosis of the choroid. The invasion of the different structures of the eye, including the iris, ciliary body, choroid, cornea, sclerotic, retina, and optic nerve, was described in detail. Symptomatology and diagnosis were also elaborated, and internal and surgical treatment were given due attention. Iridectomy was said to be applicable in but few cases and was to be condemned, while the method of election consisted in enucleation combined if necessary with total exenteration of the orbital tissues.

F. W. Pavy of Guy's Hospital presented a paper on the pathogeny of diabetes in which he descanted at considerable length on the metabolic problems involved in the study of this complex disease. There was evidence to show that an internal secretion derived from the pancreas was concerned in keeping the system exempt from the conditions existing in diabetes and in preventing the failure of carbohydrate assimilation. There were two sources, of a contrasting nature, for the sugar. In the one the sugar met with was the issue of a defective anabolism or molecular building-up, and in the other, an abnormal catabolism or breaking-down of molecules into which carbohydrate had been previously incorporated. The former corresponded with the "alimentary" form of the disease, the latter with the grave, or the "composite" form. The underlying cause of the disease was, however, to be sought in a disturbance of vasomotor control probably etiologized by an abnormal cerebral activity, and on this account it was possible to consider diabetes as a disease belonging to the neurosis class, the difference in this case being the implication of a particular vasomotor area instead of structures connected with voluntary motion, sensation, and the mind.

Dr. Charles W. Allen of New York contributed a paper on high frequency currents in skin diseases, in which it was stated that currents of high voltage and high frequency were of decided benefit in treating a large number of dermatological diseases. High frequency sparks had not only a surface, but a penetrating effect. They were useful in diagnosis, detecting disease in apparently healthy skin, and sought out, as well as destroyed, remnants and recurrences in scar tissue. Epithelioma, lupus, lupus-erythematosus, and lichen planus were among the diseases most benefited. In pruritic and painful affections the spark was of decided utility, and in the destruction of moles it acted promptly and painlessly. The author therefore considered it a great prophylactic measure against malignant degeneration in such growths.

Another Nostrum Fraud.—A man went into a chemist's shop and bought a bottle of some patent stuff, which was advertised thus: "No more Coughs, No More Colds. 1s. 1½d. the bottle." Three days later he went to the chemist, complaining that his throat was stopped up and that he could scarcely breathe. "I've drunk all that patent cough mixture," he said. "Drunk it?" yelled the chemist, "why, that's an india rubber solution to put on the soles of your boots!"—*London Tit-Bits.*

OUR LONDON LETTER.

(From Our Special Correspondent.)

DENTAL SURGEONS' MEETING—JUBILEE OF MEDICAL HEALTH OFFICERS—CANCER OF THYROID—EVISCERATION IN ABDOMINAL SECTION—CYST OF THE PANCREAS—LAMINARIA—LORD GLENESK ON HOSPITAL ADMINISTRATION—HOSPITAL FOR ANIMALS—SANATORIUM FOR MIDDLESEX—CHRISTIAN SCIENCE AND PECULIAR PEOPLE—BARON TAKAKI—LEGACIES TO CHARITIES

London, May 18, 1906.

Yesterday at the Examination Hall of the Royal Colleges the annual meeting of the British Dental Association was opened. The proceedings are being continued to-day and will close to-morrow. The members and their lady friends were given a reception at the College of Surgeons, and in the evening there was another reception by the Lord Mayor and Lady Mayoress.

The dentists have often given an object lesson to the General Medical Council as to how to maintain their register, to observe the rights of practitioners, and uphold professional status. The new President, Mr. Leonard Matheson, in his inaugural address touched on such questions, and some of his remarks will interest you. He said that if dentistry was now coming to hold its rightful place in the eyes of the public, the press, and the medical profession, it was largely due to the work of the Association. Neither the Dentists' Act, with its results of education and registration, nor individual effort could possibly have accomplished all that has been done. By remonstrances in private and prosecutions in public the Association had compelled offenders to respect the letter if not the spirit of the law, and in so doing had made clear to an ever-increasing section of the public that there is such a thing as a Dentists' Register, that registration indicates a distinction which is well worth the while of the public to consider between the legal and illegal practitioner. As to the question of amending and supplementing the Act of 1878, the President declared they must not merely seek class protection, but that which is evidently for the public weal. As the law at present stands, a person can practise without being on the Register, so long as he does not use the title of "dentist" or any description implying in the eye of the law that he has a special qualification to act as a dentist. The public is too easily gulled to enable the Association to hope to create a rational opinion, and the only course is to persuade the legislature to render unregistered practice penal without regard to the title or name assumed. Exactly the same state is that of the medical profession. I fear the task proposed is not likely to be soon accomplished.

The Society of Medical Officers of Health celebrated their jubilee on Friday last, when Sir Shirley F. Murphy, President, delivered an address. He took for a subject "The Medical Officer of Health, 1856-1906," and indicated the several ways in which the Society had assisted these officers in the various problems in which they are concerned. The administrative measures adopted for the prevention of infectious diseases, the variations in the death rates, and especially infant mortality, the consequences of overcrowding, and insanitary areas occupied a considerable part of his discourse. Passing then to the more definite subject of his address, he urged medical officers to be prepared at all times to widen the horizon of their views and to avoid any approach to a narrow specialism. In their actual administration they must not go beyond the wishes of the people as expressed by their local authorities; but their duty was to place all the facts as well as the advantages and disadvantages concerning any measures they might recommend before those authorities. Upon these and on Parliament would remain the decision as to the extent to which such measures should be enforced. He urged them to have patience, even though they had to witness disasters in family life through neglect to secure protection from disease, as in the case of smallpox. Great as had been the services rendered to the public by the Medical Officers of Health during the last fifty years, Sir Shirley expressed the fullest confidence that they would do much more in the future.

At the Clinical Society Mr. Hudson read a paper on Carcinoma of the Thyroid Gland. He described eight cases which exhibited the usual features of malignant tumor and six others in which the clinical features were not present, but the tumors showed the histological structure of cancer. Two tumors discovered at the necropsy were also described. These cases seem to indicate that cancer more frequently affects the thyroid than is commonly supposed, and also is perhaps more amenable to surgical treatment than might be expected, conclusions which are enforced by other cases related in the discussion. They further illustrate the difficulty of estimating the degree of malignancy of epithelial thyroid tumors. Evidence of invasion of adjoining tissues or of metastasis is most important.

Mr. Clutton, President, gave an account of several cases he had had, and expressed the opinion that as regards life

prognosis is better than usually thought. His first case was operated on in 1886 and is still well. In diagnosis he attached importance to a high degree of fixity of the tumor to the trachea. These tumors were often overlooked, being taken for simple adenomata. He thought metastases rare.

Mr. Wirgman differed as to this last point, many metastases having been recorded, usually in the vascular bones, from Douglas's pouch so that liquid might flow in the patient, who might be unaware of the thyroid tumor. He had met with two such cases recently.

Mr. Spencer remarked that in the thyroid a perfect gradation could be traced from simple adenoma to the most malignant growth, and this applied to metastatic as well as primary growths.

Mr. Hudson in reply said the questions of malignancy and of metastasis might depend on tissue resistance. An apparently benign growth might invade other structures in a malignant way if the patient were in a low condition.

Mr. Roughton related a case of perforated gastric ulcer in a woman of 26 treated by evisceration and irrigation within six hours of the perforation. There was little shock and rapid recovery. The reason of his procedure was that the contents of the stomach had escaped very freely, soiling all parts of the peritoneum. The small intestines were turned out and the cavity thoroughly irrigated from Douglass' pouch so that the liquid might flow in the opposite direction to the extravasated fluid and so minimize risk of infection.

Mr. Spencer remarked that the objection to evisceration was not shock so much as increase of tympanites produced, making it difficult to return the intestines and increasing the strain on the sutures. This was particularly so in late cases.

Mr. John D. Malcolm related a case of complete removal of a multilocular cyst of the pancreas, followed sixteen days later by anastomosis between the transverse and descending colons, on account of partial intestinal obstruction which developed in the meantime. The difficulty was at the splenic flexure, and after the second operation there were no further symptoms. The tumor is preserved in the College of Surgeons' Museum where there are two others, which seems to indicate their rarity. Only two were reported in the *Medical Society Transactions* and *Pathological Transactions*, but Dr. Fitz collected eight (*American Journal of Medical Sciences*)and Dr. Dunning one (*American Journal of Obstetrics*, 1905). Mr. Clutton mentioned at the meeting a case on which he operated some years ago. The diagnosis is naturally beset with difficulties. In fact, most cases have been regarded as renal or ovarian until operation. Complete removal was considered the only rational treatment.

Sir William Sinclair exhibited at the Obstetrical Society a number of fine specimens of laminaria obtained from islands off the west coast of Scotland. These specimens were superior to most that are found in the market, and good-sized uterine tents could be made from a single piece, which are certainly better than those made by joining sections of the material, for these latter are liable to cause irregular dilatation. Sir William said laminaria tents gave far better results than rapid dilators, and regretted that in some quarters they had gone out of use.

As to the last remark, Dr. Herman said they had not gone out of fashion so much as some supposed, for they had been in use in the London Hospital for the last thirty years. Dr. Spencer also stated they had been continuously used at University College Hospital for the last twenty-five years, and he could not imagine any gynecologist would dilate a rigid senile cervix by the rapid plan in order to explore with the finger.

Dr. Boxall said the only objection to tents was the possibility of infection, but laminaria could be sterilized by dry heat in the domestic oven and was improved by the process. Dr. Parsons rather preferred metal dilators.

Dr. Lewers said the point was the degree of dilatation required. It was in many cases impossible to dilate sufficiently by the rapid method without causing laceration. When that happened it would not be limited at the will of the operator. It might be slight, or it might extend through into the broad ligament or the peritoneal cavity. As a rule he used tents the day before exploring, and then if necessary a few Hegar's bougies under anesthesia.

Lord Glenesk, presiding at the thirty-fifth annual meeting of the Chelsea Hospital for Women, made some practical observations on management. He declared large debts meant bad administration. People who gave money liked to see it well used, not always sunk in the payment of debts. Their hospital was a living illustration, and though living from hand to mouth for some time, was now beginning a reserve fund. A lady who had done much for them had lately died at the age of eighty-four. This was Mrs. Everard (known as H. M. E.). She was a practical woman, knew what the hospital was doing, and gave freely while living, determined to leave nothing at her death. Since 1894 she had given this hospital some £8,000 and an emergency fund had been formed which in case of necessity could be utilized.

The Duchess of Teck on Tuesday opened a hospital for sick animals in London. It is filled up with every requisite for the treatment and comfort of the animals. During their stay they will be attended by the staff of veterinary surgeons. The object is that such care may be obtained gratuitously by poor owners for their sick animals. It was stated that the staff is prepared to receive any ailing creature from a canary to an elephant. Provision has also been made for lending a pony or donkey to a poor man while his own is in hospital.

An influential meeting was held on Tuesday to discuss the proposal to establish a sanatorium for Middlesex. The scheme has been talked about for a couple of years or so, but the money is not forthcoming at present. The projected building is to be of the simplest and least expensive character, but it was stated that it must cost £300 per bed. Does it not seem that too much is being spent in bricks and mortar? Architectural experts are apt to indulge in extravagance.

The "Dr." Adcock concerned in the "Christian Science" case, and who said he was qualified, but did not know if his name continued on the Register, as he had given up practice for "Christian Science," has been committed for trial for manslaughter. The detective who arrested him said he had an injection syringe and tablets of morphine and of strychnine upon him. In the "Peculiar People" case the man who was committed for manslaughter of his child by not admitting medical treatment, has during the interval lost another child, and the same verdict was found at the inquest, so there are two charges against him at the same time. It will be curious to note the result in the two cases —one an educated man, the other a laborer.

Durham University has conferred its honorary degree of D.C.L. on Baron Takaki, former Surgeon-General of the Imperial Japanese Army.

The late Mr. Edward Steinkopff, founder of the Apollinaris business, left an estate of over £1,200,000. After disposing of much, he left the residue in trust for his daughter for life, and then for such institutions or charitable objects as she may appoint.

The late Mr. Richard Twining left sums amounting to £1,000 among several hospitals.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE COURRIÈRES CATASTROPHE—ASEPTIC FEVER—NOTIFICATION IN TUBERCULOSIS—RENAL DECAPSULATION IN ECLAMPSIA—SCOPOLAMINE-MORPHINE ANESTHESIA—THE BACTERIOLOGICAL DIAGNOSIS OF SYPHILIS—CYSTOSCOPY IN PREGNANCY—DEATH OF M. CURIE.

PARIS, May 3, 1906.

THE spirit of unrest which has shown itself in so many of the labor organizations at the approach of the first of May has reacted indirectly even on the medical world. The compositors and printers of Paris having decided to strike, nearly all the medical publications have on this account been suspended and medical intellectual life has therefore been if not checked at least much interfered with.

The details of the catastrophe at Courrières, where more than 1,000 miners met their death, are already well known, but the most extraordinary part of the affair is perhaps the account of the wanderings of fourteen miners who after twenty days of unspeakable suffering were taken alive from the wrecked mine. Forced to sustain themselves on oats, the bark of wood, and putrid meat, and satisfying their thirst with a mixture of stagnant water and urine, they triumphed over death and emerged still living from the depths of the earth. It is hard to understand how it was that these men should have been able to withstand such conditions, why they were not poisoned by the ptomaines of the decomposing meat, and how they managed to live for twenty days in an atmosphere vitiated by poisonous vapors, without light and almost without air. The endurance and the powers of resistance, but especially the spirit of indomitable courage, exhibited by these fourteen miners may truly be termed admirable.

At the Académie des Sciences, Charrin and Jardry presented the results of their observations on aseptic postoperative fever. It happens often enough that after certain operations and even after confinements sudden rises of temperature appear which reach a considerable elevation and then disappear again with equal rapidity. Fever of this sort, in view of its intensity, is well calculated to give rise to much anxiety, for the frequency of infection after operations causes the surgeon to suspect some bacterial process, of which the prognosis is usually grave. The authors have carried out a series of experiments which

tend to show that among these elevations of temperature there are many which need give rise to no anxiety. Such manifestations are caused by chemical toxins which are not living and are therefore incapable of reproduction or of causing infection. In the serous exudations, and especially in shed blood, the authors were able to demonstrate substances, probably belonging to the class of the ferments, which could incite elevations of temperature.

At the Académie de Médecine the discussion on the notification of cases of tuberculosis and the disinfection of the dwellings of consumptives was concluded. Huchard stated that he believed that compulsory notification only after death was a totally inadequate measure, as the danger of contagion was not obviated, and on the other hand compulsory notification during life involved the gravest disadvantages. The struggle against tuberculosis then became a struggle against the tuberculous, and this was something to be avoided at all costs. In addition, it was necessary to take into consideration the position of the physician and the matter of professional confidence, which had to be preserved. He considered that the most important thing in combating the disease was the question of the soil it developed in, and that the object to be sought after was to protect those who were predisposed owing to poverty, poor ventilation, unhygienic dwellings, and alcoholism. The discussion has now been closed and M. Guéniot, the president, is about to transmit to the tuberculosis commission the various opinions that have been delivered before the Académie. The commission will combine these in one or more resolutions which will be presented to the Académie to be voted on.

The Académie then heard the report delivered by Pinard concerning the work done by Chambrelent and Pousson on decapsulation of the kidney and nephrotomy in severe types of eclampsia. The authors first stated that the etiological theory which was most widely accepted at present was that in which eclampsia was regarded as a form of intoxication through the blood stream, produced by a poison whose origin was still undetermined and which gave rise to lesions of the liver and kidney. In eclampsia renal decapsulation and incision of the parenchyma of the organ relieved the intrarenal tension and congestion. In addition the bleeding which accompanied nephrotomy was directly beneficial. The authors referred to numerous instances in which eclamptic patients whose condition had appeared hopeless had been saved by this means. They also referred to the work done by Edebohls in this connection, but while this author advised simply decapsulation of the kidney in these cases, they recommended incision of the parenchyma as well. Pinard, in concluding, said that these measures were very useful in cases of eclampsia, but he did not recommend surgical intervention except in the cases accompanied by anuria, in which there was a very considerable elevation of the intracapsular pressure in the organ.

An interesting discussion was started by Routier before the Société de Chirurgie on the subject of scopolamine-morphine anesthesia. Routier thought that the favorable effect of this combination on chloroform anesthesia had been exaggerated. There were great differences in the behavior of patients under chloroform anesthesia, and subcutaneous injections of any sort or elaborate inhalers could not change this fact. The most important factor was the way in which the chloroform was given, and he would continue to feel more confidence in a good anesthetist who used only a simple compress, than in all the so-called perfected procedures and appliances, which, after all, had succeeded in obviating completely only two of the principal drawbacks of chloroform anesthesia, the preanesthetic excitement and the postanesthetic vomiting. Terrier replied by presenting his personal statistics of scopolamine-morphine anesthesia. His list comprised seventy-one cases, and in none of these were any complications ever noted. On the contrary, patients who had previously been subjected to the action of chloroform alone and who had given rise to uneasiness by the way in which they took the anesthetic, were anesthetized in a positively ideal manner when the scopolamine-morphine combination was used in conjunction with the chloroform. Chaput also spoke in favor of the new method which he had tried in thirty cases, and Segond, who had used it in twenty laparotomies, also advocated it. He considered that the procedure was of the greatest value, particularly in dealing with nervous or alcoholic patients and with those who had suffered much discomfort as the result of former anesthetizations. Jalaguier said that he had used this method of anesthesia twenty-one times and that he had been as favorably impressed with its advantages as had been the speakers who preceded him.

At the Société Médicale des Hôpitaux, Thibierge, Lesourd, and Ravout presented a study on the bacteriological diagnosis of syphilis and the spirochete of Schaudinn. As a result of their experimental work the authors concluded that in doubtful cases of syphilis three diagnostic methods should be resorted to. The simplest was to examine scrapings of the lesions smeared on slides; if this gave negative results, sections should be made of small fragments of tissue removed for the purpose, and finally, if necessary, blood cultures should be made. These methods were identical with those which justified the diagnosis of tuberculosis in a lesion.

Bar and Luys presented an important contribution before the Société d'Obstétrique on the use of the direct vision cystoscope for the examination of the bladder in pregnancy. It was pointed out that toward the latter part of pregnancy the intravesical segregation of the urine with the segregator became impossible on account of the distortion of the bladder caused by the growth of the uterus. Nevertheless it was sometimes necessary to ascertain the condition of the urine secreted by each kidney and then ureteral catheterization appeared to be the only resource. In order to effect this the direct vision cystoscope would be found very easily applicable, both on account of its form and on account of the practically perfect asepsis with which the ureters could be catheterized. In these cases it was much more useful than the prism cystoscope. The authors then described the distortions of the bladder which might be observed during pregnancy. Finally, from the practical standpoint they emphasized the value of the direct vision cystoscope in performing lavage of the ureters and of the renal pelvis in cases of pyelonephritis.

French science has just lost one of its most promising lights in the person of M. Curie, who, as everyone knows, played so important a rôle in the discovery of radium. This eminent scientist, still in his youth, met with his death in a street accident, being run over by a truck. His important researches had secured for him the award of the Nobel prize. He spent nearly all of his time in his laboratory in the Sorbonne, together with his wife, who was his collaborator and took part in his researches.

OUR LETTER FROM COPENHAGEN.

WORK OF THE COPENHAGEN MEDICAL SOCIETY—REGULATION OF PROSTITUTION—THE WIDAL TEST WITH DEAD CULTURES—DEATH OF PROF. HASLUND.

COPENHAGEN, May 16, 1906.

As the scientific sessions of the Copenhagen Medical Society have now closed for the winter term it may be deemed appropriate to review the communications of particular interest made there. At the first meeting of the season Prof. Saxtorph read a paper on spinal stovain anesthesia. He had used the method without accident in 150 patients for operations of many different kinds on the lower extremities, and was very favorably impressed by its effects. At a later session Dr. T. F. Fischer showed some cases of epithelioma of the face cured by Roentgen-rays, and mentioned having used the treatment in 20 cases, the result being that 10 patients were cured, 6 much improved, while in four only a transitory amelioration was effected.

Dr. P. Tetens Hald read a paper on treatment of deformities of the nose by paraffin injections. He had till then treated 49 cases, all with good and for the most part even excellent results, as showed by the presentation of patients' photos and plaster-of-Paris casts. He exclusively injected in a solid state a paraffin melting at 50° C. or at a higher temperature, and was prompted to do so by the fact that all published ocular accidents had occurred after the injection of a paraffin with a lower melting point.

The most important paper of the season was without doubt that read by the well-known authority on surgery of the urinary tract, Prof. Thorkild Rovsing. In a masterly manner he treated the question of the importance and curability of vesical tuberculosis and illustrated his paper in the most interesting way by exhibitions of specimens of extirpated kidneys, lantern slides of microscopic preparations, etc.; several cured patients were also present.

Prof. Tscherning showed a case of thyroidectomy for exophthalmic goiter and of lienectomy together with other surgical rarities. Among these was an unusual case of foreign body of the bladder, consisting in the whole handle of a toothbrush. The operator, who by the examination of the patient was led to expect a stone, was more astonished at his finding than the patient himself, who, after the operation, owned to have an indistinct recollection of a public girl having pushed the handle down his urethra on an occasion when he had paid her a visit in an intoxicated state.

It is highly to be regretted that the Danish legislative body does not count more than one medical man among its members. Had the profession been more fully represented, perhaps we should have been spared a new, and I fear not too good, law tending to the regulation of the prostitution in Denmark. Here, as in all parts of the world, the contest has been between the partisans of a control of prostitutes and those who will

not admit any control of them. The latter party altered the old law according to which a female, if found guilty of prostituting herself, was first admonished and if caught *in flagranti* for a second time was enrolled among the *pucllæ publicæ*. On these (in Copenhagen amounting to about 700) the police authorities enforced a biweekly medical examination, which eventually resulted in treatment in a hospital *ad hoc*. The new law does not punish prostitution as such, and makes totally away with the mentioned odious official enrolling of females. So far so good. But the beneficial effects of the law are certainly marred to a regrettable degree by two unlucky regulations: the one authorizes the police to arrest and punish as vagabonds such suspected women as cannot convince the authorities of their being able to make their living in a decent manner. It is much to be feared that as a result only the poor prostitutes will be punished and that arbitrary proceedings on the side of the police will become more numerous than formerly, though the intent of the new law confessedly is to prevent such. Another unlucky feature is the regulation that obliges the practitioners to report to the authorities on all such patients with venereal diseases, seen and treated by them, as cease to consult them before being discharged as cured. Nobody liking to have his name mentioned in connections of this sort, the last mentioned regulation may result in the infected abstaining from seeking proper treatment, and, instead of that, going without treatment or falling into the claws of quacks. And I am afraid that it will not be counterbalanced by the excellent regulation providing private dispensaries where any venereal patient has the right to be treated free of cost, whether he be rich or poor. Though well aware of the uncertainty of statistics on this sort of subject, one cannot help looking forward with great interest to a comparison of the frequency of venereal diseases in Denmark before and after the new law.

Dr. George Dreyer, assistant bacteriologist to the University of Copenhagen, who for a series of years has contributed several valuable papers on bacteriological topics, has recently published an article of great practical interest on the use of dead cultures of the typhoid bacillus for the Widal test. The idea is not new in itself. As early as 1897 Widal was aware of the advantage of handling dead typhoid bacilli instead of live ones, and showed that the specific agglutination occurred also in cultures killed by addition of 6.7 per cent. formol. But the importance of Dr. Dreyer's work is found in two circumstances, the one being that the agglutinability of the cultures killed after this method is a little superior to that possessed by fresh living cultures, while for instance the much recommended Ficker's *Typhus diagnosticum* (also a killed culture) is considerably inferior to living cultures, as shown by Dreyer. (It is perhaps not without interest to observe, that Dreyer publishes his method with all particulars, while the production of Ficker's diagnosticum is kept a secret.) The other interesting feature of Dreyer's method is that his killed cultures retain their agglutinability unaltered for one-half to one year. As a thermostat is not strictly necessary, the method may be expected to appeal very much to the general practitioner, especially in the country, because it enables him to do his Widal tests himself without having the trouble of working with live typhoid bacilli; the only thing he has got to do is to procure once or twice a year a little quantity of the dead culture.

Some time ago the dermatologist Prof. Alexander Haslund died, aged sixty-one. He was an excellent diagnostician and very popular with the younger members of the profession, to most of whom he had been a teacher as lecturer to the University on skin and venereal diseases. His scientific works are chiefly to be found in the *Archiv für Dermatologie und Syphilis*, of which he was a coeditor.

To Prevent Struggling During Narcosis.—Gersuny has found the following plan useful in controlling the struggles of patients passing through the earlier stages of anesthesia: The hands and forearms are enclosed in long cuffs of celluloid which project several inches beyond the tips of the fingers and make it impossible for the patient to grasp the hands of the anesthetist or the inhaler; the cuffs are kept from slipping off by a tape fastened to the upper end of each and passing over the patient's shoulders. Attempts to sit up are easily frustrated by having a nurse place her hands under the patient's heels and keep them continually raised one or two inches above the surface. As long as the heels are elevated it is impossible for anyone to sit up, and it requires no muscular strength to effect this.—*Wiener klinische Wochenschrift.*

Progress of Medical Science.

Boston Medical and Surgical Journal, May 31, 1906.

The Complications of Acute Pneumonia.—H. Jackson has studied the complications of acute croupous pneumonia as found in the records of 1,320 cases treated at the Boston City Hospital. Of complications directly connected with the lung there were 22 cases of empyema, 4 of lung abscess, 3 of gangrene, 23 of pleurisy, with large effusion, 5 of unresolved pneumonia. Of lesions of other organs there were 22 cases of pericarditis, 6 of phlebitis, 3 of meningitis, 1 of joint disease, and 2 of neuritis. This tabulation is made up, not on the basis of the exact pathological findings of the pathologist, but on that of the clinical features of the disease. Hence there is no record of kidney or of heart complications, except in a few instances in which acute endocarditis was a prominent feature of the primary disease. Failure to recognize empyema is, according to the author, one of the commonest mistakes of physicians; the patient is supposed to have unresolved pneumonia. These empyema cases may be possibly tuberculous in nature. Summaries are given of the histories of the six cases of phlebitis, the three of meningitis, and the two of neuritis.

Stiff and Painful Shoulders.—An elaborate paper on this subject, with a series of excellent photographs, is contributed by E. A. Codman. These patients complain of stiffness and pain in the shoulder joint and upper arm. A characteristic complaint is the inability to put the arm back of the neck or behind the small of the back. Women cannot do up their back hair, while men cannot button the back of their suspenders. These cases are variously called rheumatism, fibrous ankylosis, deltoid paralysis, periarthritis, etc. The author is inclined to find an explanation in abnormality of the subacromial or subdeltoid bursa, as this bursa is indispensable in abduction and rotation of the arm. It may be inflamed as a result of trauma, fixation, as after certain fractures and operations on the breast, hand, and arm, and sepsis. Most minor lesions of the shoulder joint involve the bursa, and few involve the true joint. For acute cases, the indications are to relieve pain, give physiological rest during the inflammatory stage, and later to prevent adhesion of the inflamed surfaces. In the chronic cases the author uses a special splint described and figured. He emphasizes the point that complete abduction (elevation) of the humerus necessitate external rotation. This observation has not been previously mentioned as far as the author knows, nor has that of preventing the reformation of adhesions by a splint which holds the arm in abduction and external rotation, thus bringing raw surfaces opposite healthy ones, a result which the author's splint effectually accomplishes.

New York Medical Journal, May 26, 1906.

Danger to Healthy Individuals in Visiting Resorts Frequented by the Tuberculous.—In the consideration of this question J. H. Way, who lives in one of the resort towns of the Carolina mountains, refers to statistics collected at other similar places, and presents the following conclusions: Nontuberculous individuals necessarily incur no danger of infection with tuberculosis in visiting or residing at modern health resorts frequented by patients with pulmonary tuberculosis. There is less danger of contracting pulmonary tuberculosis in a well regulated modern health resort than elsewhere. Health resorts for tuberculosis are almost invariably places where it has been originally noted that the average of deaths from tuberculosis among the natives was remarkably small. The climatic and other local conditions which originally permitted so small a development of tuberculosis among the natives continues to render them relatively (not absolutely) immune, and as well to beneficially impress the visitors to such resort. Considered in the light of most recent scientific knowledge, it is doubtful if the infective dangers of street expectoration are so great as we have previously believed. The average greater degree of sanitary knowledge and practice prevailing to an extent among all classes at a modern health resort is also highly conducive to the physical improvement and gain shown by the immense majority of visitors to our mountain resorts. The most careful attention to sputum indoors, thorough ventilation, and open-air life so much in vogue at the modern health resorts for tuberculosis, render them safer and should be continued.

Dyspepsia Neurosa.—By this title M. Gross refers to an interference with the rhythmical action of the stom-

ach by some disturbance of nerve function. The local findings are generally limited to an abnormal acidity and an irregular motility. A prolongation may lead to certain anatomical change in the stomach wall. Subjectively the patient complains of hyperesthesia, not always caused by hyperacidity, so-called relative hyperesthesia, changeable appetite, constipation alternating with diarrhea, are varied by complaints of a general feeling of depression, sleeplessness, ill humor, and great liability to fatigue. In the morning the patient complains of feeling ill and of pressure about the head. The pain, a regular occurrence, is rather diffuse, and while at times it has no connection with the ingestion of food, at other times it seems caused by it. Vomiting is often attributable to pyloric spasm. One author mentions a hyperesthesia, a diffuse sensitiveness to pressure in the gastric region, which is distinctly demarkated by the outlines of the stomach. Treatment embraces constitutionally the various measures which have been found useful in neurasthenic patients in general. Locally we may apply poultices in hyperesthesia with good results, also Priessnitz's and warm hip baths. Sleeplessness can be removed by warm baths, followed by lukewarm douches, or by cold friction before going to bed. Other beneficial hydropathic measures are sponge baths and cold dressings. Sea baths are borne well only by robust individuals; the same refers to sea air. The author has never seen any utility from electricity.

Anterior Metatarsalgia and Its Treatment.—S. Epstein refers to the condition originally described by Morton, defining it as pain and discomfort about the anterior metatarsal arch, below and behind one or more toes. He goes at considerable length into the mechanics of the foot, describes the symptoms, and refers to three personal cases of erythromelalgia, or Weir Mitchell's neuralgia, all of which were in the foot. The first requisite in treatment is the wearing of a proper shoe. Daily massage and forcible manipulation of the toes go a long way in overcoming rigidity. Corns should be carefully removed. Faradism is the preferable mode in which to employ electricity. When the condition is associated with flat foot, the latter should be strapped in the adductor position. This is only a temporary measure, however, and should be supplemented by raising the inner border of the sole of the shoe, the wearing of a Whitman's plate, and exercises calculated to strengthen the tibialis muscles. Few cases require the operation advised by Morton. In the erythromelalgia cases, marked benefit followed the swabbing of the foot once a week with pure carbolic acid, followed by immediate washing off with alcohol.

Journal of the American Medical Association, June 2, 1906.

Quarantine and Its Relation to Public Health.—M. J. Rosenau reviews the recent aspects of quarantine in its relations to public health, and states that it may be likened to jails, penitentiaries, houses of detention, and other necessary evils of this world. He outlines briefly the work of the Federal quarantine service, and enumerates the diseases which have been stricken from the list of quarantinable diseases. He discusses the limitations of disinfectants, and states that disinfection is no longer regarded as a panacea. Sanitation, he declares, is the only cure for quarantine regulations, and says that if all communities, especially seaports, were to place their cities in the best sanitary condition, in accordance with the teachings of modern science, there would be little danger of disease spreading to epidemic proportions, and practically no need of quarantine restrictions. Modern sanitation is very expensive. It means thorough drainage, proper disposal of wastes, good paving, pure water, and cities constructed with sufficient breathing spaces between houses, so that all the inhabitants may receive their proper proportion of fresh air and sunshine; it also includes the destruction of mosquitos, rats, and other vermin which help to spread disease, and a proper supervision of the food supply. He discusses the lessons to be learned from the recent yellow fever epidemic, and reviews the opinions of various observers regarding the hereditary transmission of the yellow fever parasite in the mosquito.

The Renaissance of Therapeutics.—R. C. Cabot remarks that the prominence gained by surgery from its brilliant and beneficent successes is being moderated to some extent, by lessening the anxiety of surgeons for operation and by the result of hygienic treatment of osseous and glandular tuberculosis. As surgery settles into its place, a new wave of therapeutic activity is arising along other lines. The treatment of tuberculosis, which was formerly regarded as very nearly hopeless, now shows what may be called an aggressive spirit in therapeutics, the results of which are remarkable. In the cold, damp, changeable climate of Boston not merely the ideal patients, who have an incipient lesion, good courage and backbone, a country house, and real intelligence, are being cured, but some of the stupid, discouraged, slum cases, that were formerly abandoned as (under the circumstances) hopeless. Another example of this aggressive spirit is shown by the attitude of the school physician, who now insists on general physical examination of every child in the school at least once a year, whether it complains or not. The campaign against tuberculosis is now interesting the public as well as the profession. The increasing prevalence of therapeutics is another indication of advance. The physician also becomes aware of the importance of psychic factors in the production of disease. It is going to be recognized as a legitimate and, indeed, an essential part of therapeutics to seek for the relief of any cause that is producing disease. This necessitates the investigation of social, industrial, and family conditions. The recognition of social and psychic factors as causes of disease, and the measurably successful effort to reach and to modify these causes, is one of the most striking marks of the present rebirth of therapeutics. In the newer psychic and sociological fields which medicine has begun to invade, women will find a large field of usefulness. The effective application of all therapeutics (if you except surgery), Cabot states, is women's work. These changes in therapeutics are accompanied by the beginning of the end of many evils, especially the false mystery that has often encompassed the doctor and the conception of drugs as the *alpha* and *omega* of therapeutics. He concludes as follows: "(1) Therapeutics has become, within the past few years, very noticeably more effective. (2) This increased effectiveness is the result of (*a*) the aggressive spirit, as exemplified by the work of the New York Board of Health in school hygiene and school inspection, and by the tuberculosis work now being carried on in Boston; (*b*) the greater part now being taken by the laity in medicinal work, both by intelligent cooperation and by financial support; (*c*) our greater acquaintance with physical therapeutics, especially with the details on which their successful application depends; (*d*) the rise of scientific mind cure and of social work, marking a recognition of the psychical and of the social elements in all disease; (*e*) a wider utilization of the unique talents of women in the field of therapeutics. (3) With the rise of the type of therapeutics here described, we are now witnessing a limitation of the sphere both of surgical therapeutics and of drug therapeutics. The latter limitation will do much to undermine the superstitions on which the 'patent-medicine' habit rests."

Treatment of Idiopathic Epilepsy by Appendicostomy for Colonic Irrigation.—S. LaPlace considers it probable that epilepsy is due to the manifestation of a toxin accumulated in the system as a result of the intoxication of improper food or tissue metabolism, and the locality of the production of this poison is the colon. Consequently, he has resorted to appendicostomy, with subsequent irrigation of the colon through the fistula, in one case, with excellent results. He concludes that the treatment is harmless, and is based on sufficiently sound theoretical and scientific grounds; and even should improvement of the epilepsy not result, it cannot fail to do good from a hygienic standpoint in affording general relief from constipation, to which most sufferers from epilepsy are subject. The repeated flushings of the colon keep it as nearly empty as possible, and almost eliminate its presence as a reservoir for undigested and putrefying substances. Fear of a permanent artificial opening in the intestine should not be entertained. The artificial fistula closes easily, and, after months of treatment, should one desire to discontinue the flushings of the colon, the natural processes of evacuation are resumed without difficulty. The method is not expected to cure all cases of idiopathic epilepsy, but only those whose existence can be traced to this particular cause. The procedure here advocated should be accompanied by the proper dietetic measures.

Skin Grafting.—J. E. Cannaday uses bi-daily dressings of gauze wet with chloral hydrate solution (2 grains to the ounce), and protected with oil silk, as a preliminary for obtaining a clean granulating surface. When ready to graft he freshens the granulated surface with a nail brush, which he prefers to the curette. He uses Thiersch grafts, taken by preference from the patient. The grafts are shaved by a sawing motion, one-half the thickness of the skin and one-half inch by one and a half inches in size. As soon as cut they are

turned over the left index finger, skin side next the finger, and carried directly to the denuded site and pressed down on its surface, the edges being smoothed off with a probe. The process is repeated till the area is covered. He believes this direct transplantation better than the intervention of any saline or other solution, which makes the operation more difficult and less certain. He covers the grafted site with thin dental rubber dam, crisscrossed for drainage if the area is large. Over this he places a small gauze pad, anchored with zinc oxide adhesive plaster, and externally a cotton, gauze, and bandage dressing. Some method of immobilization may be desirable, and if the grafting is done on a limb, he keeps it on the level of the body, or a little elevated. Slight pressure will keep the grafts in place and prevent serum accumulation or bleeding; too much pressure kills the grafts. He has now used this method in twenty-three cases, chiefly burns and lacerated wounds, without a single complete failure.

The Lancet, May 19, 1906.

Action on Bacteria of Electrical Discharges of High Potential and Rapid Frequency.—Interesting experiments in this direction have been made by A. G. Foulerton and A. M. Kellar. The current obtained from the electric light supply was first transformed into a rapidly oscillating current of very high potential, and then into an oscillatory discharge of rapid frequency by means of a condenser and spark-gap. The bacteria were exposed to the action of the discharger while suspended in distilled water contained in test-tubes. The authors note that in all the experiments in which a decided germicidal effect was observed, it appeared that this was due entirely to the action of substances formed as the result of electrical action on the atmosphere in which the discharge occurred; and it appeared that under the time conditions of the experiments the electrical force employed was not capable of exercising any injurious action on the bacteria tested. And it is probable that when in medical practice cases of lupus and certain other cases in which there is an exposed ulcerated surface are treated by "high-frequency" discharges, the results produced are due entirely to the action on bacteria of nitrous and nitric acids formed in the neighboring air. And from a therapeutic point of view the use of high-frequency discharges in such cases must be looked upon mainly as an efficient method for bringing germicidal substances in a nascent and very active condition into contact with the bacteria present in the lesion exposed to the action of the discharge.

Peculiar Form of Hemoptysis with Numerous Spirochetes in the Expectorations.—A. Castellani reports two interesting cases, one occurring in a Cingalese, and the other in a native Indian, both adult males. The clinical histories suggested that the cases were hemorrhagic bronchitis, as tuberculosis could be excluded with reasonable certainty. Microscopical examination excluded the possibility of endemic hemoptysis from distomum, while the large number of spirochetes in the expectoration, sometimes practically without other germs, suggested that the former were the cause of the bleeding. They were always very numerous, and stained well by the Leishman method, generally taking on a bluish tint; they could be stained also with the ordinary aniline dyes, though not so well. They were generally mixed with some bacteria, but sometimes when the sputum was collected in sterile Petri dishes and preparations made at once, they were practically the only germs present. Vincent's fusiform bacilli were never observed. These spirochetes were not all alike. They might be divided morphologically into several groups. (1) Very thick individually, from 15 to 30 microns in length, with irregular waves, which varied in number but were never very numerous. The parasites, with the Leishman method, stained deep blue; they were pointed at both ends. (2) Spirochetes resembling the *Spirochæta refringens* (Schaudinn), with a few graceful waves and pointed extremities. (3) Thin, delicate spirochetes with numerous small, rather uniform waves and tapering ends. Sometimes one of the extremities was blunt while the other was pointed. (4) Very delicate parasite, though thicker than the *Spirochæta pallida*, with very few waves, generally irregular in shape.

Hypertrophy and Dilatation of the Heart in a Child without Valvular Disease or General Adhesion of the Pericardium.—G. Carpenter and S. Fisher report the case of a boy of eight years with the usual symptoms of cardiac incompetency. The apex was in the fifth space outside the nipple line. There was a systolic murmur at the apex, and a reduplicated second sound over the pulmonary area. Cardiac dullness extended over one inch to the right of the sternum, and a to-and-fro sound was heard at the base, suggesting either an endocardial or pericardial origin. The child died after having been under observation for about four months. At the autopsy the pericardium was found free from disease. Nothing could be found to account for the basic murmur. Both pulmonary and aortic valves were intact, but the ventral and tricuspid orifices were dilated, although their valve cusps were normal. The authors believe that rheumatism may cause hypertrophy apart from valvular disease and general pericardial thickening, and ascribe this result to a poisoning of the heart produced by the disease chiefly during the growing period of life. After the age of twenty years, rheumatic pericarditis causes little or no cardiac dilatation, although this inflammation is undoubtedly an evidence of the most intense form of rheumatic heart infection.

Extensive Rupture of the Liver without External Injury.—F. S. Lloyd's patient was a man who had been crushed between two wagons and had died soon after. Excepting one or two surface scratches the body showed no marks of violence. Autopsy showed the abdomen full of blood. The liver was large, in conformity with the massive physical development of the patient, pale, but healthy in substance. Through the thickest portion of the right lobe was a tremendous fissure, running backward through both capsule and glandular substance from the anterior edge to the posterior surface, and being so complete that the liver was all but divided by it into two portions, only a narrow bridge of liver tissue about an inch thick connecting them. The fissure was straight and was eight and a half inches long, the surfaces exposed by it being rough and granular looking. The greatest breadth of the torn surface was roughly four inches, tapering thence to a point toward the anterior edge. About the center of this fissure was another contused tear three inches long, running perpendicularly to it outward to the right; this, however, only penetrated the liver substance for a depth less than half an inch; one or two smaller tears radiated from the point of junction of the major tears in a stellate manner. The gall-bladder and the rest of the liver were normal, as were all the other abdominal viscera.

British Medical Journal, May 9, 1906.

Acute Yellow Atrophy of the Liver, Following Influenza.—O. M. Booth and J. Williamson report the case of a man of thirty-one years who had had, three years previously, an attack of jaundice, and who when seen by them was in an attack of influenza of six weeks' duration. Two days later he began to have convulsions, which alternated with a typhoid condition. A jaundice gradually developed itself, the liver dullness became narrow, and the diagnosis of acute yellow atrophy was made. No autopsy was held.

Tonsillitis in Convalescence from Diphtheria.—The paper of J. D. Rolleston is based upon the observation of nine hundred cases of diphtheria, seen in hospital work during a period of three years. Apart from cases of inflammation of the tonsils, which proved at the time or subsequently to be scarlatinal in origin, the tonsillitis occurred in sixty-four cases either within or usually toward the end of the first three weeks of the disease, or at a much later period. In the first class the tonsillitis found in thirty cases was invariably associated with late manifestations of the serum, which consist of a rash generally of the type of a circinate erythema, and usually associated with pyrexia, less frequently with pains in the joints or muscles, and adenitis of the submaxillary and cervical glands. The appearances presented by the throat at this time vary from an injection of the fauces with a follicular deposit on the tonsils, to large, semi-confluent patches resembling early stages of diphtheria. They are not adherent, however, and often disappear without local treatment, leaving no ulceration. Staphylococci and streptococci are generally found in rich abundance. Secondary angina in diphtheria apart from serum manifestations is not uncommon. It occurred in thirty-four of the author's cases. The average time was the fortieth day. It occurs more frequently in adults and older children, in children, and in the damp months. Symptoms are as a rule slight. The average duration of the fever is four days, but in most cases the temperature did not rise above 101°. The pulse was rapid, but examination of the heart was negative, nor was there anything to suggest a rheumatic infection. The faucial exudation was almost always discrete, disappearing in a few days without local treatment. Cultures proved that the exudate was not diphtheritic.

Lung Complications After Operations Under Anesthesia.—Analysis of 55 cases by G. E. Armstrong gives the following statistics: (1) Among the 14 cases of lobar pneumonia there were 10 of sepsis of some form. In 8 of these there was peritonitis, 3 being due to typhoid perforation; 3 had chronic nephritis, 1 aspirated vomitus, 1 suffered from fractured ribs, and 1 from diabetes. (2) There were 16 cases of bronchopneumonia, among them being 12 cases of sepsis of some form, including 6 cases of peritonitis, 1 of which was secondary to typhoid perforation; 3 had nephritis, 4 aspirated food or vomitus, 3 were trephining cases, and in 6 there was preexisting emphysema. (3) Among the 19 cases of bronchitis there were 5 of trephining, in 7 there was peritonitis, in 3 nephritis; in 2 there was preexisting emphysema, 1 with chronic bronchitis; in 1 there was typhoid perforation, and another had tracheotomy performed; this one aspirated blood. (4) Of the 3 cases of plastic pleurisy 2 were associated with tuberculous cervical adenitis, and 1 with cancer of the sternum; all these recovered. (5) There was 1 case of pleural effusion, occurring in a patient suffering from suppurative mastitis with pleurisy on the same side. (6) There were 2 cases of empyema, 1 following excision of an epithelioma from the lower lip. There was no history of pneumonia preceding the empyema. One followed an operation for appendicitis, with abscess and generalized peritonitis.

Postanesthetic Acetonuria.—A subtitle of the paper by L. Beesly is "The significance of delayed chloroform poisoning and the advantages of ether over chloroform in acute infective conditions." He has carried out a series of examinations of the urine of patients before and after operation. He finds that the similarity of the symptoms described as occurring in so-called acid intoxication, acidosis, acetonuria, and delayed chloroform poisoning, all point to a similar metabolic disturbance, one of the ultimate products of which is acetone, and that this product occurs with the greatest regularity after the administration of a general anesthetic. He believes that a certain degree of poisoning occurs after every operation. The paper is too elaborate to be abstracted in full, but is of great interest to all practitioners. The author's conclusions are (1) That two separate conditions should be recognized—acute and chronic acetonuria. (2) That ether and chloroform invariably induce a temporary acute acetonuria, which may be very detrimental even to an apparently healthy organism. (3) That this acute anesthetic acetonuria is accompanied by symptoms of acid intoxication, sometimes ending in death, when the kidneys are unable to cope with the increased formation of acetone by a corresponding capability of excretion. (4) That although ether may produce a greater acetonuria, this is less harmful than that produced by chloroform, because ether is less injurious to the cells of the liver and kidneys, and thus does not hinder their power of elimination. (5) That the more plentifully and rapidly excretion is carried on the less serious is the poisoning. (6) That the effects of the poisoning are mitigated by the administration of alkalies, which may also be given with advantage before operation if poisoning be anticipated. (7) That the usual risks of anesthesia are not increased by preexistent chronic acetonuria. (8) That anesthesia is dangerous with preexistent acute acetonuria, especially if the anesthetic is chloroform. (9) That a guarded prognosis must always be given when acute acetonuria is present with symptoms of poisoning (10) That death following the administration of chloroform with symptoms of poisoning may be due to the idiosyncrasy of the patient.

Berliner klinische Wochenschrift, May 14, 1906.

The Bactericidal Action of Radioactive Mineral Waters.—Rheinboldt describes experiments made on a certain mineral water known to possess radioactive qualities, in order to determine its effect on bacterial growth. Samples of the bottled water ordinarily sold and of a specimen obtained fifteen hours previously from the spring were allowed to act under similar conditions on equal amounts of a bouillon culture of *Bacillus prodigiosus*, and plates were made at regular intervals. It was found that the old water exerted no influence whatever on the development of the bacteria, whereas the fresh specimen had a very pronounced inhibitory effect, which reached great intensity after four hours' contact with the bacteria, and then continued for some time longer. An attempt to reimpregnate the old water with artificial radium emanations was only partially successful, as the antibacterial properties thus contributed to it disappeared again very promptly. The author suggests that possibly there are other inhibitory properties in mineral waters in addition to the radium emanations.

The Testing of Digitalis Preparations.—Focke says that the systematic testing of digitalis preparations is even more necessary than the standardization of such products as diphtheria antitoxin. The variability in the quality of the digitalis preparations used is so great, and the therapeutic importance of the drug is so high, that even though it should be necessary to increase its cost to the consumer, efficient methods of standardization should be employed. Tests made on frogs for the purpose of comparing the clinical value of digitalis preparations differing in nature are wholly unreliable and unsatisfactory, but, on the other hand, the frog lends itself admirably as a test object for determining the comparative activity of different specimens of the same type of preparation. The entire subject of the uniformity of digitalis preparations has been too much neglected, and the author proposes that in order to correct this deficiency, the now existing laboratories for the examination of food supplies, etc., be also required to supervise the strength of the digitalis derivatives sold by apothecaries.

Münchener medizinische Wochenschrift, May 15, 1906.

Analgesia of the Tendo Achillis in Tabes.—Racine discusses the occurrence of a symptom described by Abadie as affording early evidence of the presence of locomotor ataxia. This consists in great reduction or complete abolition of the tenderness normally present in the tendo Achillis when pressed between the fingers. In healthy individuals even moderate pressure in this region produces severe pain, and the author by means of a specially devised form of dynamometer was able to determine that a pressure of five to ten kilograms is distinctly unpleasant, and one of over ten kilograms is painful to ordinary persons. Individual variations in tenderness were noted, and in one or two instances there appeared to be almost total analgesia in persons who exhibited no other symptoms of tabes. On the other hand, the symptom was found present in about 80 per cent. of the tabetics examined, and the author agrees with Abadie that it is a fairly valuable and constant sign of the disease. He does not believe, however, that Abadie's claim that analgesia of the Achillis tendon is a pathognomonic early symptom is altogether justifiable, and considers that it cannot be placed in the same category with the absence of knee-jerk or the Argyll-Robertson pupil.

A New Route for Operating on Malignant Nasal Growths.—Denker describes a plan of operation which is intended to give free access to the nasal passages for the removal of large tumors without entailing the facial deformity that follows the ordinary methods. It consists in opening the nasal passage through the maxillary antrum. This is effected by an extensive incision along the junction of the upper lip with the alveolus, by means of which the lip and cheek are dissected up from the superior maxilla as far as the orbital border. In this way the opening of the bony nares is exposed, and the mucous membrane is stripped up from the bone. The antrum is then opened from without and enough of its internal wall is also removed to expose the new growth. The necessary operative procedure can easily be carried out through this opening, and at the close of the operation the cheek is allowed to drop back into place and the incision in the mucous membrane is sutured. The after-treatment of the nasal wound is managed through the nostrils. The author describes three cases in which this plan was followed. In two instances malignant growths were removed, and in the third a fibroma, probably originating in the pterygopalatine fissure, was partially extirpated. In this case access to the entire region involved could not be secured through the antrum, and for such conditions in which the retromaxillary fossa is involved, the author recommends temporary resection of the superior maxilla.

Anesthesia with the Roth-Dräger Apparatus.—Hagen reports very favorably on this method of inducing anesthesia, basing his conclusions on seven hundred cases in which the apparatus was used. The procedure consists in the administration of a continuous stream of oxygen to which accurately measured quantities of ether or chloroform, or both together, may be added. The proportions of each constituent of the mixture are readily controllable. The advantages claimed for the apparatus are that it allows of extremely accurate dosage and of the widest possible range of individualization. The anesthetic vapors are administered in greatly

diluted form and in reduced quantities. The accumulation of carbon dioxide in the body is prevented, and the stimulation produced by the oxygen is beneficial. Induction of anesthesia is easy, and is usually unaccompanied by the stage of excitement ordinarily seen. The only drawback to the method is its expense, which is considerable, in spite of the fact that only about one-half as much ether or chloroform is required as when the older methods of administration are employed.

Deutsche medizinische Wochenschrift, May 17, 1906.

Observations on Sahli's Desmoid Reaction.—Einhorn affirms that this test of gastric efficiency is not as reliable as it has been claimed to be by its originator. The procedure is based on the principle that catgut can be digested only in the stomach, and that the pancreatic juice does not affect it. Small bags of rubber tissue containing a little methylene blue or iodoform, and tied up with a strand of raw catgut, are given to the patient, together with an ordinary meal. If the gastric function is good the test substance used should be demonstrable in the urine or saliva six to eight hours after the administration of the test pill. Einhorn found that in four cases of gastric achylia a positive reaction was obtained by this method, apparently indicating that digestion of the catgut must have occurred in the intestine. In one instance the stomach contents, removed several hours after the test pill had been given were free from any blue color, although the urine passed shortly afterward was blue. The author therefore concludes that the test is unsatisfactory, because catgut can be digested in the intestine as well as in the stomach.

Experimental and Clinical Observations on the Nature of Phthisis Bulbi.—Schirmer has conducted a series of experiments on rabbits' eyes, in the course of which he produced artificial atrophy by the introduction into the anterior chamber of small amounts of mercury, salt solution, adrenalin solution, etc. As a result of this work and of his clinical observations, he concludes that the condition of primary hypotonicity present in phthisis bulbi, which often appears even a few hours after the onset of an inflammation, is due to the circulatory disturbances attending the process. The result is that an abnormally albuminous aqueous humor is secreted in abnormally small amounts. In favorable cases this condition disappears again as the inflammation subsides, and the intraocular pressure then returns to the normal. In the unfavorable cases so many vessels in the ciliary processes are destroyed in the course of the inflammatory process that even after the termination of the circulatory disturbance the remaining vessels are not competent to supply adequate quantities of intraocular fluid. In consequence, intraocular pressure is permanently reduced and the walls of the bulb in contracting through their own elasticity increase in thickness, thus giving rise to the nonirritative type of phthisis. If in addition to the destruction of the vessels inflammatory circulatory disturbances persist, the secretion of aqueous humor overrich in albumin in small quantities continues, and the clinical condition resulting is that of phthisis dolorosa.

Lung Stones.—Bürgi describes two cases of this singular affection. In the one, that of a man of thirty-three years, there was advanced pulmonary tuberculosis. The patient on one occasion coughed up fifteen hard concretions of about the size of a pea. The other patient was a young woman, in whom the diagnosis of tuberculosis was probable, but was not altogether substantiated. During a period of several months she coughed up large numbers of pulmonary concretions, varying in size from that of a pinhead to that of a pea. In the course of a year her general condition improved greatly and the pulmonary signs disappeared. Examination of the stones in each instance showed that they were composed of mucus, epithelial débris, etc. The inorganic constituents were for the most part calcium phosphate and magnesium phosphate.

French and Italian Journals.

Subperitoneal Fibrous Body in a Woman Three and One-Half Months Pregnant; Laparotomy; Enucleation; Recovery.—Pozzi removed a fibrous body from a patient who was three and a half months pregnant. This body was as large as two fists. It was wedged in the pelvic inlet, and if it had been allowed to remain would probably have caused grave dystocia at term. Pozzi determined at operation that this fibrous body had no connection with the gravid uterus. It was in such a position that it pressed upon the rectum. It was enucleated and the cavity was tamponed. The recovery of the patient was excellent, pregnancy continuing normally.—*La Tribune Médicale, March 31, 1906.*

Albuminose of Bence Jones and Kahler's Disease.—E. Cavazzani presents a case of Kahler's disease in a female, in whose urine albumose was demonstrated, and calls attention to the pathological interest of this substance which may lead to knowledge of the function of the medulla of the bones, especially with regard to the production of an internal secretion of unorganized material. He has noted in experiments on animals a toxic influence of this substance manifested by dyspnea and muscular asthenia. Merletti has observed albumose in some cases of eclampsia in a prodromal period before the convulsions occurred, and regards it as a phenomenon preceding the intoxication of eclampsia. In the puerperal state albumose does not arise from a medullary genesis, but in all probability depends on the active processes of proteolysis which go on in the zone of the epithelial portion of the placental villi.—*La Riforma Medica, April 7, 1906.*

The Indirect Effect of Alcohol on the Heart.—O. Dauwe declares that alcohol has a directly harmful action on the function and the vitality of the cardiac muscle, and consequently, far from being a cause of increased pressure, its action on the heart can only hinder it. Another action, then, must be found for alcohol which will be strong enough to overcome the cardiac depression. Kochmann is the investigator who has determined this. A special influence exerted by alcohol on the abdominal plexuses which governs the abdominal circulation and that of the inferior extremities has been discovered. This action, which probably has its principal seat in the splanchnic ganglia, acts through an energetic vasoconstriction. The result of this action is the increase of general pressure, which causes a more active circulation in the coronary vessels of the heart. This effect on the circulation is sufficient not only to compensate the depressing action of alcohol on the cardiac muscle, but also to cause the action of the heart to be strengthened.—*Gazette des Hôpitaux Civils et Militaires, April 10, 1906.*

The Eye in Relation to Acquired Syphilis.—A Cantonnet declares that the effects of syphilis on the eye are very frequent and very grave. Among other lesions which he mentions are the following: The eyelids sometimes are the seat of the chancre; the conjunctiva in some cases is also the seat of this lesion; the cornea may be attacked by interstitial keratitis. Rarely is the sclerotic inflamed. The uveal tract is affected by secondary syphilis with considerable frequency. The choroid, the retina, and the optic nerve may also be attacked by this disease. The orbit may be the seat of osteoperiostitis or gummata, exostoses, or osteomata. The lacrymal gland is affected in some cases. Paralysis or neuralgia may be noted in the nervous apparatus of the eye. The writer puts iritis in the first rank of these lesions due to syphilis. The general treatment should be very energetic, for ocular syphilis is a very grave affection.—*Revue Française de Médecine et de Chirurgie, April 10, 1906.*

Anemia of Infancy.—A. G. Petrone characterizes anemia in infancy as frequent, though less so than in the adult. Numerous conditions that may produce it exist in the baby, and they combine with the lack of the resistance of the hematopoietic organs of the baby to morbific agents. The only rational classification of anemia depends on the hematology. The essential symptom of anemia is oligochromemia, dependent on lowered globular resistance. There are three groups, chlorotic, simple, and pernicious anemias. In the chlorotic type the oligochromemia is produced by lessened globular resistance without diminution of the number of the red blood corpuscles. There is insufficiency of the amount of iron for the formation of hemoglobin, which may be congenital and depend on scarcity of the reserve iron which the infant takes from the mother's blood, on a premature exhaustion of this reserve, or on exaggeration of hemolysis in the first few days after birth. Simple anemia has its oligochromemia produced by oligocythemia or by lessened number of red corpuscles combined with lessened globular resistance. There is often polychromatophylia, anisocytosis, and normoblasts in the circulation. Pernicious anemia is characterized by an intense oligocythemia, oligochromemia, megaloblasts in the circulation, anisocytosis, poikilocytosis and polychromatophylia. All ordinary causes of anemia may operate in a sufficient degree to produce the pernicious form and in addition intestinal parasites, hemorrhage, malaria, syphilis, and intestinal autointoxication may be mentioned. There are many complicated forms of anemia connected with splenomegaly.—*Gazzetta Medica di Roma* March 15, 1906.

Book Reviews.

Précis de Diagnostique, Chimique, Microscopique, et Parasitologique. Par les Docteurs Jules Quiart et L. Grimbert. A l'usage des médecins, des pharmaciens, des etudiants en médecine preparant le troisième examen, et des étudiants en pharmacie. Paris: F. R. de Rudeval, 1906.

In this volume of 960 pages with 500 figures a very satisfactory exposition is given of the subject of clinical diagnosis by laboratory methods as practised in France. To the American critic certain omissions appear strange, such, for example, as the absence of all mention of the Fleischl hemoglobinometer or its modifications, and the preference of the blood-counting apparatus of Malassez over that of Thoma, which also is not referred to. The technique of staining blood films is not so fully described as is customary in American or German works, and in numerous other respects the volume differs from the orthodox teaching of the German and American schools. This criticism is not intended to be condemnatory, however, for the volume presents many features of much excellence, notably the sections devoted to parasitology, which are unusually complete. The illustrations are very numerous and for the most part are satisfactory, those in the blood again being the weakest. While not of a nature to supplant other textbooks, the work presents enough new points of view to be a desirable supplement to other books on the subject.

Sex and Character. By Otto Weininger. Authorized Translation from the Sixth German Edition. London: William Heinemann; New York: G. P. Putnam's Sons, 1906.

After having read this volume through one is tempted to repeat Johnson's time-honored remark regarding the performance of the dancing dog—that the wonder is not that the feat should be done so well, but that it should be done at all. No one could deny that, considered solely as the work of a youth who died by his own hand at the age of less than twenty-three years, the present book is a remarkable achievement and represents an astounding degree of familiarity with many departments of learning. Unfortunately it also affords a striking example of the gulf between knowledge and wisdom, and it is impossible to attach to this farrago of misogynistical diatribes any significance as a contribution to scientific literature, and as belongs, for example, to the not less pessimistic but entirely rational essay of Möbius on "The Physiological Weakmindedness of Woman." The author, with the customary self-complacency of the megalomaniac, presents his own unsupported assertions as logic and offers invective as argument. The inconsequential way in which he denies to woman the possession of any spiritual or psychical faculty other than the coupling instinct in its most restricted sense is more suggestive of the *jeux d'esprit* of G. Bernard Shaw than of any more serious philosophy, and it is out of the question to regard the book as anything but the product of a mind diseased. The work has interest solely to the psychologist and alienist as being the outpouring of a disordered mentality, but unfortunately it is of a type to attain popularity among the laity, as is attested by the fact that six editions of the German original have already been distributed.

The Crux of Pastoral Medicine. The Perils of Embryonic Man: Abortion, Craniotomy, and the Cesarean Section, Myoma, and the Porro Section. By Rev. Andrew Klarmann, A.M. Second, Revised and Enlarged Edition. New York and Cincinnati: Fr. Pustet & Company, 1905.

The facts that the first edition of this little volume, contrary to all expectations, was welcomed by the medical profession, that there exists a pressing need of a common meeting ground for physician and priest at the bedside of the patient, and also that there is a tendency of the laity to an evasion of the moral responsibility incurred in the marriage relation, have actuated the author in presenting a second edition of this work.

He shows how the problems of life and generation in the light of modern biological, physiological, medical, and surgical progress have but lent emphasis to the authoritative rulings of the Church on the questions involved. The stand taken by the author in regard to abortion, the Porro operation, and the moral responsibilities involved in marriage may seem extreme to many, but desperate diseases need desperate remedies, and the benumbed conscience, in too many instances abetted by the physician and ignored by the theologian, is sorely in need of such awakening as the perusal of this little book will stimulate.

Surgical Nursing, and the Principles of Surgery for Nurses. By Russell Howard, M.B., M.S., F.R.C.S., Lecturer on Surgical Nursing to the Probationers of the London Hospital, etc., London: Edward Arnold, 1905.

The growth of the profession of nursing has been marked by the appearance of numerous books in which are laid down the principles of both medicine and surgery with the idea of making the nurses' work more intelligible. How much of this is finally absorbed by those for whom it is intended is questionable, for there are so many practical duties to be performed that a nurse has little opportunity to think of the theoretical aspects of the matter. But up to a certain point such books as that here referred to are of value both in the training school and as a work of reference later. This particular one may be described as *multum in parvo*, for almost the entire domain of surgery is discussed in brief paragraphs, together with a variety of other subjects. There are a number of items which will be found differing from those usually associated with American practices, but aside from this the book forms a lucid and quite comprehensive handbook on the subject of nursing.

Food and the Principles of Dietetics. By Robert Hutchinson, M.D., Edin., F.R.C.P. Assistant Physician to the London Hospital and to the Hospital for Sick Children, Great Ormond Street; Author of "Lectures on Diseases of Children;" "Patent Foods and Patent Medicines," Joint Author of "Clinical Methods." With Plates and Diagrams. Revised Edition. New York: William Wood & Company, 1906.

Writers on dietetics have been busy of late years in keeping pace with the demands for information on the subject of feeding in sickness and health that the present era of clinical research in medical problems has stimulated. Dr. Hutchinson's book promptly attained universal recognition in its first appearance a few years ago, and that its value has been generally appreciated is shown by the necessity for this new edition after so short an interval. The author manages a highly important subject in a manner to bring forward to the full its interesting aspects, and by his agreeable style renders the book entertaining as well as authoritative. The dietetic problems that must be encountered in daily practice are often difficult of solution, but the present volume can safely be recommended as one of the most satisfactory guides that has yet been written. A feature of especial interest and one that may often be used in impressing some medical lesson on an unbelieving patient, is the very free use of ingenious diagrams to indicate the percentage composition of the various articles of food. The problems in relation to the amount of food required under different conditions, the value of alcohol and other stimulants, the most advantageous methods of cooking, the matter of diet in diseases of metabolism, etc., are all discussed in a very practical way. The conclusions are those reached by an observer of wide experience whose object has been to assist the practitioner in the management of the difficult cases of nutritional disorder that often fall to his lot.

The Ophthalmoscope and How to Use It. With Colored Illustrations, Descriptions, and Treatment of the Principal Diseases of the Fundus. By James Thorington, A.M., M.D. Author of "Refraction and How to Refract," and "Retinoscopy;" Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. 73 Illustrations, 12 Colored Plates. Philadelphia: P. Blakiston's Son & Co. 1906.

While the successful use of the ophthalmoscope is an art that can be acquired only by diligent practice, the beginner's progress will be much hastened if he has a clear conception of the optics of ophthalmoscopy and their practical application. Dr. Thorington has presented the principles involved in the clearest possible fashion, and his directions for the learner are admirably conceived and expressed. The portion of the work devoted to the pathological conditions to be detected by the ophthalmoscope is equally satisfactory and includes terse descriptions of the treatment for each lesion. The volume is a fitting companion to the author's previous works on allied subjects.

Die Behandlung der Krankheiten der Nase und des Nasenrachens. Von Prof. D. A. Onodi, Budapest, und Prof. Dr. A. Rosenberg, Berlin. Berlin: Oscar Coblentz, 1906.

Familiar ground is traversed in this freely illustrated textbook, and yet it has a certain charm of freshness. The authors have drawn upon their personal clinical experiences and include the very latest therapeutic advances in medication and surgery. No less than one hundred and sixty-three pages are devoted to the consideration of sinus diseases, and many of the illustrations in this section have been made apparently from anatomical specimens prepared expressly for this purpose. Another feature not always notable in German text-books is that the entire contents have been well paragraphed so that it is easy to find any particular subject. At the present time it is difficult for a text-book to say much that is new to anyone who follows the current literature of any of the specialties, for most of the advances are first exploited in some one of the journals, but we have no hesitation in saying that the present volume is a thoroughly up-to-date exposition of nasal and nasopharyngeal maladies.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-seventh Annual Meeting, Held in Boston, June 5, 6, 7, and 8, 1906.

(Special Report to the MEDICAL RECORD.)

GENERAL SESSIONS.

First Day—Tuesday, June 5.

DR. LEWIS MCMURTRY OF LOUISVILLE, KY., PRESIDENT, IN THE CHAIR.

THE first general session of the fifty-seventh annual meeting of the Association was called to order in Mechanics' Hall at 10.30 in the morning. The officers and guests entered in procession at that time, and marched from the rear of the hall to the platform, led by Governor Guild and the Rev. Dr. Edward Everett Hale. Following the Governor walked Mayor Fitzgerald, escorted by Dr. Herbert L. Burrell, and after them the officers and invited guests of the Association, each escorted by some member of the local committee. Dr. Paul Thorndike was chief marshal, assisted by Dr. L. T. Wilson. Among the ex-presidents seated on the platform were Dr. Henry O. Marcy of Boston, John A. Wyeth of New York, Charles A. L. Reed of Cincinnati, Frank Billings of Chicago, William W. Keen and John H. Musser of Philadelphia, and Joseph M. Matthews of Louisville.

The Rev. Dr. EDWARD EVERETT HALE was introduced by President McMurtry, and made the opening prayer, in which he petitioned for peace and that those assembled together might be prospered in their deliberations and in their work of ministering to the physical ills of suffering humanity.

Addresses of Welcome.—Governor CURTIS GUILD of Massachusetts then delivered an address of welcome, saying that he had come in the name of the Commonwealth to welcome the physicians from all over the country, to extend to them the privileges that the State could give, in order that their visit to Boston might be full of delight and also instructive. He hoped that while the visitors were inspecting the various city institutions they would not omit those under State control, such as the free distribution of diphtheria antitoxin, which was carried on under the careful auspices of the Commonwealth; also those institutions which look after the interests of the feeble-minded, and which had made the name of Dr. Fernald a household word; also the insane hospitals, the schools for the blind, and other worthy institutions. American physicians had ever been distinguished for their patriotism and devotion to the duties of their citizenship. One of the earliest sacrifices to our freedom was that of Dr. Warren at Bunker Hill. Another conspicuous Massachusetts doctor, who had well served in Cuba and was now rendering conspicuous services to his country in the Far East, was General Leonard Wood. War was a curse, but one war, conducted by medical men, had been a blessing to the world—that was the campaign against yellow fever in Havana, in which the number of human lives saved was much greater than that of those sacrificed in the Cuban war. This war had been waged and carried to a triumphant issue by surgeons of the United States Army.

President ELIOT of Harvard College, in his address of welcome, paid tribute to the noble qualities of the medical profession, and recounted the many benefits its members conferred on the community at large. He said that he welcomed the American Medical Association to an exceptional community, in which physicians and surgeons had for generations held equal rank with the members of all other learned and scientific professions. Massachusetts had long recognized in physicians and surgeons as a class powerful contributors to the public health and happiness, to the advancement of medical knowledge, to the industrial and economic interests of the community, and to its moral welfare. For generations this fortunate community had enjoyed the privilege of knowing intimately physicians who illustrated the highest qualities of human nature—men courageous and resolute under responsibility, imperturbable in the presence of danger, conservative and yet bold, in professional relations patient, cheerful, and tender, diligent learners throughout life, and diligent teachers of sound doctrine concerning health and disease, virtue and vice. Experience of these noble qualities in the best physicians and surgeons during the past two hundred years had led Massachusetts to recognize completely the dignity and serviceableness of the profession of medicine, and to treat it, therefore, with the highest official and social consideration. This was more than could be said with accuracy concerning the standing of the physician in many older and more conspicuous communities. He then spoke of the many advantages in point of hygiene, sanitary regulations, hospital accommodations, etc., that had been conferred on the city of Boston through the efforts of its medical men, and said that the community paid its homage of admiration and gratitude to the profession, and extended to its medical guests the most cordial hospitality and expressions of good will.

Dr. A. T. CABOT welcomed the members and foreign guests in behalf of the Massachusetts State Medical Society, of which he was President. He spoke of the sanitary work being carried on by the physicians of the State, especially in the fight against tuberculosis. He suggested that preventive work in this direction might be done on a large scale by the Association, whose meetings here he was sure would be productive of a decided forward step in medical work.

Mayor JOHN F. FITZGERALD followed with greetings on behalf of the city. He referred to the previous meeting of the Association in Boston forty-one years ago. Since then much progress had been made in the healing art, and many brave and heroic contests had been waged by medical men against yellow fever, tuberculosis, and other scourges of mankind. He hoped the visitors to Boston would not fail to note what the city government was doing in the discharge of its share of the responsibility for the health of the people. It provided sanitary living conditions, a pure water supply, inspection of milk and vinegar, registration and quarantine of all contagious diseases, hygienic instruction in the public schools and public parks, gymnasia, playgrounds, and baths. He spoke of the distinguished men who had at one time or another been numbered with the faculty of the Harvard Medical School. He mentioned the work of the Massachusetts General, the Boston City, the Carney, and the Children's hospitals, and said there was yet to be erected a hospital for tuberculosis—a foe as insidious and implacable in Boston as the typhoid fever which scourged Philadelphia and Pittsburg. He promised a monument to any member of the medical profession who might discover the means of effectively checking the ravages of this great evil.

Dr. HERBERT L. BURRELL then made the report of the Committee of Arrangements.

Dr. MCMURTRY, the retiring president, introduced the president-elect, Dr. WILLIAM J. MAYO of Rochester, Minn., who at once delivered the

President's Address.—This was a discussion of the medical profession in this country as a unit, and of the problems, technical, ethical, and social, which confronted it. After briefly reviewing the present status of the American Medical Association, and congratulat-

ing its members on what had been accomplished by the organization, Dr. Mayo pointed out that the backing of an authoritative body of this sort would help the profession very much in fulfilling its sacred duty to the public in instituting sanitary reforms. New and fundamental truths had followed each other so rapidly that we had scarcely been able to digest them, and much less could we expect the public to have kept pace. The layman's view was that of twenty-five years ago. He accepted with avidity new dogmas and "pathys" based on theories incredibly foolish in the light of modern investigation, and we had allowed him to become fixed in these beliefs. We had permitted the public to be educated by "patent-medicine" advertisements and the voluble charlatanism of the commercially interested. In return we were classed with these schemers, and efforts for the general good were believed to be selfishly inspired. The Utopianism of our profession was too idealistic for ready comprehension in this commercial age. The time had come for the public to be taken into our confidence; if we wished better results, we must enlighten the people, for with them lay the final word. General sanitary matters of the greatest importance were becoming understood through medical influences. The public had been and was being educated in regard to the "great white plague," tuberculosis, and statistics were beginning to show the effect of this diffusion of knowledge. The good that had resulted from the education of the public in regard to the propagation of disease by mosquitos, and especially the necessity for quarantining patients with yellow fever or malaria, was already perceptible, and society must also be taught the early symptoms of cancer, the greatest foe of humanity, that its manifestations might be recognized while in the curable period. A propaganda of this kind, inaugurated by the profession of Germany, had borne fruit. The typhoid fever question was then discussed, and the culpability of municipalities that failed properly to safeguard their water supplies was dwelt on. The crusade against patent medicines was commended. Dr. Mayo then said that one of the few misfortunes of the individual freedom afforded by a republican form of government was that it enabled the most ignorant man, through prejudice, to interfere with and delay needed legislation, with the result that, by the time the law could be passed, the immediate object to be obtained had often disappeared. In Germany compulsory vaccination had practically caused smallpox to disappear from the army and country, a person properly protected being immune. In the State of Minnesota inability to enforce vaccination in the late smallpox epidemic permitted, from a few sources, 27,876 persons to become infected with this disorder; all due to a small but vociferous band of anti-vaccination agitators. Contagious disease in any place was not a matter of local or state interest alone, as the ease and freedom of transportation rendered local control impracticable and properly placed it in the hands of the general government. The keenness with which the American people were watching the affairs at Panama argued well for the future. The communication of Dr. Charles A. L. Reed awakened public interest. His portrayal of red tape and obstruction to sanitation in the Canal Zone had resulted in obtaining for that most able army medical officer, Colonel Gorgas, power to carry out the necessary reforms, and had made the Canal Zone the most sanitary place in Latin America.

In considering the matter of military and naval sanitation Dr. Mayo pointed to the successful methods of the Japanese medical corps in the recent war as an illustration of what could be effected in this direction if proper support were given to the medical authorities. Our own army and navy medical departments had worked intelligently against overwhelming odds. Their individual members had international reputations honestly achieved. Their schools for the special training of their men were in the highest degree efficient and deserving of every praise; but the departments had been so small as to be unable to act even as nuclei about which in time of war competent forces could be gathered and the militia of our country entered into conflict fearfully handicapped. The indications, however, were that these matters would now be rectified, and if so it would guarantee to the patriotic American that should he again be called on to serve his country his enemies would be in front and that he would not be destroyed by his own side through neglect of sanitary laws. The United States Public Health and Marine-Hospital Service had been and was doing splendid work in sanitation. Its skilled investigators had revolutionized quarantine measures and had placed preventive medicine on a solid basis. Their powers should be extended so that such unnecessary outbreaks as occurred in New Orleans should not be repeated. They should be given control of national quarantine in all its phases.

Dr. Mayo then took up the subject of medical education, state licensure, and reciprocity. What was needed, he said, was a higher standard of requirements and more and better supervision of professional schools. The Council on Medical Education was working hard and was now in a position not only to show what should be done, but to initiate needed reforms. No more important work had ever been taken up by the profession. At the present time medical education was uncontrolled and each State had its own standard of requirements. We could not rid ourselves of dogmas and "pathys" until we could secure a universal primary law as to the minimum amount of knowledge on fundamental branches. To accomplish this the American Medical Association must cooperate with and encourage medical colleges to do better work. The profession owed it to itself to investigate in some manner what the schools were doing and to make it known whether or not they fulfilled their obligations to the student. No well-conducted college could object to such reasonable supervision. Another question of great importance was that of reciprocity in medical license. The conditions now were well-nigh intolerable and restrained the individual freedom guaranteed by the Constitution. The boundaries between states were imaginary lines; yet a physician on one side of a border could not relieve human suffering on the opposite side without becoming amenable to the law or subjecting himself to vexatious examinations which he had already successfully passed in his own State. This must be met and speedily by agreement between examining boards as to the minimum of requirements. After all, this was but a part of the educational problem. If we could solve this, licensing boards could at once adopt more uniform examinations and reciprocity.

In considering some of the abuses from which the medical profession suffered Dr. Mayo spoke first of the matter of life insurance examinations. It was a matter of professional pride that, in the general condemnation of the life insurance companies, although every other part of the control had been shown to be corrupt, no breath of scandal had touched the medical department. Yet the local examiner had the most cause of all to be dissatisfied, owing to the reduction that had been made in the fees for examinations. The general officers of some companies had taken great credit on themselves for voluntarily reducing their salaries 20 per cent., and it was a rank injustice that the one body of men who had emerged clean from the insurance scandals should suffer the most for the crimes of others. A thorough medical examination to

prevent fraud by the admission of unsafe risks was essential. With few exceptions the line companies paid a fair fee, and less should not be accepted. The casualty companies were the worst offenders, and some concerted action should be taken to compel them to mend their evil ways. Lodge practice was another scheme by which officers of an association drew salaries ostensibly to give medical services at a figure below the possible point at which a professional man can live and continue his education. The people were badly served, as competent physicians could not be secured to do the work, and the whole scheme was properly condemned by the various medical associations all over the country.

Hospital abuse by patients who were able to pay, through the neglect and indifference of the trustees, was prevalent, and thereby the profession was robbed of just returns for labor and the funds of charitable persons were misused to an extent which was almost beyond belief. All hospitals should have competent individuals whose business it was to see that no one secured free treatment who was able to pay. It was a misfortune that the large majority of hospitals had no physicians among their directors. Hospital management was often extravagant and wasteful, due to official influence in furnishing comfortable berths for incompetent relatives or unfortunate friends in some salaried executive position. Fortunately the list of grievances was not large, and Dr. Mayo believed that they could be harmoniously adjusted if taken up with the proper authorities in a conciliatory spirit. Our first object must be to see that no poor person should be subjected to the slightest inconvenience or annoyance, and that every worthy charity should have our united support; but we must look to it that the charitable practitioner's time, knowledge, and skill should not be misused.

In speaking of the practice of medicine as a business Dr. Mayo said that one of the demoralizing tendencies in this commercial age was the money standard of success. Physicians were not called or chosen; accident or environment brought about their choice of profession. While professional life broadened the mental horizon and increased sympathy, it could not change man's nature, and men who were unfair in business affairs were to be found in the profession. The one crying evil, which fortunately was not widespread, was the giving of commissions—in other words, the selling of the confidence which the patient has in his practitioner—to some specialist who will divide the fee in return for reference of the case. The one secretly takes money from the patient without his consent, and the other, in order to complete the bargain, charges more than he should. This was equally harmful to the one who received and to the one who gave. Some attempts had been made to justify it, but the very fact that it was secret showed that both parties were ashamed to have it known and was an acknowledgment of its moral obliquity.

Dr. Mayo then urged the establishment of a better and more ethical relationship between the physician and the pharmacist and deprecated dispensing by the former and counter-prescribing by the latter. Finally, he spoke of the necessity for continued study and efforts at self-improvement for all physicians, and emphasized the desirability of frequent trips for the purpose of observation of the work of others. In conclusion he made a plea for unity of spirit and purpose in the profession, saying that the vital need of the medical profession was a harmonious organization—an organization that would encourage right thinking and good usage among ourselves, help to secure needed medical reforms, compel redress of grievances, and promote and encourage the highest interests of its individual members; and in this lay the future usefulness of our profession as a whole.

Evening Session—Tuesday, June 5.

The second general session was held in Jordan Hall at 7.30 P. M. It was occupied by the delivery of two of the general addresses.

Oration on Medicine.—Dr. Frederick C. Shattuck of Boston, Mass., delivered this address, taking as his title "How Progress Comes in Medicine." He began by saying that during the past year there had been no very conspicuous advance in medicine. Advance there had been, of course, but it had been all along the line, rather than in any one direction. He proposed, therefore, to attempt roughly to sketch some features of the progress of medicine in the past, its irregularity, apparent lack of logical sequence, dependence on the progress of science (knowledge) as a whole, the way in which advance along a very narrow line might lead to advance along the whole front. He said that we might compare the whole body of scientific workers to an army determined to enter into and possess the empire of ignorance, a country of vast extent, and presenting every conceivable physical difficulty to advance and occupation. As organized to-day, we might distinguish six army corps—anatomy, physiology, chemistry, physics, pathology, clinical history. The speaker then traced the development of the study of gross anatomy, which he said was about as well, though not so widely, known three hundred years ago as to-day. The contributions of Harvey, Malpighi, Leeuwenhock, Bichat, Hooke, Schleiden, Schwann, Wolff, and Virchow were noted, and their significance in the upbuilding of the science noted. In reference to the nervous system, Dr. Shattuck said that in the past hundred years the anatomy of the central nervous system had not been illuminated by anatomists. The microscope showed that the gray matter was composed mainly of cells, the white of fibers. No mere anatomic study could possibly have differentiated the function of gray and white matter, the anterior and posterior nerve-roots, the motor and sensory nerves running in a common cable. Charles Bell, the surgeon, by vivisection, made a great step in physiology and thus advanced anatomy. Marshall Hall, the physician, and Johannes Mueller, the physiologist, again made a further advance in explaining reflex action and its mechanism. Waller, the physiologist, taught us the lesson of the degeneration of nerve fibers separated from their centers. Anatomy never could have taught us the great lesson of cerebral localization, nor could animal experimentation or physiology alone. The starting point came from the clinician, who, through careful comparison of the experiments of disease on the human being during life and after death, pointed out the way for physiological experiment to follow. Critical clinical study first, pathological anatomy second, physiology third, anatomy fourth; structure and function, function and structure; indissoluby bound together; advance in one must lead to advance in the other. Chemistry was passed over lightly by the speaker, and then the development of pathological anatomy was outlined. Morgagni might be regarded as the founder of pathological anatomy, John Hunter of its greater outgrowth—pathology. Pathological anatomy, however, remained sterile until wedded to clinical observation. Laennec was the high priest who officiated at this alliance. Borrowing percussion from Corvisart, who ressurrected it from the grave of Auenbrugger, and, with the aid of physics, developing immediate auscultation, he compared the signs of thoracic disease in life in the ward with the changes wrought by it after death, and in ten years performed one of the most stupendous feats in medicine, putting the recognition of cardiac and

pulmonary disease in the living at a level from which it had advanced little for sixty-odd years, when the physicist with his *x*-rays made a good advance. Not only so, but Laennec's conception of tuberculosis in the lungs was far more true than that to which a too exclusively anatomic point of view led Virchow, whose great authority again led astray Buhl, Niemeyer, and a host of pathologists and clinicians. Louis followed close on Laennec and enforced the lesson of the value of method and accuracy in the study of disease. It was he who inspired the young American pupils to separate typhus and typhoid fever. Neither pathological anatomy nor clinical study alone sufficed; in conjunction they succeeded. The power to distinguish between the two diseases clinically had done much to bring about the practical extinction of the contagious typhus. Later developments had been the discoveries in the fields of malaria, trichiniasis, Texas cattle fever, sleeping sickness, tsetse fly disease, relapsing fever, etc., and these were some of the triumphs in the application of bacteriology to medicine. Bacteriology was brought into being by the conjunction of the perfected microscope; the chemist Pasteur, who gave the death-blow to the doctrine of spontaneous generation; another chemist, Hoffman, who made his own fortune and then promoted the welfare of humanity by his discovery of the aniline dyes, which enable us to see and distinguish organisms many of which are otherwise invisible or unrecognizable; and the physician, Koch, whose solid media on plates so greatly facilitated the isolation and perpetuation of pure cultures of this and that organism. Cut out any one of these four links, and we should not be where we were. Laennec's conception of the unity of tuberculosis of the lungs was confirmed, and it was proved that lupus and scrofula, which the great Hebra suggested to be manifestations of syphilis in the second or third generation, was tuberculous in nature. Smallpox, appendicitis, pancreatitis, anesthesia, and myxedema were taken as examples of other conditions in which progress had been particularly striking. In this connection Dr. Shattuck said that the tendency of the present day was too much toward the limitation of the term scientific medicine to that part of investigation carried on either apart from hospitals or by men not directly dealing with the sick. The work of the clinician might be every whit as scientific as that of his laboratory brother. The purely laboratory man had the advantage that he could inaugurate, systematize, and govern his experiments, most of which must be on animals. The clinician had the advantage that the experiments performed for him by disease were on human beings, and were oftentimes of such a nature as could not possibly be made artificially. On the other hand, the clinician was apt to find his time and strength so drawn on by individuals clamorous for relief that his highest work suffered. Before turning aside from the work of the clinician, the speaker mentioned one other advance which had been made and several riddles which still confronted us. In the index of Watson's Practice, a book not read to-day as much as it should be, American edition of 1872, neuritis was found only as optic neuritis. James Jackson had recognized paralysis due to alcohol. Buzzard popularized the knowledge that the trouble was seated in the peripheral nerves in these cases, and that alcohol was only one of many toxic agents liable to cause this result. How easy it was to-day to recognize multiple neuritis, usually to determine its cause in any given case; but there were just as many cases of it fifty years ago as there were to-day. Jaundice was formerly a disease. It was now a symptom only. Rheumatism we now recognized as a tangled skein, the threads of which we were just beginning to unravel. We were dissatisfied with diabetes as a final diagnosis, and were groping for light which might enable us to differentiate the causes of sugar as we had those of bile in the blood and the tissues. We suspected an infection behind purpura. We spoke of purpura simplex and purpura hemorrhagica. We knew that there were many infections which, when intense, were liable to cause hemorrhage. Our ignorance was dense as to the part played in any case by individual peculiarity, as well as to other features of many cases of purpura. Physics had contributed the Roentgen rays to the armamentarium of the physician, as also such means of diagnosis as were involved in the ophthalmoscope and other methods for illuminating the cavities of the body. The debt of medicine to all those half-truths which were too indiscriminately classed under the terms quackery or charlatanism, was real and should be recognized. We believed homeopathy to rest on assumptions unfounded in fact, untenable to-day. The most bigoted of us, however—for there was a bigotry of science as well as of religion—could not deny that homeopathy had advanced medicine, leading to a clearer knowledge of the limitation of the therapeutic action of drugs, of their uses and abuses. The power of suggestion, the influence of mind over body, whether exercised through hypnotism, mind cure, faith cure, Christian science, what you will, threw a flood of light on physiology and pathology, stimulated the study of experimental psychology, illuminated the influence of the nervous system on the circulation, and thus on nutrition. An eminent orthopedist recently classed the natural bone setters, so-called, as forerunners of science, at a time when ignorance as to the action of trauma and disease on joints was profound. They, relying on common sense and observation alone, achieved results which science, timid from knowledge of its ignorance, failed to achieve. There was always a germ of truth in every form of irregular (unscientific) healing—a fact which it behooved us to recognize and be ready to apply. In conclusion, Dr. Shattuck said that he had tried to illustrate from the history of the past the apparently inconsequent advance of knowledge, the correlation of the sciences, the way in which a fact seemingly perhaps unimportant was always potentially fruitful, often bearing fruit of a totally unexpected kind, it might be after many days. In a positive sense we knew more than our predecessors; in a relative sense we might be said to know less. The farther we advanced into the empire of ignorance, the larger we found it to be, each mountain peak showing higher peaks in the distance.

Oration on Surgery.—Dr. Joseph D. Bryant of New York delivered this address, taking as his title "The Nature and Progress of Malignant Disease." After expressing his sense of appreciation of the honor conferred in inviting him to address the American Medical Association on this topic he prefaced his discussion of the subject by stating that in the course of his address he would use the terms malignant disease and cancer in the general sense, since only a general idea of its nature and progress could be considered in the comparatively short time allotted for the purpose. He then began by saying that cancer was a general and not a local variety of disease. The field of its activity was quite as extensive as was the world itself. The vertebrate order of creatures was more or less afflicted with cancer throughout the entire classified series. The highest vertebrate orders of life suffered from cancer more than did all other orders combined. The civilized and the domesticated classes of higher rank suffered more from this form of infliction than did those of lower rank, or of the natural state. Man everywhere paid distinctive vital tribute to this disease; not, however, in equal proportions, but in accordance with the standard of the civilization of which he was a part. The higher the standard the greater was the contri-

bution to malignant fate; the humbler and more natural the standard the less onerous was the demand. The rulers of mighty nations and the humblest human factors of savage existence, each in their respective ratios, succumbed to the mysterious lethal influences of cancer. Also fish and flesh, staple articles of food of man, each in a varying measure, were the abode of malignant action, and more especially was the latter class thus affected. The fish of pure streams and ponds and those of salty habitations were in no small degree the subjects of cancer. The genteel trout and the beneficent cod were examples of this fact, respectively. Even the invertebrate oyster in one instance was widely reported to have yielded to malignant change, though in this instance the growth was really a benign one and not a cancer as was at first supposed. Dr. Bryant then spoke of the modern efforts to discover the true nature of cancer, and mentioned the various governmental and other commissions that were investigating the subject in this country and in Europe. In this connection, he stated, it was not amiss to heed the fact that experimentally and practically the transmission of cancer from man to animals or from one animal to another of different species had not yet been successfully witnessed beyond gainsay, notwithstanding the repeated attempts to attain the purpose and the results of long critical observation. On the contrary, the apparent transmission of cancer between animals of like species and its unquestionable extension by metastasis in those already afflicted was of common knowledge. The vegetable kingdom suffered at times and in isolated places from a form of local progressive disease apparently akin in nature to the malignant characteristics of the animal economy. In fact, the realization that these peculiar vegetable afflictions were caused by a parasite in many instances prompted the renewed suggestion on the part of Hutchinson that growths of similar appearance in man might later be found to depend on the presence of parasites. Since that time, more especially during the last fifteen years, the contention in this respect between the supporters of the parasitic and nonparasitic ideas regarding this disease has been continuous and spirited, and as yet without a generally satisfactory conclusion. The occurrence of cancer among the ancients and its description by the early physicians was then reviewed and the history of the disease traced up to comparatively modern times when John Hunter recognized the influence of trauma as a causative factor. From the period of Virchow's earlier researches to the present day, theories regarding the nature of cancer had multiplied to a bewildering extent. The two extremes at present were the following: (1) That cancer, like many other morbid processes, was due to a microorganism; (2) that cancer represented a morbid proliferation of certain normal cellular elements as the result of diminished inhibitory action. The development of the parasitic theory of cancer was then outlined as well as the geographical distribution of the disease. In speaking of the apparently increased morbidity from this cause noted of late, Dr. Bryant said that the undoubted increase in human longevity of recent time added many, indeed, to the list of those who from augmented years fell within the age limit of cancer attack, and thus apparently increased the spread because of a seeming greater morbid activity. And, too, it should not be forgotten that many from without sought harbor in a city for the relief which its hospitals and extended experience afforded, some of whom, unfortunately, added their sad contribution to the city's death rate from cancer. On the other hand, the life-saving means now employed in defending and rescuing the young from the baneful onset of infectious disease, was increasing the number of the living, and, therefore, neutralizing proportionately the apparent increase in death from cancer. After giving some statistics relative to the occurrence of the different forms of cancer the speaker said that while it had long been conceded that external influences, traumatic and otherwise, contributed to the frequency of accessible cancer in a greater or less degree, it was also self-evident that other and more potent agencies than these must be invoked to account not only for the occurrence of inaccessible cancer, but also for its great preponderance over those accessibly located at all periods of life, more especially the dominant one, that above 25 years of age. The increase in cancer visitation, in connection with advancing years, had long been a matter of common knowledge. But that the location of cancer, at all times of life and especially in adult life, should be of inaccessible, rather than of accessible nature, was more than remarkable. It was even startling, suggesting in no common tone the idea that, directly or indirectly, subtler influences than external traumatism or infecting agents could exercise were active in the development and spread of cancer. The possibility of the entry of the causative factor through the gastrointestinal tract was considered, and it was stated that there was no good reason to believe that the question of food had great importance in this connection. In dealing with the outlook for the future in the treatment of cancer the speaker emphasized the necessity for early surgical intervention. He believed that the outcome of operative endeavor in malignant cases had well-nigh reached the highest possible success, unless aided by increased faith and lessened secretiveness on the part of the sufferers from a malignant infliction. Since it now appeared that cancer was located most often in the deep internal parts, beyond the safe limits of unaided sight and mere touch (inaccessible cancer) two and one-half times more frequently than was accessible cancer, regardless of age or sex, then, indeed, was the fact doubly impressed, of the necessity for prompt acknowledgment of the presence of morbid manifestations and prompt determination of their nature. The handicap imposed by inaccessible cases because of their greater distance from the surface, often enabled the disease to advance undiscovered to a degree forbidding operative action when their presence was finally known. In too many instances of cancer, especially the inaccessible kind, the reasonable suspicions of its presence on the part of the patient or friends were quieted by the soothing platitudes of medical advice, until all opportunity of relief was at an end. The physician and the surgeon should join in the observation and treatment of all such cases as these, early fostering a mutual plan of action that contemplated prompt explorative investigation in doubtful instances, and forbade delay in those of undoubted character. The necessity for educating the laity in regard to the evidences of beginning malignant disease, and also for maintaining careful supervision of patients once operated on in order to guard against relapses was pointed out. In conclusion Dr. Bryant said that the public must be warned against falling into the hands of quacks, and surgeons themselves should avoid substituting new, untried methods of treatment for established operative procedures.

Second Day—Wednesday, June 6.

The third general meeting of the Association was held in Jordan Hall, Wednesday evening, to listen to the address on State Medicine of Dr. William H. Sanders of Montgomery, Ala.

President's Reception.—After the general meeting on Wednesday night a reception was tendered by the medical

men of New England to the President of the American Medical Association. It was attended by immense numbers, though the rule was enforced that no one not wearing an official badge should be admitted. Over 4,000 members were at the meeting, and as many guests. All these attended, besides those invited from the city.

HOUSE OF DELEGATES.

First Day—Monday, June 4.

The meeting was called to order by Dr. Lewis S. McMurtry of Louisville, Ky. Dr. McMurtry said that this was the third time in its history that the American Medical Association had met in Boston. The previous meetings were held in 1849 and 1865. The present meeting promised to be the largest and most enthusiastic in the history of the Association, and it seemed only proper that the historic old town of Boston, so revered by all the country, should be the scene of a record session. The speaker said that undoubtedly one of the most important features of the present session was the coming of members from a united profession in New York State. That this reunion had been accomplished with unanimity and perfect harmony was a triumph of professional dignity. He said that one of the important things which must engage the attention of the House of Delegates was the subject of the discussion of proprietary medicines now occupying so much attention. The discussion had been precipitated by the decision of the Council of Pharmacy and Chemistry to exclude from the *Journal of the American Medical Association* advertisements of all remedies the makers of which did not furnish an accurate formula of their components. Much had been said in the rather acrimonious discussion of this subject of the existence of a ring or clique said to be intrenched within the Association, but Dr. McMurtry assured the House of Delegates that, so far as he, as President of the Association, knew, there was no such thing as ring or clique. There was no officer or board or committee which was not directly created by the House of Delegates and responsible to them.

Report of the Secretary.—Dr. George H. Simmons of Chicago then read the secretary's report. Last year on June 1, 1905, there were 19,285 members of the association. Down to May 1, 1906, the names of 5,559 were added to the list of members, 1,208 names were dropped, 171 because of death, 619 because of resignation. The net gain was, for eleven months, 4,351 members. The total membership May 1, 1906, was 23,636.

Report of the Board of Trustees.—Dr. T. J. Happel of Tennessee presented the report of the Board of Trustees. He announced a surplus in the treasury, deducting $10,000 of indebtedness, of over $236,000. The annual income of the association amounted to about $275,000. The annual expenses to approximately $250,000. The net surplus each year above all expenses was about $25,000.

Report on Medical Legislation.—Dr. C. A. L. Reed of Cincinnati, O., then presented the report of the committee on medical legislation. He said that the past year had been an extremely busy one, the committee having to do with legislation with regard to: 1. A Department of Public Health, with Representation in the Cabinet. 2. The Army Medical Reorganization Bill. 3. The Pure Food and Drug Bill. 4. Amendment of the Lunacy Laws of the District of Columbia. 5. Governmental Regulation of Indigent Consumptives. 6. Antinostrum Crusade. 7. Government Recognition of the Services of Dr. James Carroll. 8. Regulation of Medical Practice in the Government Reservation of Hot Springs. 9. Bill for the Relief of the Widow of the Late Surgeon-General Wm. A. Hammond. 10. Bill to Restore the Canteen in the Army. 11. Bill Regulating the Treatment of Inebriates in the District of Columbia. 12. The Postoffice Attitude Toward Nostrums.

The National Legislative Council.—Dr. Reed declared that this was a feature of legislative organization of the American Medical Association that deserved every possible encouragement. Many do not realize its possibilities for good, but there is scarcely any phase of medical life between the annual meetings that was of more importance or vital significance.

Bureau of Medical Legislation.—This represented a development of the organization of legislative effort for medical purposes that the committee considered should be once more brought to the attention of the House of Delegates.

Organization to Suppress Quackery.—The committee considered this as almost the most important function of the legislative committees of medical societies. It had been asked to take a prominent part in a movement whose sole object shall be to deal with the question of quackery as represented not only in the manufacture and purveying of poisonous or otherwise deleterious proprietary medicines, but in the dishonest representations that were made by unscrupulous advertisers.

Necessity for Legislative Committees.—This was emphasized by the conditions which had developed as the result of the investigation of the Chicago stockyards. There was need, it was said, of vigilant trained minds to appreciate the possibilities of abuse and bring about correction of evils that threaten health so nearly. The question, then, of proper compensation for those who give their time to such work as will bring legislative relief for these evils must be earnestly considered if the association would not abuse the privilege it has of taking the time of its members.

Reciprocity in Medical Practice.—Dr. W. L. Rodman of Philadelphia, Pa., said that reciprocity of licensure between the various States was the burning topic in the practice of medicine at the present day, and every one admitted that there were serious injustices worked in individual cases by the present confusion of State laws. The committee suggested that a council on Medical Education should be intrusted with the recognition of the attainments and the moral character of applicants to practise and that their recommendation should have weight with all State examining boards. Ten years of practice should be considered the equivalent of passage of an examination. Uniformity could only be brought about by the fusion of many elements in medical life. The examining boards, the association of medical colleges, and the State societies might work together for it. The outlook would be hopeful if a start were once made.

Second Day—Tuesday, June 5.

The House of Delegates was called to order by Dr. William J. Mayo, who had been installed as President of the Association at the first general session.

Walter Reed Monument Fund.—In the absence of Dr. Keen of Philadelphia, who was unable to be present, the report of the Dr. Walter Reed Monument Fund was read by Dr. Simmons. Nearly $20,000 had been actually collected and about $1,200 additional subscribed. Most of this had come from members of the medical profession. The commercial interests of the country, though so much benefited by the successful investigations of Dr. Reed, had done practically nothing in the matter of contributions to a monument that would properly commemorate what was, after all, one of the most distinctive advances in medicine of the last hundred years. The committee's report further commented on the fact that only $25 of the amount had come from Cuba, though that island had been rescued by Dr. Reed's work from its greatest plague—the one thing that had seemed to preclude the idea of its becoming the center of great commercial undertakings. The Southern States, though so favorably affected by Reed's discoveries, had not been much more generous, and scarcely more than $1,000 had come from that region. As having accomplished its work, the committee asked to be discharged, though it had been hoped originally that $25,000 would be collected.

Report of Organization Committee.—Dr. J. M. McCormack of Bowling Green, Ky., read the report of his

work as chairman of the Organization Committee. The most interesting phase of it had been the question of arousing public attention to medical questions. Another point toward which, in his capacity as professional organizer, he had been working was the establishment of courses of post-graduate study in medical societies. He had been greatly hampered in his work by the machinations of the makers of proprietary medicines.

Amendment to Constitution.—After having laid over for two years, having been further modified last year, this amendment to the constitution was adopted after some debate in which the danger of concentrating too much power in the hands of the Board of Trustees was pointed out. The amendment last year read: "If, after a place of session has been selected, it becomes apparent that satisfactory transportation rates cannot be secured, or the Association cannot be properly entertained and cared for, the Committee on Transportation and Place of Session be and are hereby authorized to change said place of session, but said change shall not be made later than three months preceding the date fixed for the annual session." To this the following modification was made: "The time and place of session may, however, be changed by the unanimous action of the Board of Trustees at any time prior to four months from the time selected for the meeting." By an amendment to the bylaws the Committee of Arrangements of the Place of Meeting remained at all times under the control of the Board of Trustees. The Board of Trustees shall have full control of all arrangements for the annual sessions and shall provide meeting places for the Association, the House of Delegates, and the various sections. It shall also have control of all exhibits. The Board of Trustees in their discretion may appoint a local committee of arrangements which shall be at all times under the control of the Board of Trustees. An amendment to the bylaws was passed empowering sections of the Association to elect a delegate and an alternate. Such delegates, as also those appointed from the Army and Navy and other commissioned medical services of the United States, to serve for but one year. A special amendment to the bylaws was passed, allowing commissioned medical officers of the United States Army and Navy and of the Marine Hospital Service to become members of the Association without the payment of the usual dues.

Scientific Exhibit Report.—Dr. F. B. Wynn of Indianapolis, Director of the Scientific Exhibit, made his report on the gradual development of this department of the annual meeting. It began in 1900, at Atlantic City, with a simple pathological exhibit. Now it had extended to a large exposition of most features of modern medicine. Its growth had brought about the establishment of medical museums in many State and county societies, and in general the collection of all sorts of interesting medical material, and undoubtedly had suggested the idea of the recent exhibit of the National Tuberculosis Association, which admittedly had accomplished so much good. Further popular exhibits of medical objects would help in the medical education of the masses and the general crusade against disease and the campaign for sanitary evolution.

Loving Cup from Board of Trustees.—Dr. T. J. Happel of Tennessee, chairman of the Board of Trustees, then presented to Dr. F. B. Wynn, for the trustees, a loving cup in recognition of the successful work he had done (even assuming the pecuniary obligations of the first exhibit until relieved of them by the trustees) in organizing this exhibit, which had now become one of the most interesting, instructive, and valuable features of the annual meeting of the Association. Dr. Wynn, in accepting, emphasized his disclaimer of deserving all the commendation for the success of the exhibit. He named many men in many cities without whose help it would have been impossible.

Amendment as to Roll Call of Delegates.—As the result of the report of the Committee on Reporting of Minutes, it was resolved that henceforth there would be a roll-call of the House of Delegates, attendance to be noted accurately in the minute book.

Vote of Thanks.— Dr. Phillip Mills Jones of San Francisco, Cal., offered a series of resolutions, all of which were adopted. A vote of thanks to Dr. George H. Simmons was the first clause and with its preamble included an indorsement of all the work he had done. A vote of thanks and indorsement of his work was also given to Dr. J. N. McCormack, the official organizer. It was resolved that the Trustees should henceforth be nominated orally in the House of Delegates and elected separately.

Independent Medical Journals.—The committee disclaimed any intention on the part of the National Association or on that of the State Societies to injure the independent medical journals owned or edited by physicians. These had in the past done excellent work for the development of medicine and the diffusion of the kowledge of medical advances. Many of them still continued to accomplish this valuable purpose. The House of Delegates then was asked to recommend to the support and patronage of the members of the American Medical Association such medical journals as did not receive unethical advertisements.

Fireproof Vault for Records.—The committee presented a resolution for the construction of a brick fireproof vault in the basement of the American Medical Association's building in Chicago for the preservation of all records of importance and especially of those relating to the licenses of physicians. Because of the neglect of such a precaution all records of medical license in San Francisco were lost, the records of the State Medical Society, of the County Medical Society, and even of the County Clerk having been destroyed. Fortunately all the data had been sent to Chicago for the Medical Directory of the Association and could now be recovered.

The American Medical Directory.—The work of making a medical directory of the county was approved and it was announced that it would not cost more to members than the actual expense involved in its publication. This might be large the first year, but subsequently would be less, though its value would grow from year to year.

The Pure Food Bill.—Dr. C. A. L. Reed, chairman of the Committee on Medical Legislation, introduced a preamble and resolutions which were unanimously adopted, calling upon Congress to place the pending pure-food and drug bill on its passage during the present week.

Insurance Fees.—Dr. J. N. M. McCormack of Bowling Green, Ky., introduced a resolution asking for the appointment of a committee to investigate the present situation as regards medical life insurance examiners' fees. The recent reduction in fees had been made without any due reason. The medical departments of the large life insurance companies had been the only ones unsmirched by the recent investigations, yet when the reform economies had been introduced the medical examiners had suffered the most. Certainly the former fee was not excessive.

Medical Libraries for San Francisco Physicians.—Dr. Frank Billings of Chicago introduced resolutions asking the cooperation of the American Medical Association in the provision of books for the physicians of San Francisco who had lost their all by the earthquake and fire.

The Army Medical Bill.—A resolution was introduced commending this bill, which had the approval of the President of the United States and of the Secretary of War, but which had been before Congress for two years without being acted upon. The bill would improve the medical service of the Army especially. The President of the American Medical Association was instructed to send a telegram to the speakers of the House of Representatives at Wash-

ington asking him in the name of the association to use his best efforts to secure the passage of the bill as soon as possible.

Relief Contribution for San Francisco Physicians.—A resolution was introduced and passed unanimously appropriating $5,000 for the needy physicians who suffered by the San Francisco earthquake and fire. This resolution was referred to the Board of Trustees. On motion after some discussion it was resolved that this fund should not be for distribution only to members of the American Medical Association in and around San Francisco, but to all physicians in good standing. Because of the fact that in some known instances at least physicians in other parts of California lost their all it was resolved to leave to the Board of Trustees as informed by the California State Medical Society the question of distributing this fund to physicians outside of San Francisco also wherever it was deemed advisable.

Remission of Annual Dues.—On motion of Dr. J. N. McCormack of Kentucky the annual dues of all members of the American Medical Association living in San Francisco were remitted for the next year. The same rule was to apply to sufferers from the earthquake in other parts of California. The whole matter was referred to the Board of Trustees for eventual decision, and the resolutions were to be considered as at most advisory, not imperative.

SECTION ON MEDICINE.

Dr. Herbert C. Moffitt of San Francisco, Cal., in the Chair.

First Day—Tuesday, June 5.

Some Clinical Observations in a Case of Acute Lymphatic Leukemia, Suggesting Infection as an Etiological Factor in the Disease.—Dr. Philip Marvel of Atlantic City read this paper. He said that the etiology of leukemia, notwithstanding the great progress made in recent years, still remained in doubt, but the morbid phenomena of acute infectious diseases had impressed him with the strong conviction of their resemblance to the clinical manifestations of the case of acute leukemia or lymphemia which he reported in very great detail, that he wanted to call attention to it. He first referred to the anatomy and physiology of the palatine or faucial tonsils, which were apparently the chief, if not the primary, points of attack in the case reported, and which bore a relational comparison to the cases to which reference was to be made. It was not without interest in this connection that reference was made to the coincidence that infections much more readily occurred in childhood and in early life than in advancing or mature age, which was equally true of leukemia, especially of the acute lymphatic form. It was very unfortunate that an autopsy was not obtainable. The special features to which he wished to draw attention were, first, the undefinable cause of the pain in the limb, being the first noticeable evidence of the disease; secondly, the slowly progressive anemia, coincident with menorrhagia; third, the acute attack of tonsillitis, and its relation to the subsequent enlargement of the lymphatic glands in the neck, face, axilla, and groin, with the thyroids, liver, and spleen; fourth, the absence of pathogenic change in the blood cells. Clinically supporting the diagnosis were the following observations: The rapidly progressing anemia, conspicuous preponderance of lymphocytes, general debility, pathogenic change in the lymphatic glands, enlargement of the spleen, liver, and thyroids, early appearance of petechia, ecchymotic or purpuric areas, hemorrhagic dyscrasia, gastrointestinal irritation, and associated with the latter part of the illness, profuse sweating. The clinical evidences pointing to infection in this case were strikingly similar to those recognized in scurry sepses and other accepted bacterial diseases. A review of the cases of acute leukemia, previously reported, showed a remarkably large percentage of tonsillitis, associated with the earlier symptoms of the disease, hitherto not considered important. If one followed closely recent studies in numerous systemic infections that had been the immediate evidences of a streptococcic tonsillitis, *e.g.* endocarditis, myocarditis, nephritis, articuloarthritis, peritonitis, appendicitis, and a variety of conditions, called rheumatism, etc., and these were occasioning no slight interest in the relationship, and which he believed did exist, between the streptococcic invasion of the palatine tonsils and the pathogenic involvements which followed, the inference was not without interest. Reasoning *a priori*, the foregoing, he said, would seem strongly supportive of the position taken, viz., that the acute streptococcic tonsillitis occurring as the earliest definite manifestation in this case, if not immediately causative, the streptococci or their toxins had much to do with the pathogenic change and subsequent behavior of the lymphatics and blood tissues, and incidentally with the serious metabolic disturbance, functional failures, and death which followed.

The Relation of Excessive Gastric Acidity to Gastric Symptoms.—Dr. J. Dutton Steele of Philadelphia read this paper. He said that his object in presenting this paper was to confirm Dr. Stockton's observations, and he proposed to go a step farther to show that excess of acid alone was not capable of producing the symptoms of gastric irritation seen in so-called hyperacidity. There must be some other condition present which rendered the gastric mucous membrane more sensitive than usual, so that it could not stand an amount of acid that would be easily tolerated if the mucous membrane was in a normal condition. In order to determine what produced this hyperesthesia of the gastric mucous membrane he presented an analysis of a series of thirty cases with symptoms of hyperacidity, which showed quite clearly that the irritation occurred, not only when the per cent. of the acid was high, but often when it was within the middle and lower grade. This would indicate that the mucous membrane was so hypersensitive that it was intolerant not only to high grades of acid, but often to middle or low grades. In about one-half of his cases the cause for the irritation and pain laid in the existence of decided gastric motor insufficiency or of hypersecretion. In his cases three had undoubted signs of alimentary hypersecretion. Ten cases had decided retention. In fourteen cases of his list no cause could be demonstrated for the hyperesthesia. In seven the acidity was of the higher grade and in the other seven of the lower and middle grades, including one case of achylia. In almost all the cases the gastric symptoms were directly connected with overworry or fatigue, or were the part of a general nervous irritability. In all the patients the gastric symptoms improved and finally disappeared under a treatment directed toward relieving the nervous strain and raising the level of nutrition without paying much attention to the conditions of the stomach. The result of the treatment, quite as much as anything else, would indicate that the hyperesthesia was a local manifestation of a general nervous irritability. That was, it was a sensory neurosis of the stomach. If what he said was true, namely, that the hyperesthesia rather than the acidity was the point of attack in our therapeutics, then considerable light was thrown upon the treatment of the condition. Dr. Steele then considered briefly the following three points in the treatment: the diet, the use of sedatives, of alkalies and of nux vomica. Regarded from the standpoint of the treatment of hyperesthesia of a nervous origin, a liberal and unirritative diet would be the most suitable; its liberality would improve nutrition, and in this way help general nervous irritability. All food should be given in such a form as to produce the least possible irritation. To relieve the pain the acid should be neutralized after the height of digestion, and this required the use of alkalies at about the time the pain would

appear. The various nervous sedatives had proven very useful in temporarily relieving the discomfort in these cases with irritative symptoms. In the rare cases of achylia with hyperacidity symptoms they were the only means of relief. The beneficial effects of nux vomica in spite of the apparent contraindication to its use in cases of hyperacidity symptoms, were perfectly explained when we considered that it was a sensory neurosis and not a temporary increase in gastric acidity that we were treating. His own experience had shown that nux vomica given as Musser suggested was an excellent remedy in those cases where one was attempting to remove a local neurosis by increasing the general nervous stability of the individual.

Dr. De Lancey Rochester of Buffalo emphasized the importance of making numerous examinations of the gastric contents and under different kinds of circumstances before coming to any definite conclusions as to the presence of superacidity. With regard to the motor insufficiency as a cause of the pain, he said it was not simply this but the attempt of the stomach to empty itself, producing a sort of colicky pain.

Dr. Charles G. Stockton of Buffalo said the subject of hyperesthesia in this connection was very important, and more of these cases were seen than those of hyperchlorhydria. The profession, too, should recognize the fact that sometimes symptoms may be made very acute merely from disturbances of the general nervous system, and which can be relieved by measures only of a general character.

Dr. H. A. Hare of Philadelphia said that the giving of drugs to relieve the pain in this condition was similar to the homeopathic form of treatment, not, of course, following the principle of *similia similibus curantur,* but characterized by an endeavor to treat the symptoms instead of the cause producing the symptoms. Most of the drugs recommended in many text-books for the relief of these cases were under the group of nerve sedatives. They not only did no good, but they did much harm in many instances. Many of these cases that had resisted treatment by drugs, diet, etc., had recovered by following out a plan of rest cure. It was again very important that an examination of the gastric contents should be made several times, at the identical same time of day, under the same identical circumstances, and by the same identical man, if definite results were to be gotten.

Dr. Smith of Boston said that if the hyperchlorhydria was due to a general neurosis this condition then should be treated.

Dr. Chas. N. Hughes of St. Louis spoke of the work of a man who wrote three-quarters of a century ago who anticipated some of the views that were now being offered in this country and abroad, and in this book the relation between the stomach and the brain was entered into further. A consideration of this would result in great value in the management of dyspepsia or apepsia.

Dr. John A. Witherspoon of Nashville, Tenn., believed that it was not only necessary to examine the stomach contents, but also to examine its size and its capacity for drainage; the essential part of the treatment in these cases was directed to drainage of the stomach.

Dr. Sippy of Chicago said that the complexity of symptoms commonly designated as hyperchlorhydria were often treated by the general practitioner, and he wished to call attention to the fact that pain was not a common symptom. There was complained of more a feeling of discomfort or fullness. When pain was present as a constant symptom it almost always meant the presence of an ulcer.

Dr. Max Einhorn of New York discussed the paper. Dr. Steele closed the discussion.

Post-Critical Fever and Other Sequelæ of Croupous Pneumonia.—Dr. James E. Talley of Philadelphia read this paper and said that a study of the last 325 cases at the Presbyterian Hospital formed the basis for the article. He said that almost naturally one thought of suppurative conditions somewhere as the commonest cause of the persistence of fever after the crisis in pneumonia, though apparently endocardial and pericardial inflammation was a close second. Among the suppurative cases they found five of empyema, one being interlobar, one encysted, and one genuine case of lung abscess which was large enough to be diagnosed antemortem. After relating the histories of many cases Dr. Talley said that the causes of post-critical fever in croupous pneumonia were evidently manifold, and the exact cause could only be determined in a given case by careful and repeated examinations of the patient. Even when such examinations were apparently negative, one should be slow in attributing the fever simply to delayed resolution or autolysis alone. The number of small abscesses found in the stage of gray hepatization, post-mortem, would incline him to believe that it was not alone the slow resolution, but perhaps more often a varying degree of this purulent tendency, especially in the stage of gray hepatization, that explained the fever. Though the abscesses were usually multiple, one case showed distinctly one small abscess which in itself might have caused the persistence of fever, and it was conceivable that such an abscess might discharge undetected or, surrounded by an encysting wall, gradually absorb and the case recover without the exact cause of the fever ever being known. Even an encysted empyema, if small, might be hard to demonstrate. The value of the *x*-ray in detecting these conditions in the chest were variable. It was the common experience of a thickened pleura in this class of cases that rendered the *x*-ray of less value. Given a previous consolidation without much thickening of the pleura, and the shadow was less uniformly dense than that of fluid in the pleura; so that under such circumstances a loculated empyema or a full abscess cavity was apt to stand out by its dense shadow in contrast to the less homogeneous shadow of a resolving pneumonic consolidation. Under such circumstances an empty cavity was even more evident, surrounded as it usually was by its wall. One case showed that an area of bronchiectasis with the bronchial tubes filled with secretion simulated an abscess. The mistake was all the more natural, as there existed above a well-defined cavity of an abscess that had discharged. It was doubtful if the number of endocardial or pericardial involvements in this series really represented the vast importance of the subject, and that which must be attached to this cause as the factor in many fatal cases. One must be alert for this complication, especially in those who have an old endarteritis or atheroma. The case detailed showed that the right side of the heart was by no means free from serious involvement. The development of a systolic murmur might be explained by the anemia well known after pneumonia or by the relative insufficiency due to a weakened heart muscle; but the development also of a diastolic murmur usually meant that there was genuine endocarditis, as proven by the autopsies.

Dr. De Lancey Rochester of Buffalo, Dr. N. S. Davis of Chicago, Dr. Lichty of Pittsburg, Dr. Alexander Lambert of New York, and Dr. LeRoy of Nashville, discussed the paper.

A Case of Colon Bacillus Septicemia.—Dr. DeLancey Rochester of Buffalo, reported in minute detail this case. The patient had a septicemia due to an organism belonging to the *Bacillus coli* group. This organism in the beginning did not have the characteristics of the *Bacillus coli communis,* but under subsequent cultivation developed them. The organs and tissues had the gross lesions of septicemia.

Proprietary Medicines and Their Abuses.—Dr. George Dock of Ann Arbor, Mich., read this paper. In discussing some of the remedies proposed for the present abuses he said that one was the exclusion of advertisements of proprietary remedies, at least those of unknown composition, from medical journals, and there were some good reasons why this view should receive consideration. A scientific periodical journal certainly made a more pleasing impression when it was

free from all advertising. Merely keeping such advertisements out of the journals would, however, not stop the nuisance, for the same matter, or more, would be forced upon us in other ways. Nor would the exclusion of such matter from journals be a likely aid to the morals of those who now fell victims to the wiles of the advertiser. It would hardly be expected that physicians would abandon the reading of journals with advertisements of nostrums, but if the goods advertised were not bought the obnoxious pages would soon disappear. It would seem possible to exclude the most exaggerated or obviously baseless claims, but even this was not so easy as might seem at first glance. A decided gain would come from a freer criticism of all kinds in our medical literature. A fear of frankness seemed to bind upon all; much depended upon trade affiliations, but it seemed to spread beyond them. The best proprietary remedies would continue to be made and advertised; all sorts of claims would be made for them, and the profession could not directly stop those things, even though they thought it desirable to do so. They could, however, learn how to use better than they did now well-known remedies, and in that way lessen the use of the others. Although they could not draw a sharp line between unprincipled time-serving or the affectation of ultra-modernity, they could at least express their opinions of crude experimentation. They could look as coolly upon new drugs as they did upon a new phase of mental healing or a new application of massage. If this were done, production would be less rapid, the vogue of each novelty shorter, the possible virtues of some more quickly determined. He asked how the profession could be brought to a better attitude as regarded the present evil. What was needed was (1) broader and deeper training in preliminary and biological branches, and the cultivation of exact habits of mind; (2) a more intense study of pathology, not merely to acquire anatomical data, but to learn the actual results and extent of the lesions in common diseases, so that the student might offset speculation with fact; (3) a more intimate study of clinical medicine, that could come only from more prolonged and more personal investigation at the bedside. Dr. Dock summed up by stating that proprietary medicines were increasing as the result of natural developments. Their abuses sprang partly from the exaggeration of legitimate commercial methods, partly from the credulity of the medical profession. The remedy for the latter was wholly in ourselves, and he asked that all do what they could to overcome this at least.

The Physician's Responsibility in the Nostrum Evil.—Dr. Richard C. Cabot of Boston considered this phase of the question.

Dr. W. S. Thayer of Baltimore, Dr. H. A. Hare of Philadelphia, Dr. McClellan of Chicago, Dr. S. Solis-Cohen of Philadelphia, Dr. Hutchinson of Arrowhead Springs, Cal., Dr. Francien of Philadelphia, Dr. LeRoy of Nashville, Tenn., discussed the paper.

Drs. Dock and Cabot closed the discussion.

Indications and Contraindications to the Use of the X-Rays in Medical Cases.—Dr. D. L. Edsall of Philadelphia considered this topic.

Drs. Brown and Price discussed it.

Second Day—Wednesday, June 6.

The meeting this day was a joint session with the Section on Pathology.

Some Observations on the Effect of the Withdrawal of Fluid from the Thorax on the Blood Pressure.—Dr. Joseph A. Capps of Chicago read this paper. He said pleural exudates were often under a positive pressure of 5 to 26 mm. during expiration, and that this positive pressure acted in direct opposition to the normal intrathoracic negative pressure impeding the flow of the venous blood from the abdomen into the thorax when the exudate was large. An effort was then made (by the respiratory muscles) to restore the negative pressure within the chest; deep inspiration increased the intrathoracic negative pressure to such an extent that compensation, or partial compensation that the venous flow was maintained. If such compensation failed, the right heart received an insufficient amount of blood; the left heart did not fill the body arteries, the blood-pressure sunk rapidly and death became imminent. The withdrawal of fluid from the pleural cavity was attended with less danger than its introduction or accumulation. Unfavorable symptoms usually came on suddenly, so that any sign that would warn of the approaching danger would be of great benefit, and the observations were made with that view. In his observations of 15 cases of pleural effusion, four of which were tapped twice, he took the blood pressure at short intervals before, during, and after thoracentesis, in each of which aspiration had been used. The blood charts exhibited widely varying features, but there were some constant features, as follows: during the excitement of preparation and pain of puncture, a temporary rise in temperature; during withdrawal of fluid, pressure fell and reached the lowest point at the time of or subsequent to the removal of the needle, the average fall in the 19 aspirations being 20 mm.; pressure taken an hour or two afterward was usually 5 to 15 mm. lower than the initial pressure, the average fall in the 19 being over 8 mm. Some special influences had also been noted, as follows; the amount of fluid withdrawn was an important factor in determining the degree of the fall; the rapidity of the withdrawal was no less important, other things being equal, slow aspiration causing less fall than rapid; the duration of the effusion was of greatest importance, and in the recent cases the fall was not great and the recovery was rapid; in long-standing cases the fall was greater; senile changes in blood-vessels and heart seemed to favor rapid and deep fall with slow recovery, however; heart disease alone appeared to have little effect, neither did pneumothorax appreciably affect the blood pressure; up to a certain point arterial pressure increased with increase in pressure of intraabdominal fluid; beyond this it fell, and this fall was regarded as of the nature of a temporary collapse, due to sudden relaxation of the splanchnic vessels. The rate of withdrawal of the fluid was found of more importance than the amount withdrawn, though the final pressure was more affected by the amount. Pressure externally on the abdominal wall at end of drainage raised pressure 5 to 20 mm. Cases which underwent a marked fall during operation showed the most marked improvement.

Chronic Nontuberculous Affections of the Lung.—Dr. Sherman G. Bonney of Denver read this paper. He said that bronchitis and bronchiectasis, while strictly excluded by the subject, almost invariably coexisted with emphysema, chronic interstitial pneumonia, pneumonokoniosis, and nontuberculous bacterial infections, the clinical manifestations of which were reviewed in his paper. The chief interest attached to the study of nontuberculous pulmonary conditions related to their simulation of consumption, so that a clearer differentiation would be of value. Cases indigenous to Colorado were such as exhibited morbid changes developed as a result of local conditions. So-called miners' phthisis was difficult of dissociation from consumption, as it presented the rational symptoms of tuberculosis, even to frequent pulmonary hemorrhages, and occasionally showed the presence of the tubercle bacilli. In these cases the author said that bacilli appearing only after long observation were not to be considered an etiological factor of importance, as the terminal infection had merely been engrafted upon a soil previously made receptive. The actual morbid processes consisted of chronic bronchi-

tis, emphysema, bronchiectasis, pneumonokoniosis, with occasional cavity formations resulting from anemic necrosis and other causes. Such cases developed in the mining districts (of Colorado) almost exclusively. Predisposing causes were long hours underground, breathing atmosphere devoid of oxygen, extreme dampness, exhalations from the candles, smoke resulting from the blasting, the constrained position, frequent wetting of the feet, alcoholic habits, immoderate exercise at high altitudes, and unhygienic surroundings when not at work. The distinguishing feature being the chronic bronchitis and emphysema and bronchiectasis, the development of which was due to the frequent paroxysmal cough, weakening of the bronchial walls from emphysema, and pressure exerted by stagnating secretions. Corresponding to fibrous tissue proliferation of interstitial pneumonia, bronchiectatic cavities developed; through the ulceration of the mucous membrane these might be transformed into genuine pulmonary cavities, or they might develop by reason of necrotic softening of the tissues, in which event they were more likely to increase in size and had wider bearing on the course, especially if communicating with a bronchial tube. Secondarily to these changes were marked circulatory changes manifested by venous engorgement and enlargement of the right heart. Symptoms which arose from this group of chronic disturbances were of gradual development, relating chiefly to dyspnea, cough, and expectoration, loss of weight and strength, and cyanosis. The physical signs upon inspection consisted of dyspnea; capillary dilatation upon chest in front, changes in configuration of thorax commonly ascribed to emphysema, sometimes unilateral or bilaetral retraction of the apices. Upon palpation the signs were signs of partial consolidation, usually at apices, moist râles, fine and medium sized, unilateral dullness; cavity signs in almost any portion of the lung, exactly as in tuberculosis. The prognosis was regarded as almost invariably unfavorable. The essential diagnostic feature was the differentiation from pulmonary tuberculosis. Another class of cases observed were those designated as "imported cases," being the cases sent to Colorado under a diagnosis of tuberculosis. Chronic influenza was mentioned as being capable of exhibiting all the rational symptoms of tuberculosis. In cases under treatment where there was absence of tubercle bacilli the amelioration of symptoms had been disproportionate to the required periods for corresponding improvement in similar cases showing the tubercle bacilli.

The Treatment of Pleurisy with Effusion.—Dr. F. Forchheimer of Cincinnati read this paper. He said a number of explanations had been offered to show how serous effusion was removed by nature, the oldest being that of absorption, either by blood-vessels or lymphatics. The mechanism was merely a "lymphatic pump," but when there was a great effusion lymphatic absorption was entirely suspended, because expiration could not take place. The author regarded it as more likely, however, that the compression of the lung was the predetermining factor. This intrapleural pressure had been found to be as great as 40 mm. of mercury. If these explanations were accepted, it would then appear that absorption was arrested by inflammatory processes deposited upon the endothelial layer; also by intrapleural pressure. Absorption by the pleura, being diminished by exudative processes, the inflammation of the pleura itself must be reduced, for which the present treatment consisted of the use of the ice bag, local hydrotherapy, rest in bed, strapping the affected side, counterirritation. The second indication mentioned was the loosening of the intrapleural pressure by the removal of the fluid. General and local treatments had been employed; the general aiming to modify the blood structure in such a way that absorption took place, for which purpose use was made of cathartics, diuretics, diaphoretics, diet, and the milk cure, but the local treatment was preferred by the author as fully covering and meeting the indications, and of the two local methods, counterirritation and emptying the fluid, the latter was declared the most successful and practicable. The author believed that the fluid should not be allowed to remain in the cavity until the development of dangerous symptoms, or even to collect, because of the danger of the formation of adhesions, and because a man having a pleuritic effusion was not to be considered as in a good condition, as dangerous symptoms might develop at any time. Proper precautions were necessary. The aspirator should at first contain air, and the attempt should not be made to withdraw all the fluid at one sitting. No more should be withdrawn than necessary to relieve the symptoms, as natural absorption would then take place. Patients should be in as nearly a recumbent position as possible and the patient should be watched during the operation, and if there was violent and spasmodic coughing, constriction, faintness, and pain the operation should be suspended for a while. In chronic serous effusion a different condition was present, and accordingly somewhat different methods, suitable for the relief of that condition, would be required. In empyema the treatment differed in principle from the treatment of serous effusion. The treatment was a purely surgical one, and the indication would be the opening and draining of the abscess. Of course some of the cases recovered where aspiration was the only treatment, but the proportion of recoveries had been small, and it would be impossible to say just which case would get well. The earlier the abscess was opened, the less would be the mortality. Difficulty arose at times in getting the abscess to heal up. When the adhesions covering the lung were removed, it expanded, so that even a rigid walled abscess could be made to heal up.

Dr. J. C. Wilson of Philadelphia said that he heartily indorsed the appeal that had been made in the papers for an early removal of the pleuritic effusion because the effusion was to be regarded as a foreign body interfering with the mechanical functioning of the thoracic organs, and was liable to become a focus for the production of toxins.

Dr. J. N. Hall of Denver called especial attention to the points brought out by Dr. Bonney, stating that there were many factors not usually mentioned in the text books. These men worked from two to two and a half miles above sea-level, and lived in camps one or two thousand feet below the mines. They developed hearts of a weight out of proportion to the body weight; they also increased in lung power. Emphasis was laid again upon the remarks of Dr. Bonney as to the predisposing causes.

Cytology and Pleural Effusion.—Dr. Percy Musgrave of Boston read this paper. He said the following cells had been observed in pleural fluids: lymphocytes, polynuclear leucocytes, mononuclear leucocytes, eosinophiles, mast cells, endothelial cells, free and in clumps, or so-called plaques, red blood corpuscles, nucleated red blood corpuscles, masses of both sarcoma and carcinoma cells. Cells found in common in the blood and in pleural fluids differed in that the latter might have undergone degeneration. The white corpuscles as a rule had undergone a shrinkage, which was true in a lesser degree of the polynuclear leucocytes. The technique of the examination was described as consisting merely of the withdrawal of the fluid under aseptic conditions, which was centrifugalized for five or ten minutes. A loop of this mixture would be placed on a cover slip and allowed to dry, and then stained. The author believed that many of the differences as to the value of cytodiagnosis were due to careless technique. The author believed the method of value, and when the cytological findings were contrary to clinical findings, the cytological findings were confirmed at autopsy.

Bacteriology of Pleural Effusions.—Dr. L. W. Ladd of Cleveland, Ohio, read this paper. He said that an analysis of the cases reported in his paper would show that many of the cases, and in fact most of them, where effusions (pleural) occurred were tuberculous, though not all; that there seemed to be a tendency in the

tuberculous pleurisies to develop on the left side with greater frequency than on the right, which was also true of tuberculous empyema; that it was not always possible to demonstrate the organisms in the effusion; in pleural effusions develop acute lobar pneumonia, the organisms were discovered the oftener the diagnosis was made.

SECTION ON OBSTETRICS AND GYNECOLOGY.

DR. C. S. BACON OF CHICAGO IN THE CHAIR.

First Day—Tuesday, June 5, 1906.

The Legal Responsibility of the Physician for the Child in Utero.—Dr. C. S. BACON of Chicago, Chairman of the Section, delivered an address with this title. He called attention to the fact that physicians, as well as other biologists, regarded the child in the womb as no less a human being than after its expulsion. Its lack of some of the functions of the child *ex utero* did not disprove this statement. The legal status of the child *in utero*, however, did not conform to its biological status. He emphasized the fact that no one had a right to take the life of the child *in utero* unless for the protection of the mother, as provided by law in some States. It appeared that in most States the law made no difference between the child twenty-four hours old, for example, or in the non-viable stage, and the child about to be born, or in the viable stage. According to the ancient English common law, upon which our law was founded, the embryo or fetus before the term of quickening had no legal rights whatever, no offense being committed by its destruction. The child was supposed to exist only after it moved in the uterus. This was the common law until shortly before the separation of the Colonies from the mother country, now superseded by statutes passed by various States. Some States still provided more serious punishment for the destruction of the fetus after viability. If the mother died as a result of abortion, the one who performed the act was a murderer; if she died as the result of the use of drugs or instruments prescribed by another, the one so prescribing was guilty of manslaughter. It was not within the province of the paper to discuss the relative value of the mother's and child's life. In some States the statutes required that the advice of two physicians be secured in order to produce an abortion, and it was always necessary to show that the condition of the mother required an abortion. Nearly all physicians acknowledged that embryotomy must at times be resorted to. The indications for destructive operations had gradually narrowed. The legal responsibility of the physician was comparatively simple—if he believe that a sacrifice of the child's life was necessary to save that of the mother he was justified in operating, though he should always have consultation. Many operations would be legal that would be morally wrong.

Fibroid Tumors of the Uterus; A Study of 2,274 Consecutive Cases, Including Also a Study of 3,544 Myomata Uteri in Their Relation to Cancer of that Organ.—Dr. CHARLES P. NOBLE of Philadelphia read this paper, in which he gave a mass of statistics, from his own experience and that of others, to show that the percentage of deaths resulting from necrosis, sarcoma and carcinoma is far greater than that resulting from operation for the removal of fibroids. He had become early convinced that the classical teaching concerning fibroids was erroneous. As early as 1894 experience taught him that 30 per cent. would die if the tumors were not removed. As early as 1891 he had become convinced that the presence of fibroids acted as the cause of the development of carcinoma in the body of the uterus. The true way to estimate the gravity of fibroids was to study their morbid anatomy in consecutive cases, as well as their secondary effects on the the uterus was more often associated with fibroids than fibroids had a causal relation to the development of cancer, particularly cancer of the body of the uterus. Malignant disease more frequently resulted from the presence of fibroids that was usually believed. Relatively to its frequency adenocarcinoma of the body of the uterus was more often associated with fibroids than was epithelioma of the cervix. Some fibroids had undergone atrophy after the menopause but he was not familiar with a single authentic case in which a fibroid had entirely disappeared. It was very well known that the dangers arising from fibroid tumors were greater after the menopause than in a woman under forty years of age, which fact was emphasized by Bland-Sutton. The mortality of the operation for removal of fibroid tumors was greatly improved. Deaver, in 105 cases, had 3 deaths, and he himself, in 133 cases, had had one death. The type of tumors in which removal was debatable was small tumors, not growing and producing few symptoms, a question which must be decided in the future.

Dr. MASSEY of Philadelphia said that all the conditions enumerated in the paper as the possible outcome of the presence of fibroids should be diagnosticated before the patient be subjected to the dangers of operation. He thought medical men in dealing with life and death should be most careful to look on all sides of the subject.

Dr. HERMAN J. BOLDT of New York thought the gravity of the condition should be estimated by the symptoms presented by the individual in the particular case under observation. He did not advocate operating because it was known that certain things might happen, but because the woman had symptoms which interfered with her life. The fact that many women with fibromata had malignant degeneration he believed to be purely a matter of coincidence. He thought the mortality rate, taken case after case, would be considerably higher than that obtained by Kelly and Noble; it would be six or seven per cent. rather than one or two. The danger from embolism and thrombosis did not rest entirely with large tumors, but might be present with small tumors, and without as well as with operation.

Dr. CARSTENS of Detroit said the mental symptoms as well as the physical should be considered. If the knowledge of the presence of a tumor had a depressing effect upon the patient's mind, causing her to lose sleep and appetite and to become weak and nervous, the tumor should be removed, just as should one that, from constant bleeding, caused a woman to become weak and anemic and thus prone to take on pneumonia or almost any other disease.

Dr. GORDON of Portland, Ore., said he read a paper in 1884 before the American Gynecological Society in which he made the statement that if a woman came to him with a fibroid and he found that the symptoms of which she complained were due to the fibroid, unless she were a young woman and exceedingly desirous of having children, he would advise hysterectomy. He had no reason to change that opinion up to the present time. He believed the pendulum had swung too far in the direction of conservative surgery.

Dr. LAURENCE of Columbus, Ohio, deprecated conservatism is these cases. The same conservatism had to be gone through with with reference to appendicitis. He emphasized the point made by Dr. Carstens concerning the liability of a patient exsanguinated by a fibroid tumor to take on pneumonia and various other conditions. Surgery done as a *dernière resort* was bad surgery. The Apostoli method he heartily condemned.

Dr. MARCY of Boston said the way to cure a patient was to operate when it should be done and to do it in the scientific way in which it should be performed. He considered the Apostolli method a dangerous one. He advocated the early removal of uterine tumors and the restoration of the patient to the active walks of life.

Dr. ALFONS VON ROSTHORN of Heidelberg, Germany, said the conservatism of a few years ago had largely disappeared because of the better results obtained from modern

methods of operation. A small tumor, found perhaps by accident, might produce a series of symptoms strange to the small size of the tumor and to the locality in which it originated; on the other hand, cases might be met where the whole abdomen would be filled with myomata and yet such patients would go on for years without symptoms. He supposed that the teaching concerning the cessation of danger from fibromyomata with the appearance of the menopause had been abandoned.

Dr. A. DÜHRSSEN of Berlin, Germany, had found in his own experience that more cases of fibroid tumors died without than with operation. In a series of 200 cases of myoma he had observed that more cases died from anemia, sarcomatous degeneration, etc., than from operation. When early operation was advised the mortality was not more than 1 per cent., and he considered enucleation of a fibroid one of the most dangerous operations.

Dr. FREDERICK of Buffalo, N. Y., said from April, 1902, to the present time he had performed 177 operations for fibroids with a mortality of 2.6 per cent. He believed a fibroid tumor, if not malignant, was a malign disease because it went through the same growth, youth, adolescence, and decay, as the organism as a whole was subject to. All growths which dipped deep enough into the uterine wall, with blood supply enough to carry them on, showed a tendency to death.

Dr. HUMISTON of Cleveland, Ohio, said that up to five years ago he was so conservative that he had a mortality of 5 per cent.; since that time he had been an extremist and his mortality had been *nil*. He operated on all cases with symptoms.

Dr. REYNOLDS of Cleveland, Ohio, said he believed malignancy to be more common than statistics show. The mortality in moderate-sized fibroids not showing decided symptoms he believed to be less than 2 per cent. He emphasized the dangers of pregnancy in the presence of fibroids. He advocated hysterectomy in elderly and myomectomy in young women.

Dr. J. WESLEY BOVÉE of Washington, D. C., agreed with Dr. Noble in his deductions. Abortions were more common in persons with fibroids, and the dangers of pregnancy were increased. He would not hesitate about operating in a case of ovarian tumor, nor should one hesitate in early cancer of the cervix, even if it had given absolutely no symptoms.

Dr. Noble, in closing the discussion, gave further statistics upon which he based his deductions. He said that every time Dr. Boldt operated for ovarian cyst where the woman is not in immediate danger he violated the rule which he laid down for operating only in the presence of symptoms which warrant operation.

The Treatment of Tuberculosis of the Urinary Tract in Women.— Dr. EDGAR GARCEAU of Boston read this paper. He said the treatment of tuberculosis of the urinary tract in women had been much more satisfactory the last few years than heretofore. A better means of diagnosis had contributed to this end, as well as improved therapeusis. The vesical mucous membrane could now be treated locally with the greatest ease and accuracy by the employment of Kelly's cystoscope. Early cases of the disease were sometimes best treated by change of climate, which method of treatment should be tried first if the disease had not progressed too far. The local treatment of vesical tuberculosis depended upon the stage of the disease. In those cases in which there was only vesical injection local treatment was intolerably painful and harmful. When, however, tubercles had begun to appear, especially if there were ulcers in the bladder, a great deal could be accomplished with corrosive sublimate and nitrate of silver. The corrosive sublimate should be employed as recommended by Guyon. At the same time hygiene, rest, etc., should be insisted upon. If ulcers were present they should be treated by applications of pure nitrate of silver, the applications being repeated once or twice a week as occasion demands. When the disease was well advanced there might be a secondary infection with numerous granulations and ulcers on the vesical surface. He recommended for such cases cauterization of the whole bladder under ether. In the event of failure of this method cystotomy should be performed. The Guyon treatment should be resumed after healing of the fistula in the latter method. He cited a case in which he had done cystotomy and the fistula remained open for two years, during which time Guyon's treatment was persistently carried out. Nephrectomy should not be advised in case of renal tuberculosis with extensive coexistent tuberculous infection elsewhere in the body. A tubercular ureter was best treated by complete incision down to the bladder. He reported two absolute cures in a list of eighteen cases.

The Formation of Vesicovaginorectal Fistula Combined with Closure of the Introitus Vaginæ for the Purpose of Overcoming Certain Forms of Urinary Incontinence.—Dr. REUBEN PETERSON of Ann Arbor, Mich., in this paper reported in detail the case of a woman who had incontinence of urine and prolapse of bladder following the radical removal of a suspicious malignant growth of the urethra. Formation of a vesicovaginorectal fistula and closure of the urethra and introitus gave relief from incontinence. The rectum served the purpose of a bladder, the patient being able to hold urine for a number of hours. There was no irritation of rectum, vagina, or bladder, and careful microscopical examination of the urine failed to show any ascending renal infection, as would be expected by the experimental work of Frank, the author, and others. There would be no ascending renal infection where the vesical orifices were retained, no matter by what method the vesicorectal anastomosis be made.

Dr. NOBLE of Philadelphia said he thought tuberculosis of the urinary tract in woman far more curable than Dr. Garceau reported from his experience. In sixteen or seventeen cases of tuberculosis of the kidney which he had treated all the patients recovered from the operation and were perfectly well at present. Treatment of tuberculosis of the bladder resolved itself into whether it is primary infection or secondary infection of the kidney. He long ago gave up all methods of early diagnosis except securing the urine from each ureter by means of the ureteral catheter and injecting this into guinea-pigs. The study of the tubercle bacilli was misleading because if a negative report were rendered one would not know but that the bacilli were present, and a positive report might mean that the smegma bacillus was mistaken for the tubercle bacillus.

Dr. BOVÉE of Washington said the results as suggested by Dr. Noble, were largely dependent upon whether the disease was localized in those organs or whether it was not, and affections of the bladder disappeared if the kidney and ureter were removed. In cases where the kidney was removed and the ureter not the latter subsequently had to be removed.

Success: The Surgical Desideratum.—Dr. A. ERNEST GALLANT of New York City read this paper, summarizing as fololws the factors which, in appropriate cases, helped to bring about surgical success: (1) A most careful consideration of antenatal and postnatal diseases, and the chronicity or acuteness of the present condition before deciding to operate or not to operate. (2) The liberal use of water by mouth and rectum, before, during, and after operation. The free application of tincture of green soap, rubbed into the skin until dry when preparing the field of operation and the hands of the operator and assistant. (3) Minimum morphine, before anesthesia; the ether administered by the patient herself, in the first stage; care that the head is properly elevated; and a minimum quantity of ether employed. (4) A reasonably short incision, a reasonably quick operation, and a reasonable number of sutures to close the wound. (5) After operation the careful prevention of chilling the body; the cautious use of morphine and sedatives; lavage to allay undue

vomiting; and colonic massage and kneading for relief of distressing intestinal distention. Continuous rectal irrigation for tympany. (6) For the invigoration of the tired patient, and to prevent muscular atrophy and cardiac weakness, general massage daily, with passive and active movements while in bed and calisthenics when first about. (7) For the prevention of hernia and enteroptosis or support of prolapsed organs we apply the abdominal "stock," Rose's plaster bandage or a special corset, put on while the patient is in the dorsal-inclined posture.

Dr. ROSENTHAL of Ft. Wayne, Ind., said he always made it the practice to wash out the stomach under profound anesthesia after surgical operations. The vomiting was thus lessened, there was no complaint of thirst, and the patient was more comfortable generally.

(To be continued.)

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

AT a stated meeting held April 12, Dr. H. E. RADASCH exhibited specimens of "Well-shaped Erythrocytes." Dr. W. M. L. COPLIN exhibited "Unusual Forms of Pseudonucleated Erythrocytes in the Thyroid Gland from a Case of Acute Strumitis." Dr. E. M. L'ENGLE exhibited "A Cystic Tumor of the Mesentery." The globular mass, as large as a tangerine, was removed with a portion of the bowel and was found to be a thick-walled cyst, containing matter of buttery consistency, in which were found crystals of leucin and tyrosin. Hooklets were looked for, but not discovered. In the discussion it was suggested that the cyst might be of chylous origin. Dr. G. E. PRICE exhibited microscopic sections of normal neurofibrils, also neurofibrils from a case of pernicious anemia, and neurofibrils from a case of hydrophobia. Dr. DAVID RIESMAN exhibited "Carcinomatous Tissue Passed by Bowel in a Case of Carcinoma of the Colon." The patient was a woman who had passed blood from the bowel, and in whom a tumor in the sigmoid flexure of the colon was palpable through the vagina. Operation was undertaken and the mass removed, but recurrence took place with metastasis, and the patient died eighteen months later, under most unhappy conditions. Toward the last it was necessary to administer as much as 13 grains of morphine daily. This afforded only the smallest measure of relief, and the patient took little nourishment besides. The masses passed by the bowel were as large as English walnuts. They were found to be adenocarcinomata. Dr. W. J. FUNKE read a paper entitled "Etiology of Cholelithiasis; Bacteriological Study of 102 Calculi." Bacteria were found in a considerable number of the calculi, especially in the more recent and softer ones. The formation of the stones is to be attributed to stagnation of the bile in the presence of bacteria capable of causing precipitation of the chemical constituents of the secretion. Dr. WILLIAM G. SPILLER presented a communication entitled "Muscle-fibers in a Tumor within the Spinal Dura." The patient was a man presenting weakness in the lower extremities, with increased reflexes, and loss of control of the sphincters. After death the prostate gland was found the seat of a malignant growth, with metastatis to the cerebral dura, while in the conus medullaris was found a small formation containing muscle-tissue and supposed to be a fetal inclusion or similar congenital structure. Dr. WILLIAM PEPPER presented a communication entitled "A Probable Case of Infection with the Fasciolipsis Buski." The patient was a man who had always lived in the city, and examination of whose blood disclosed the existence of a considerable eosinophilia—from 21 to 33 per cent. Careful examination of the stools disclosed the presence of ova that corresponded in their dimensions most nearly with those of the Fasciolipsis Buski, but it was not possible to discover the parent fluke in the discharges, although large doses of thymol were administered on several occasions.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 2, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	351	179
Diphtheria	347	57
Measles	931	38
Scarlet Fever	192	18
Smallpox	10	3
Varicella	85	1
Typhoid Fever	25	6
Whooping Cough	49	6
Cerebrospinal Meningitis	22	17
Malarial Fever	.....	.....
Totals	2,012	325

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending June 2, 1906:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
California, Los Angeles	May 12–19	6	..
Colorado, General	Apr. 1–30	10	..
Florida, General	May 19–26	2	..
Illinois, Galesburg	May 19–26	1	..
Kentucky, Covington	May 19–26	1	..

NEURONS AND NEUROFIBRILS.

A BRIEF REVIEW OF THE PRESENT TEACHINGS.

By JOSEPH COLLINS, M.D.,

NEW YORK,

PROFESSOR OF NEUROLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL,

AND G. EDWIN ZABRISKIE, M.D.,

NEW YORK,

INSTRUCTOR IN NEUROLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Ten years ago the "Neuron theory," *i. e.* the theory that the nervous system was made up of a collection of anatomical and genetic nerve entities or units constituted of cell, fiber and terminal ramifications, having no connection save by contiguity, was generally accepted. In 1891, Waldeyer, the Berlin anatomist, set forth the idea of the neuron based largely upon the conception of Gerlach and Deiters and upon work that had been done by means of the Golgi and Cajal methods of staining, which, as is well known, reveal particularly the outlines of nerve cells. He maintained that nerve fibers are collections of axis cylinders which emerge directly from nerve cells, that there is no relationship to a fiber network at the point of origin, and that all nerve fibers end free in terminal ramifications without anastomosis or network formation of any kind. The neuron theory seemed entirely to harmonize with the cell theory, and the application of it to the problems of neuropathology seemed to divest many of them, particularly the systemic and combined systemic diseases, of their obscurities. In short, it appeared to harmonize so well with physiological, histological, and pathological teachings that it soon became almost universally accepted. It is not our purpose to call particular attention to the wide application of the neuron theory, to clinical medicine and to psychology, nor to the fact that in some instances it has been carried to an absurd degree.

Gradually in latter years an increasing interest has developed in the histology and microchemistry of the nervous system; and with this has come from many workers in these fields a decided opposition to the neuron theory so that to-day it is in the strict sense partially or wholly rejected by many of the most trustworthy workers in the fields of neurohistology and biology. Apathy, Bethe, Nissl, and others have sought to establish that the fibrils of nerve cells form a continuous system, without beginning, without end, like the vascular system, binding one cell body with another and thus uniting the neurons between them. Without in any sense holding a brief for those who oppose the neuron theory, we propose briefly to review some of the more important evidence that now exists to show that the nervous system is not made up of a collection of units, of invariable constitution with free endings, having no connection with one another save by contiguity, and to attempt a judgment of the evidence thus reviewed.

The temporal evolution of our knowledge of the nervous system falls into periods. The work that was done from 1835 to 1885—fifty years—and the work that has been done since 1885—twenty years.

After the discovery of the nerve cells by the zoologist Ehrenberg, and the study of them by Valentin, Purkinje, Wagner, and others, it was demonstrated by Deiters that nerve cells were made up of a cell-body and prolongations, protoplasmic and axis-cylinder prolongations, unlike in structure and behavior; the former being of the same constitution as the cell split up soon after their origin and terminate not far from the cell. The latter, of much more compact structure, were directly continuous, Deiters maintained, as nerve-fibers.

When Remak depicted axis-cylinders, or, as he called them, the "primitive bundles," he described them as finely-striated structures, but not distinctly fibrillated as did Fromann in 1864. The latter depicted fine fibrillary striations in the cells of the anterior horns and in their protoplasmic prolongations, especially distinct in the latter. The opinion generally held at that time by anatomists was that axis-cylinders or "primitive bundles" were homogenous in structure and that their peripheral terminations, at least in case of muscle plates, were in ends external to or beneath the sarcolemma.

In 1859 Lionel S. Beale, Professor of Physiology and Pathology in King's College, London (whose death was recently announced), published an article in the Philosophical Transactions (1860, page 611) in which he maintained that complete nerve circuits existed, *i.e.* that there was no free ending of nerve fibers anywhere. Nerve fibers, he said, passing to a muscle, divide into a vast number of exceedingly fine pale granular fibers which ramify upon the external surface of the sarcolemma, connected with which fibers at certain intervals are oval nuclei; and these fine fibers, after an extensive, and in many cases very circuitous course, join with other fibers to form dark bordered fibers which at length pass toward the nervous center either in the same bundle as the dark bordered fibers passing toward the muscles, or in other bundles.

He prepared tissues for examination by soaking them in or injecting them with some highly refractive fluid such as simple syrup or glycerin to which a little chromic acid had been added. Beale did an enormous amount of work in support of his claims, published various articles, illustrating them with excellent drawings, and offered to demonstrate his specimens to anyone who would take the trouble to look at them. He concluded from his work upon the different tissues of the body that nerve fibers never end or terminate by free extremities, but that in all cases complete circuits exist and that the circuit is the fundamental origin of the nervous apparatus. In other words, his position was almost identical with that of those who hold to the neurofibril theory of to-day. Beale was treated

with scant courtesy by his contemporaries and apparently even that was accorded to him only because of personal friendship with some of the leading German anatomists. Kühne, Kölliker, Margó, and Engelmann all denied the accuracy of his diagrams and the reality of his descriptions, while some of the French anatomists, notably Rouget, essayed disdainfulness and superiority, saying: "It is easy to assure oneself that the description of Beale is wholly inexact and no time should be wasted upon it by the experienced and attentive observer." Time has shown that Beale was accurate to a degree that can scarcely be believed when one remembers that the only reagents that he worked with were syrup and glycerin. It is largely due to Joris, in his prize essay published by the Belgian Royal Academy of Medicine, "Nouvelles Recherches sur les Rapports Anatomiques des Neurones," that attention has been called to the remarkable work of Beale. In the hundreds of articles, monographs, and reviews that have been written on neurons and neurofibrils in the past ten years, Beale's name is not mentioned. For instance, Bethe, in the third chapter of his "Allgemeine Anatomie und Physiologie des Nervensystems," says that the fibrillary structure of the nerve cells and its prolongations received its first great impetus from Schultze. In reality Schultze confirmed the discoveries of Beale while demonstrating the existence of isolated nerve fibrils and showing that they were specific elements of the nervous tissue. His article formed a chapter in Stricker's Handbuch der Geweblehre, 1871, which, being the most popular text-book of histology in the German language, was widely read and became very generally known. On the other hand, Beale's articles were published in the *Philosophical Transactions,* a vehicle rarely encountered by German savants, it would seem, and in the *Archives of Medicine,* of which he was editor. His position as a teacher, his membership in the Royal Society, his repute as a master of microscopical technique, apparently did not help him to a serious hearing. That Beale was master of the situation, however, and that he believed firmly in his findings, can be proven to anyone who will take the trouble to read the article in the *Archives of Medicine,* Volume IV., 1863-1870, entitled "An Anatomical Controversy," in which he deals with those who sat in judgment upon him in a most masterful manner.*

There is no doubt whatsoever that Max Schultze extended Beale's ideas very materially, but Schultze had the advantage of examining cells of tissues that had been hardened in chrome salts, in iodized serum, and in osmic acid and bichromate of potash. Schultze showed that the "primitive bundles," as he called them, constituted the specific structural element of the nervous substance. He demonstrated the distinct fibrillary striations which are entirely independent and parallel both in the protoplasmic and in the axis-cylinder prolongations. He pointed out that the non-medullated fibers split up at the end so as to form a bush-like condition of the finest fibrils. In ganglion cells treated with iodized serum he was able to see the finest striations and to trace these striations through the entire cell from one side where they came in to the other side where they passed out through other prolongations. In other words, he showed to his own satisfaction that the fibrils did not originate in the body of the cell. These discoveries led him to the conclusion that the fibrils were the essential thing in the construction of the nervous system, and that ganglion cells were no more than stations for the fibrils, which stations served to make it possible for fibrils coursing in a prolongation to get into connection with many other prolongations and also with axis-cylinders. His idea was that the nerve fibers were simple fibrillary bundles, and he therefore divided them into two classes—naked fibrillary bundles and fibrillary bundles with medullary sheaths. Despite the fact that this line of investigation was pursued with much success by other investigators, and notably by Kupffer (who, by the way, Apathy states, was the real discoverer of the neurofibrils, Sitzungsber. d. Naturwissenschaft. Atlas d. Bayerisch Acad. d. Wissensch. Med., 1883, page 473), H. Schultze, Dogiel, Flemming, and many others, it was not until 1897 when Apathy made his contribution entitled "Das leitende Element des Nervensystems und seine Beziehungen zu den Zellen" (Mittheilungen der zoologischen Station, Neapel, Volume XII.), that neurofibrils began to have an important place in the literature of neurology and histology. In several communications dating back to 1883, he had pointed out the fundamental facts of his observations and conclusions, but these were published principally in the Hungarian language and were unnoticed. In the volume that appeared in 1897 the pen pictures and verbal descriptions were so distinct and comprehensive that at once the matter was given the attention which it demanded. He maintained that the neurofibril is the essential and specific constituent of the nervous system. He had studied in detail the nervous system of the leech by the aid of a method now well known which depicted the nerve fibrils with such distinctness that they could be followed from one end of the preparation to the other. These neurofibrils appeared as deep dark threads on a slightly tinged background, or, as Bethe says, like telegraph wires against a clear sky. On cross-section of sensory or motor fibers they appear as dark spots or small, somewhat spiral lines, indicative of their spiral course.

These neurofibrils were found wherever there was nerve organization, *i.e.* in nerve fibers, in ganglion cells, in sensory epithelial cells, in glandular cells, and in all these tissues they were sharply differentiated. There was no vagueness about their outline, they were well-defined, individual morphological elements and nowhere could an ending of one of the neurofibrils be found. Apathy believed the individuality of the neurofibril, the uninterrupted course, and the endlessness to be its most striking features. In end organs, such as muscle fibers, sensory epithelial cells, glandular cells, etc., the fibrils interlace so as to form networks. In ganglion cells they seem to terminate in a similar way. The majority of the fibrils which enter ganglion cells through the protoplasmic prolongations of unipolar cells or through the many prolongations of the multipolar cells, interlace in such a fashion as to form a very intricate network. A similar network formation is found in the neuropil (the nerve cell in contradistinction to the ganglion cell), here only network, the very fine network occupying the center of the cell, is made up of very many more fibrils. Conducting primitive fibrils pass into the interior of the

*In Vol. V. of the same journal will be found an unsigned article entitled "German Criticism and British Medical Science," undoubtedly from the pen of Dr. Beale, which throws an interesting side light upon the controversy: "It has been said that science is of no nationality. . . . Such dreams must be dispelled; Germany has spoken; the investigation of Nature's minutest and most delicate secrets is *her* prerogative only. Anatomical observations are made in Germany only, and it is not possible to discover any structure elsewhere. Other countries must expect and listen to the story of what she finds. To her alone belongs the right to discover! Nay, it is doubtful if light for microscopical illumination is to be obtained elsewhere."

ganglion cell, and just as many elementary fibers leave it after the "trellis" formation. Termination, dissolution in or connection with the cell nucleus the fibril does not have.

In this conception of Apathy, the neurofibrils either go toward centers and penetrate ganglion cells, or they go toward the periphery and ramify around muscle cells and penetrate sensory or secretory cells. In invertebrates Apathy demonstrated motor fibers which extend from the cell to the muscle to which they go, and sensory fibers very much thinner than the motor which pass into the "elementary trellis" and from there into the cell. Apathy divides the cells of the nervous system into two distinct classes—nerve cells and ganglion cells. The former are analogous to muscle cells; they produce the material that conducts, *i. e.* the material that produces fibrils.

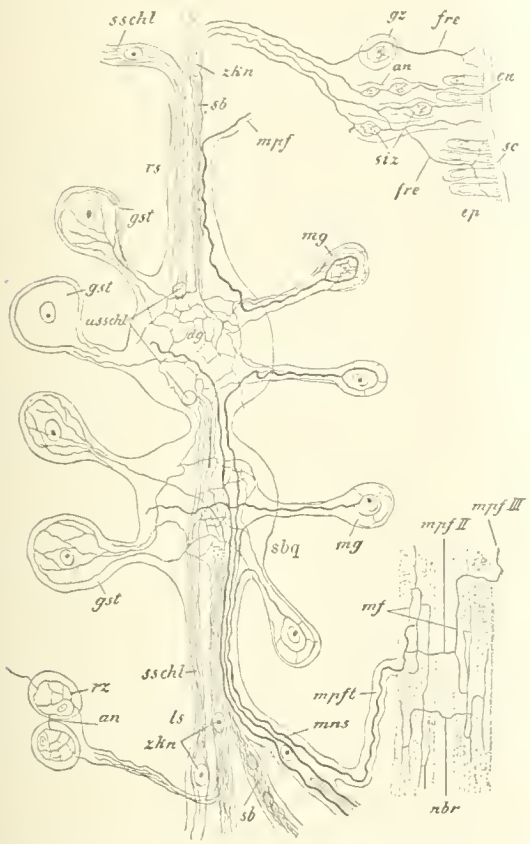

Fig. 1.—Apathy's Schema of course and communication of the conducting pathway in cross-section of a cornite of Hirudo. The two ganglion valves with motor *mg*, and sensory or merely connecting *gst* ganglion cells. The three kinds of nerve spindles or nerve fibers *sb*, *sschl*, *mns*, their arrangement in the center, distribution in the central mass of fibers and connections with the ganglion cells; their arrangement at the periphery: muscle fibers, epidermal and subepidermal sensory cells with their terminal branching in its epidermis (*fre*), *usschl* where a sensory tube *sbq*, where a sensory bundle curves into the central mass of fibers in a longitudinal direction, *mbe* conducting bridges between muscle fibers. We see from the upper right the perceptive sensory surface, the centripetal conducting febril path, which enters into the elementary gutter and thence in the ganglion cell and its mesh work. Thicker fibers which later become united in bundles as the motor nerves pass from the motor ganglion cells to muscle (lower right) and branch in the manner already described.—(From Hartmann, "*Die Neurofibrillenlehre.*")

The ganglion cells are interpolated in conductive paths like cells in an electric circuit; they produce that which is to be conducted. In ganglia these ganglion cells are arranged around the periphery and are of two kinds, large and small. Neurofibrils entering the large cells form at once an intramedullary network and from this network new fibrils detach themselves and go out through the same prolongation. Thus a prolongation conducts in two directions. Primitive fibrils may pass through a number of ganglion cells before they enter into the formation of networks. In the prolongation of the small cells there is to be found an individual fiber which is characterized by its considerable volume; this is the motor fiber. All fibrils coming out from ganglion cells enter the formation of a common network occupying the center of the ganglion. This common network is the "elementar gitter" of Apathy, or, as it may be translated, elementary trellis or screen. In some instances fibrils come directly from the cell without passing through this central network.

At the periphery of the body there is a very similar disposition of the nervous element. The neurofibril forms in the secretory cell an intracellular network, the branches of which, leaving the cell, anastomose with fibrils coming from neighboring cells to form intercellular networks.

In 1896 the teachings of Apathy were accepted by Bethe, who confirmed his findings in invertebrates by the use of other methods of investigation. Extending Apathy's conception, Bethe attempted to show that in the phylogenetic development of animal life, so-called plasmatic nerve-nets constitute the lowest method of connection of nerve cells. The fibrils of these plasmatic networks form only the intercellular trellis which constitutes the direct connection between the peripheral sensorium and the muscles. In the nervous system of all higher animals there occurs somewhere a mixture of the fibrils coming anywhere from the surface which make up the fibril trellises, and, according to Bethe, it is the position of this trellis which constitutes the difference between the different forms.

As we ascend in the scale of the vertebrates we find that the fibril gets more and more outside the cell, until finally it gets entirely out between the cells, so that, according to Bethe's view, within

Fig. 2.—Large multipolar cell from the reticular formation of the medulla of a rabbit (Cajal method).

cells fibrils merely pass through, having no more intimate relation than that caused by such passing. Either the fibril trellises remain near each other and have long pathways to receptory and effectory organs, or long pathways form between remote fibril trellises. Recent work done according to the methods of Cajal and Bielchowsky seems to corroborate in general Bethe's opinions, but it is difficult to obtain reliable information of the fibrils in central cells with these methods. Apathy maintains that there is an intercellular trellis formation in vertebrates. Hartmann (Die Neurofibrillenlehre, Braumüller,

Vienna and Leipsig, 1905) is inclined to accept this inasmuch as his preparations showed that a part of the fibrils which pass into many ganglion cells have a trellis formation which, in the large pyramidal cells, for example, lies near the basal part of the cell; in the smaller cells this takes up nearly the entire cell.

In addition, fibrils in variable numbers go from dendrite to dendrite and from axis-cylinder to dendrite through the cell without perceptible relation one to another.

Ansalone has pointed out (Contributo allo studio delle Neurofibrille nella midolla spinale dei vertebrati superiori, *Annali di Neurologia,* Ann. XXII., fasc. 3, 1904) that the neurofibrils of the cells in the spinal cord vary in appearance according to the region of the cell which is under inspection. The prolongations also present very variable pictures. In the peripheral portion of the cell there is no network in the proper sense of the term, the neurofibrils running in shape of thick cords from one pole of the cell to the other, without dividing or anastomosing. The cellular element is not at all differentiated from the surrounding tissue; and it stands in connection with fine fibrils which reach it in a direction nearly perpendicular to that of the neurofibrils. In the deeper regions of the cell the neurofibrils form a network, the communications of which with the nucleus vary according to the section plane of the cell. The fibrillary network may either cover the nucleus completely, presenting a greater condensation and a finer quality of work mesh at this level, or it may pass over it like a bridge in the form of more delicate threads. Again, it may be strictly limited to the nuclear outlines where it terminates.

Schaffer, who has recently published a paper on the subject (Recherches sur la structure dite fibrillaire de la cellule nerveuse, *Revue Neurologique,* No. 21, 1905) comes to somewhat different conclusions. The author investigated the finer fibrillary structure of the nerve cells in the spinal cord, the oblongata, and the pyramidal cells of the cortex and concluded that there are two systems of reticular structures in the nerve cells; first, a pericellular external network with thicker meshes at the periphery of the cell-body and in the protoplasmic processes, which is identical with Golgi's net; the beams of this network which represent a sort of cortical substance of the cell, form the meshwork of the cell process also, which become more plainly outlined in the presence of swelling from the general parallel arrangement of the fibrils. All the fibrils of the cell-body as well as the processes anastomose with each other and the fibrillary cellular structure is therefore really a pseudofibrillary structure of a reticular character, although presenting a parallel striped appearance in certain localities. Another net is formed by fine fibrils, which form a polygonal wide meshwork, by branching off from the crossbeams of the first net towards the interior. This internal reticular system appears denser around the nucleus; it also sends its prolongations into the protoplasmic processes. The internal and the external intracellular network stand in close connection with each other. The author finally observed extracellular fibrils which approach the cell-body in a Y-shaped oblique direction, or parallel to the pericellular network, blending with the cell-body. This Y-shaped branching of the fibrils he also considers with Bethe as sufficient proof of the existence of an endocellular network. Altogether, it does not seem to us that his evidence is sufficiently strong to support his claims, even though the evidence offered by others and that which we ourselves have seen would tend to support the view of independence of the axone fibrils from those in the dendrites.

Donnagio, working with an original method (Anatomia e fisiologia delle vie di conduzione endocellulari Atti del XII Congresso della Società freniatrica, Ital. in *Riv. sperim. di Fren.,* Volume 31, *T.* 1, 1905), concludes that "the existence of a network of fibrils in the ganglion cell, besides long fibrils which traverse the cell chiefly at the periphery, must be accepted as conclusively proven. It still remains doubtful whether or not these long fibrils anastomose with each other." Acording to structure, two types of ganglion cells may be distinguished: Cells containing only a network of fibers, and cells containing long fibrils in addition to a network. The axis-cylinder receives fibrils from the network principally.

Bethe also found by his method that ganglion cells of vertebrates are surrounded by close-meshed netform trellis which he calls the Golgi nets and which he believes is of nervous nature.

He has framed an hypothesis concerning the transmission of the nervous current from this network to the cell and to the dendrites. The dendrites, *i. e.* the protoplasmic processes, of the cells end blind. Probably the fibrils pass into Golgi nets and unite with the fibrils which proceed from the splitting up of the centripetal nerve fibrils to form network formations as in invertebrates.

Nissl agrees that the Golgi net is a new and important structural element of the nervous system, but he does not believe that the neurofibrils go out from the protoplasmic prolongations unchanged into the terminal endings of the centripetal medullated fibers. This Golgi network Bethe finds at the surface of all the cells of the central nervous system. In the cerebrum, cerebellum, Ammon's horn, and in the gelatinous substance it extends diffusely. In other regions such as the motor nuclei, the dentate nucleus, the olives, etc., it confines itself to the surface of the cell, but where two cells or two dendrites touch the Golgi network reaches from one directly to the other. It is limited to the gray matter. It does not seem to have any relationship to the vessels, the neuroglia, or the pia. But the nervous nature of this Golgi network, unfortunately for Bethe's theory, has not been proven. Cajal, Lugaro, Donnagio, Marinesco, and others maintain that this network represents nothing else than artificial coagulations of certain albuminoid substances in the interior of vessels. Nissl changes Bethe's hypothesis so that the neurofibrils of the cell border and in the terminal ramifications undergo a change which permits their colorability, a condition previously impossible. (See Fig. 2.)

Bethe's conclusion is that the nerve fibril is a multicellular formation in which the ganglion cells and the end organs are united by neurofibrils, the ganglion cells themselves being of slight functional value. The neurofibrils are the essential specific constituent of the nerves and they are the nerve substance in general. Engelmann's opinion that the axis-cylinder section of medullary substance and the nucleus of Schwann, situated between two nodes of Ranvier may be looked upon as a cell, it has been thought, has received corroboration from Bethe, who found, he maintains, that at Ranvier's nodes the fibrils alone pass through a sieve-like membrane. This, he thinks, fortifies the opinion that these constitute the confines of the cell. Retzius insists that at the above-mentioned places not only the neurofibrils but also the perifibrillary substance is seen to pass through, that the number of the neurofibrils

and also the perifibrillary substance is decreased; therefore a rarefaction of the entire substance of the axis-cylinder takes place at the nodes of Ranvier.

Nissl maintains that the complex called a neuron is not the sole nerve element. There are cellular elements which do not have their origin from ganglion cells, and there is a specific tissue of as yet unknown texture lying outside the cells, the so-called "nervous gray." This substance is of a fibrillary nature. According to him, dendrites as well as axis-cylinders terminate blind in this gray substance. Therefore, something must exist which is interpolated between the end of the axis-cylinder which is synonymous with the cessation of the medullary sheaths, and the Golgi nets and the nerve cells situated in the vicinity of the axis-cylinder termination. This is the nervous gray. He has never been able to demonstrate it, but he has attempted to show mathematically that this nervous substance must exist. He says that if the demonstrable cortical elements are added together a large portion of space remains unoccupied, but the work of Bielchowsky and Wolff on the cerebellum by the use of the former's silver method which impregnates neurofibrils and plasma with a remarkable clearness and which demonstrates the continuous transition of axis-cylinder fibrils and closely united peri- and intracellular nets, would tend to upset this.

The relationship existing between cell fibrils and axis-cylinder fibrils is still a matter that requires very great elucidation. Held and Wolff maintain that they have seen fibrils leave the terminations of the axis-cylinders and enter the body of ganglion cells, by means of Cajal's method and Bielchowsky's method respectively. Mahaim studied the nervous system of the cat, the crow, and the human subject, by the various Cajal methods. He did not in a single instance observe fibrils penetrating into the cell body. He is of the opinion that Wolff's reticulum is the result of faulty technique; this is not, however, true, for the relatively thick fibers which Held saw penetrating the cell. The author believes that this is an anatomical "semblance," for the experimental methods show by chromatolysis the marked difference existing between sections of axis-cylinders arising from a cellular nucleus, and sections of axis-cylinders penetrating into a nucleus. The relation between the pericellular terminations and the body of the cells cannot, therefore, be very intimate; and it may be stated that these terminations "are not a part of the cells." The author hopes that it will prove possible by means of appropriate experimental methods to observe degenerated pericellular masses surrounding an intact cellular body.

Bartels, studying the fibrillary structure of the ganglion cell layer of the retina by means of Bielchowsky's fibril method, maintains that he has succeeded in demonstrating the presence of fibrils which pass from a protoplasmic process through the cell and into the axis-cylinder process. He also observed other fibrils passing from one dendrite into the other, without traversing the cellular body itself. Finally fibrils were noted connecting the processes of different cells. On the other hand, Vermes (Ueber die Neurofibrillen der Retina, *Anat. Ang.*, Volume 26, Helft 22-23, 1905), who studied the retina of the horse, dog, rabbit, cat, guinea-pig, and also of the human subject by means of the Cajal and Bielchowsky fibrillary methods does not consider that the continuity of the neurofibrillary layer has been demonstrated. Ramon y Cajal (Trabajos del Laborator de investigacion biol. de la Universidad de Madrid, III., 4, dic. 1904) shows that the differentiation of the fibrils in the cells of the retina begin within the plasma zone from which the dendrites arise, and they begin with the beginning of function; they are begotten by function from the cell protoplasm.

The field in which the question of contact or continuity has been most hotly contested, however, is that of the terminal arborizations of axone at fibrils about the cells.

The recent investigations of Cajal, Bielchowsky, Holmgren, Michotte, and others, show that the neurofibrils appearing on the surface of the cell come in contact with it by means of bulbous formations known as the terminal buttons. Bielchowsky, Held, and Holmgren believe that the terminal buttons are fibril net-like structures and that the fibrils of the buttons pass into the interior of the cells. But the terminal buttons are in intimate relationship on the surface of the cell through anastomosing fibrils which form a close network. Bielchowsky holds that this formation is identical to that which Held calls the pericellular Golgi nets.

Cajal divides the terminal buttons, or terminal masses, as he calls them, which were discovered by

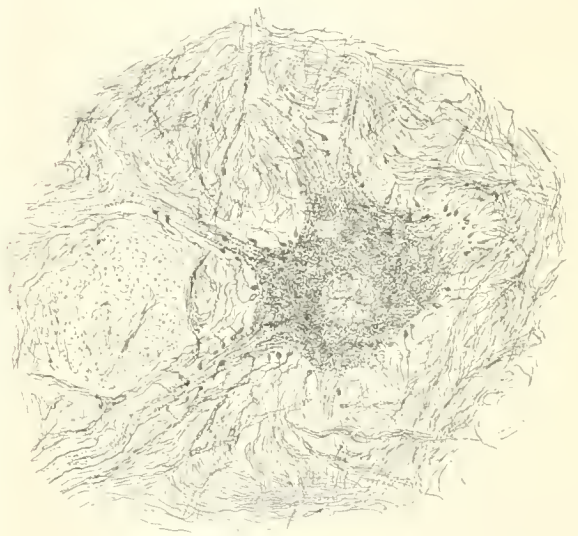

Fig. 3.—Multipolar cell with terminal buttons (Cajal method).

means of his method into two forms, the end club and the transition club. The former come from the vicinity of the cell in form of a fine thread which swells up as soon as it reaches the cell body and closely hugs the cell membrane or the dendrite with its basis. The transition form are fusiform thickenings of certain fibrils, which also become applied to the cell membrane. The end-clubs are found in large numbers at the cell body, sometimes giving it a mottled aspect like a tiger skin. They are never absent at the dendrites. Only isolated end-clubs occur at the root cone of the axis-cylinder. Van Gehuchten and Marinesco have corroborated (Boutons terminaux et reseau pericellulaire, *Le Nevraxe*, Volume VI.) these observations of Cajal's.

In specimens prepared according to Cajal's method, these end-clubs were observed to be independent of each other as well as of the cell. Cajal's method being an elective nerve fibril method, the pericellular nets, if they exist at all, can only consist of protoplasmic substance.

Held (Zur weiteren Kenntniss der Nerven-endfüsse und zur Structur der Senzellen, Abh. der K. Sächs. Ges. d. Wiss. Mat. Phys. LI. No. 2, Volume 29, 1903-1904) found nets in the ganglion cells by

means of Cajal's method. He disagrees with Cajal concerning the connection of the so-called terminal feet or buttons, and shows by photographs of his preparations that the terminal buttons are connected in continuity with the protoplasmic substance of the cell body; and that the fibrillary net which exists in the terminal button communicates with that of the cell. Hence the terminal buttons really constitute connecting links between locally remote ganglion cells of the central nervous system, in the longer or shorter path of their axis-cylinder processes. But, as we have said above, Held's views in this matter have not been accepted, neither have they been corroborated by acceptable investigators.

Fig. 3 shows fairly well the formation of these terminal buttons as they appear in Cajal preparations. No single plane, however, such as the drawing must necessarily represent, can give an adequate idea of the enormous number which literally cover the cell and dendrites. This and other preparations which we have carefully studied, seem to bear out Cajal's views very forcibly, in as far as we have been quite unable to demonstrate fibrils passing from the end feet into the interior of the cell. Even successful Bielchowsky preparations, or the illustrations of Wolff, do not establish the continuity question firmly enough in our estimation to make their position sure. One should not forget that we are dealing with very minute structures only to be seen with very high magnification, and there is such a dense network of similar structures that it becomes quite impossible to determine absolutely their ultimate destruction.

The more important communications that have appeared during the past few years on the subject of the disposition of the neurofibrils of the periphery of the body must now be briefly reviewed.

Ruffini (Ultraterminal Neurofibrils in Human Motor Endplates. *Rivista di Pathologia nervosa e mentale*. Firenze, October, 1900. Vol. V., Fac. X) states that he reexamined his old gold-chloride specimens of human motor endplates with the result that certain details were discovered, which lead him to believe that in man as well as in lower animals a closed system of anastomoses may originate from the motor ramifications (as discovered by Apathy in Hirudinea). It is quite possible, he believes, that sensory nerve fibrils enter also in connection with this anastomotic system. Ruffini noticed that extremely fine fibrils, of variable length supplied with small "varicosities" sometimes originate from the endplates. These "ultraterminal fibers" seem to terminate after a longer or shorter course within the same muscle-fiber, or more commonly in an adjacent muscle-fiber, either with a varicosity or without one. Occasionally the fibril terminates in a small secondary endplate, from which another thin fibril may take its origin. This goes to show that in man the so-called "motor endplates" are not the real termination of the motor nerve fibers; since other fine fibrils arise from them, the fate of which cannot be definitely determined.

Apathy, in discussing this communication limits himself to some very general theoretical considerations upon the importance of this fact as an argument against the neuron theory. He says that Ruffini's preparations afford proof that nerves do not terminate (or at least, do not invariably terminate—he, for his part, believing that they *never* do) in the endplates of the muscle; just as in the Hirudinea they do not terminate in the "terminal crests" described by him and which correspond exactly to the motor-plates of vertebrates. In vertebrates also, and in a very superior vertebrate at that—exceedingly fine nerve paths emerge from the terminal plate, passing in various directions through the muscle-fiber, branching and entering into adjacent muscle-fibers, just as they behave in the Hirudinea.

If it is permissible to judge from experiments made upon animals of such "inferiority," Apathy continues, his observations lead him to predicate the probable ulterior fate of the ultraterminal branches in the following fashion: In part they may pass through some neighboring muscle fibers—in their way as yet unseen—and in part they branch immediately in the interstitial substance between the muscle-fibers, becoming isolated elementary fibrils. These elementary fibrils then pass to the elementary peripheral net which spreads its large and uneven meshes in the interstitial substance between the muscle fibers. But the elementary net receives in its turn other elementary fibrils which come both from other motor plates, and from nonmotor nerves, from the nerves of general nonspecialized sensation (here perhaps from the nerves of muscular sense). It is another question, which nerves, in vertebrates, are those nerves of general sensation. In the Hirudinea, Apathy was recently able to recognize those nerves in a special type of nerves described by him in 1897, and designated as "sensory tubes."

Dogiel (Der fibrilläre Bau der Nerven End-Apparate in der Haut des Menschen, und der Säugethiere; und die Neuronen-Theorie. *Anat. Anz.* Vol. 27, Nos. 4-5, 1905) describes the termination of neurofibrils in tactile disks, the typical and modified Vater-Pacini corpuscles, the typical and modified Meissner corpuscles, and the papillary bundles of Ruffini, with the assistance of specimens obtained by means of Cajal's neurofibril method from the human skin and from the skin and mesentery of the cat. He concludes that all sensory end-ramifications consist of more or less small-meshed and completely closed nets of neurofibrils, which are placed in a larger or smaller mass of perifibrillary substance. The shape alone varies in the individual end-apparatus; round, sometimes curved, small disks of variable diameter (tactile disks, Grandry's corpuscles, swellings at the axis-cylinder ramifications of the typical and modified Meissner corpuscles), angular scales (human skin, tree-like terminations of sensory nerves of the cutis, mucous and serous membranes, intermuscular connective tissue, tendon); fusiform, club-shaped, round or oval, sometimes flattened, formations (Herbst corpuscles, typical and modified Vater-Pacini corpuscles). The neurofibril nets are either in direct contact with their surroundings (connective tissue, fibril bundles), or with special cells (tactile disks) or they have a special sheath. The most marked difference lies in the number of neurofibrils constituting the aggregate of all nets together, in which terminate the processes of a sensory cell, not in the shape of the terminal apparatus. These either reunite by means of individual neurofibrils, or by means of twigs consisting of several neurofibrils; all, together, or a certain portion, forming other end-nets in such a way that the individual terminal apparatus seems to be connected with its fellow (tactile disks, Grandry's corpuscles, leaf-shaped terminations, tree-like ramifications). All the neurofibrils of a peripheral process stand in direct communication with the intracellular net; the perifibrillary substance continues to the process, together with all its terminal nets, where it reaches the maximum amount, as that portion of the cell body which is not differentiated into fibrils. The central process differs in no impor-

tant feature from the behavior of the peripheral process; the small, club-shaped thickenings, with which the terminal ramifications rest upon the motor cells and their dendrites likewise consist of closed nets of this character. The neurofibrils do not, however, enter into organic connection with the intracellular net or the undifferentiated protoplasm; simply resting immediately upon the cell. Each sensory cell represents a neuron, which communicates neither with other cells of the central nervous system, nor with other units. The neurofibrils belonging to a neuron, form at least three, closed and firmly united nets: the intracellular, the peripheral, and the central net. Cell colonies exist beyond a doubt in the central nervous system, meaning that cells of the same type unite by means of their dendrite ramifications. According to their function the closed terminal nets rest either upon the body, or the dendrites, of another colony, or of an individual neuron, or upon non-nervous elements (muscle cells).

In contradistinction to the Apathy-Bethe neurofibril theory, the author points out that the neurofibrils are to be interpreted simply as products of the differentiation of the nerve-cell protoplasm, and that they serve to build all the terminal apparatus and ramifications, assisted by a portion of the non-differentiated plasm, the perifibrillary substance. The different psychomotor and psychosensory functions belong not only to the neurofibrils, but also to the nerve cell, and all its parts. It is not at present possible to pronounce upon the function and importance of the neurofibrils.

Klomer, working on the crista of the mouse ("Zur Kenntniss des Verhaltens der Neurofibrillen an der Peripherie," *Anat. Anz.*, Nos. 16-17, Vol. 27, 1905), says the fibrils are seen to approach the cells, entering to a moderate degree into plexus-like ramifications. They then penetrate into the cell at the lower pole, and diverge in shape of a ball, sometimes dividing into branches. The interior of the cell presents a trellis of narrow meshes, which is especially dense directly toward the base of the nucleus. Imperfect staining with methylene blue and Golgi results in the picture of the so-called terminal calices. The fibrils are seen to traverse the cells of the spinal ganglion with a distinct trellis formation, after which they pass to the habenula perforata. Especially in embryos (rodents and mice), nuclei may be seen very plainly enclosed by very fine neurofibrils. At their egress from the habenula the fibrils diverge at blunt angles. From this point on, fibrils begin to pass in a spiral, rarely in a radiating direction, to the basis of the innermost cells. The others pass in regular flexions of approximately a right angle toward the three outer spiral fiber columns, in such a manner that the fibrils which pass to the first column present one flexion, those passing to the second two, and those passing to the third three flexions. From the fibrous strands the fibers run upward in a curve to the bases of the outermost cells, and enter the cell, forming a very fine trelliswork in the basal portion especially. Free nerve terminations could not be made out at all. The author points out that the behavior of the nerves varies surprisingly in the crista and macula of different animals. The neurofibrils in the Pacinian body are rather numerous, the perifibrillary substance staining deeply and forming a distinct plate at the peripheral end, under which lies a small trellis of neurofibrils with distinct meshed formation. Concerning the effectory terminations, the author assumes a similar structure, supporting his views by the description and illustration of motor endplates and the intracellular ends of the glandular nerves from the skin of amphibia. The author was unable to discover special terminations in the myocardium, the fibrils invariably returning to form strands of parallel fibers, however fine they may have grown before. Neurofibrils do not occur anywhere without being accompanied by their matrix, the perifibrillary substance, which may be either the protoplasm of a nerve cell, of a receptory or effectory cell. Both plasma and fibrils are capable of conducting, perhaps to a different degree, just as special contractile fibrils still occur in contractile protist plasm.

Schiefferdecker (Nerven und Muskelfibrillen, das Neuron, und der Zusammenhang der Neuronen, *Sitzungsbericht der Niederrheinischen Ges. für Natur-Heilkunde*, Bonn, December 12, 1904) observed that not only do the fibrils increase in size during the contraction of a muscle fiber, but also the strips of sarcoplasm between them, the latter contracting more strongly than the former. Accordingly the sarcoplasm can no longer be considered as an indifferent substance in the muscle fiber. The conditions existing in the muscle fiber resemble those of the nerve fiber and nerve cell. Here neither the fibrils nor the plasm serve independently for conduction; but the entire nervous activity is to be interpreted as a chemical or chemicophysical process, resulting from a mutual action of the plasm upon the fibrillary substance. The chemical interaction increases in direct ratio to the surface of the fibrils. Accordingly, the intensity of the process constantly decreases from the cell-body toward the nerve termination. The author suggests a number of new terms. The indifferent protoplasm "becomes myoplasm" as soon as the cell is plainly recognizable as muscle cell, and it gradually matures into "sarcoplasm" with the formation of fibrils. In a corresponding fashion it is permissible to speak of successive "protoplasm," "neuroplasm," and "myoplasm," in the evolution of nerve cells. To the axoplasm and the axofibrils of the axis-cylinder correspond the teloplasm, and the telofibrils in the nerve termination.

The alterations of the neurofibrils caused by experiments and by disease has latterly been studied a great deal. Marinesco (*Revue Neurologique*, p. 5, 1905) studied by Cajal's fibril method the cells of the twelfth nuclei after cutting the nerve, and noted during the first stages of reaction and reparation disappearance of the fibril network, the fibrils arranging themselves in bundles or in streaks. Later the net makes its reappearance centrally around the nucleus, with simultaneous thickening of the fibrils (increase of the reduction capacity of the fibrils). Marinesco saw similar pictures in the spinal ganglion cells after section of the sciatic in rabbits, only in this case the changes occurred earlier and disappeared later.

According to Cajal, in the hungry, resting hirudo and in resting animals while digesting, the fibril apparatus is very thick. The fibrils are thin when one warms the animals and immediately after they eat. If the animal starves the fibrils are destroyed and in part reabsorbed.

Tello (Trabajos del Laborator de investigacion *Biol. de la Universidad de Madrid*, III, 2-3, p. 113, 1904) says that in the lizard, during its winter sleep, the disposition and the number of fibrils are very unlike those in the lizard during its activity.

In the hibernating adder and the lizard, the fibrils in the cell are enormously thick. They stretch themselves out in the spring to extraordinary fine threads, and all transitional states may be seen in one cell. One never fails to see in these animals the passage

of fibrils out from the cells; they go only in the dendrites and the axis-cylinders.

It would seem that in these lower vertebrates, as in Hirudinea, the perinuclear fibril apparatus is the most mighty.

Ramon y Cajal ("Variations Morphologiques du Reticulum Neurofibrillaire dans certains Etats Narmaux et Pathologiques," *Comp. rend. de la Soc. de Biol.*, LVI, 8, p. 372, 1904) shows that the fibrils do not all behave in the same way. The ganglion cells in the cord of the hibernating lizard show definite changes in the neurofibrils when exposed to heat. They become finer, more abundant and lose their bundle formation. The terminal buttons remain unchanged.

The condition of the neurofibrils in the brains of cases of general paresis have been studied considerably. Jansky ("Neurofibrils Under Normal and Pathological Conditions," *Casopais lék.*, 1905) shows that the structure of the neurofibrils is definitely altered in progressive paralysis. The findings consisted in hypertrophy, varicosity, granular transformation, and refraction of the fibrils, more especially in the smaller ganglion cells. Nothing of special interest could be made out in a case of senile dementia; while in another case of catatonic dementia præcox of several years' duration the histological examination yielded the following results only: A distinct, diffuse chromatolysis seen by the Nissl stain, the silver impregnation showing apparently normal conditions. The same striking difference was observed in another case of dementia, in which also a marked chromarolytic change in the cells accompanied an unaltered structure of the fibrils. Advanced alterations with breaking down of the chromatic substance are thus seen to be in no way dependent upon destructive disturbances of the fibrils, or to determine the latter, since the two histological elements stand in no demonstrable relationship to each other.

Jansky's findings are not in harmony with those of Dagonet (La persistance des neurofibrilles dans la paralysie générale, *Comp. rend. de la Soc. de Biol.*, Vol. 57, 1904). He examined the brains of three patients who had died of general paralysis, using the Ramon y Cajal method. Portions of the cortex taken were from different regions (parietal lobe, central and third frontal convolutions, anterior portion of the third frontal lobe, occipital lobe, cerebellum, vermis, oblongata, and cord). The extracellular fibrils were found to be universally preserved in all portions, including those in which the brain substance presented marked changes, the fibrils being normal in character. The intracellular or secondary fibrils could also be plainly seen and demonstrated. In the most marked atrophic cells the fibrils formed undulating bundles around granular masses. There was no granulation or pigmentation of the fibrils. The fibrils of the Purkinje cells and cord cells were equally well preserved.

On the other hand, Marchand (Lésions des Neurofibrilles des cellules pyramidales dans quelques maladies mentales, *Comp. Rend. de la Soc. de Biol.*, Vol. 57, 1904) has found very distinct alterations. The neurofibrils were examined according to the Ramon y Cajal method, in the pyramidal cells in the left ascending frontal convolution, central portion, and also of the second left frontal convolution, central portion, in the following diseases: Paralytic dementia (two cases), senile dementia, dementia præcox, idiocy, acute delirium, insanity, and paranoia (one case).

In the third case of progressive paralysis the lesions of the neurofibrils were most marked in the cells lying close to the meninges. Around the nucleus the neurofibrils were seen to disappear. A rather diffuse but distinct alteration of the fibrils around the perinuclear zone, consisting in atrophy of the protoplasmic processes, with disappearance of the fibrils, was observed in senile dementia. The lesions of dementia præcox were less extensive, presenting numerous pyramidal cells with normal fibrils side by side with cells whose fibrils were partially destroyed. In idiocy and microcephalus the cells were observed to contain many fibrils, but were small and had few protoplasmic processes. The lesions of insanity and acute delirium were rather similar; an irregular atrophy of the primitive fibrils, beginning around the perinuclear zone and spreading irregularly toward the sides. The amount of fibrils was found to be normal in paranoia.

Ballet and Laignel-Lavastine (*Revue Neurologique*, 1904) have likewise observed certain modifications of the neurofibrils in the cortical nerve cells of a patient having general paralysis, which were not found in the cortical cells of three patients who had died of pulmonary tuberculosis. The modifications of neurofibrils which might be expected *a priori* in general paralysis are not visible in all the cells. Like Marinesco, they noted the marked contrast between the fragmentation, granular transformation, and rarefaction of the fibrils of the medium and small pyramidal cells on the one hand, and the integrity of similar fibrils of the large pyramidal cells on the other hand. In most of the small and medium pyramidal cells the more or less clear perinuclear region is devoid of fibrils. At the base of the prolongations the fibrils are often torn asunder, wavy, or reduced to black points—some of which seem to be rods as the microscope is being adjusted. These configurations are found in a few large pyramidal cells also. Generally, however, only a rarefaction of the fibrils in the vicinity of the nucleus is visible.

Finally, it was demonstrated that in control brains the fibrillary network surrounding each cell is much richer and denser than in the brain of a general paralytic. From this point of view it is necessary to guard against error by comparing sections of exactly the same tint only, since silver impregnation increases in intensity as fields lying closer to the margins are examined.

Marinesco (Lesions of the neurofibrils in certain pathological conditions, *Comp. Rend. de la Soc. de Biol.*, 1905) believes the majority of those pathological conditions in which the chromatophil substance of the ganglion cells is markedly altered, likewise present corresponding lesions of the neurofibrils. The author was able to demonstrate such lesions in acute myelitis, purulent meningitis, foci of softening and atrophic convolutions; the neurofibrils showing variations differing in degree, imperfect staining capacity, diminution in size, complete atrophy, granular degeneration, or thickening and disintegration. In hemiplegia and paraplegia the pyramidal cells present secondary changes analogous to those following division of the axis-cylinder in peripheral nerves. Where the disease runs a rapid course, the neurofibrils likewise undergo rapid alteration. The primary seat of the lesion is also of importance, the neurofibrils rapidly degenerating and entirely disappearing in subcortical lesions and in lesions of the internal capsule. The first neurofibrils to be involved are those in the vicinity of the nucleus; the neurofibrils of the processes following in grave lesions only.

Parhon and Papinian (Note sur l'altération des neurofibrilles, etc., *Comp. Rend. de la Soc. de Biol.*, 1905). The neurofibrils of the ganglion cells of the

brain were found to be more or less altered in patients having pellagra with marked cerebrospinal symptoms. As a rule the neurofibrils of the small ganglion cells presented slight changes only, while they were almost entirely absent in large cells, such as the pyramidal cells. The nucleus also was markedly altered in the large pyramidal cells. The cervical portion of the cord was more seriously affected than the lower portions, and the root cells worse than the cells of the columns. The anterior horn cells were most deeply involved, presenting alterations resembling those of the pyramidal cells in the zone of Rolando.

Gentes et Bellot (Altérations des neurofibrilles des cellules pyramidales de l'écorce cérébrals dans l'hemiplégie, *Comp. Rend. de la Soc. de Biol.,* 1905) state that in cases of hemiplegia, where the pyramidal tract has been destroyed by the hemorrhage, a number of normal pyramidal cells are found side by side with cells whose fibrils are diminished in number, thickened, fragmented at the periphery, or entirely destroyed, especially in the central portion of the cell. No alteration was observed in a case where there was only a compression of the pyramidal tract.

Wimmer (Investigations concerning the neurofibrils in the cerebral cortex in pathological conditions, *Hospitalstidende,* No. 30, 1905) examined cases of general paralysis, delirium tremens, senile dementia, idiocy, and also one case of chronic trional intoxication by means of the Ramon y Cajal method, with Bokay's modification. In all these cases he observed a more or less marked degeneration of the fibrils in the pyramidal cells, especially in the small and medium-sized cells. A form of degeneration characteristic of each individual disease could not be demonstrated.

Bielchowsky and Brodmann (*Journal of Psychology and Neurology,* V, 1905, p. 173), in discussing the changes in the fibrils in pathological conditions, say that the scanty histopathological examinations chiefly consider the qualitative alterations in individual cells only. These procedures, however, are capable also of furnishing reliable data for the quantitative defects caused by pathological processes, and moreover they afford a view of the nervous fiber belt situated between the cells. The authors' findings were obtained exclusively by means of the Bielchowsky method. For the purpose of obtaining control specimens they began by examining definite areas of three normal brains, followed by the examination of exactly the same convolutions in seven pathological cases of an absolutely typical clinical course (dementia paralytica, dementia senilis, and idiocy). The results of their observations are proof positive of the reliability of the Bielchowsky method, the authors attaching special importance to the following points:

1. With reference to the normal histology of the cerebral cortex, the silver image is capable of completing and improving the customary parenchyma methods in various ways. The entire cortical structure appears much better differentiated in regard to the formation of fibers as well as of cells. (*a*) The nervous fiber-felt is much denser in the outer cortical layers, notably the first, second, and third layers, than in the medullary sheath specimen. Besides the medullated fibers, exceedingly numerous nonmedullated elements, especially in ramifying protoplasmic processes of the ganglion cells, participate in its formation. (*b*) The shape of the cells is very manifold, on account of the large number and great extent of the dendrites which are represented. The Bielchowsky method permits the differentiation of new types of cells, and based upon this, a finer differentiation of the layers in various segments of the convolutions. (*c*) The fibrillary structure of the cells permits the division of cell types hitherto considered as homologous, for instance, various forms of giant pyramidal cells (d). The last-named properties result in a greater variability of the cortical arrangement in general within individual layers as well as entire cortical areas.

2. For the pathological histology of organic psychoses, the fibril preparation furnishes results applicable in the uniform valuation of all nervous components. Pathognomonic characteristics of individual elements of the cortical parenchyma cannot be recognized in the fibrillary picture.

(*a*) As the principal characteristic of progressive paralysis, the parenchyma presents remarkably profound alterations in all the cells even to the disappearance of entire cellular layers with relatively fair preservation of the fibrous constituents. This circumstance is important for the functional valuation of the cell, the significance of which has of late been underrated.

The cell of general paresis is generally characterized by the early and extensive destruction of the processes and by the resolution of the fibrils, with temporary persistence of individual fibers in the body of the cell. The fibrous felt is markedly thinned out, especially in the finest elements.

(*b*) In senile dementia, in contradistinction to general paralysis, the outer shape of the cell with its dendrites is well preserved, as are likewise the cortical layers. The cellular structure is characterized by enlargement and bunching of the fibrils. The intercellular loss of fibers is less pronounced and affects coarser and finer constituents more uniformly than in general paralysis.

(*c*) In idiocy the shrunken convolutions presented radically different findings. The arrangement of the layers, the forms of the cells and the fibrillary structure were quite atypical. The number of fibers and cells was notably decreased.

Our own observations have led us to conclude that one should be very cautious in accepting the various descriptions of alteration in the neurofibrils. That alterations do exist in pathologic states is probable enough to be almost certain, and it is only against the tendency to accept too readily the attempts to classify them that we advise. This seems specially true of the Cajal method, depending as it does upon the well-known rather uncertain powers of penetration which silver salts possess. In the most successful preparations by this method there are always two zones, where the staining is absolutely unsuccessful, even in the middle zone, where the stain is most successful, all the cells are not impregnated regularly and evenly, and we have found not infrequently badly stained cells in normal preparations which resemble quite closely some of those described as pathologically altered.

Marinesco has given elaborate descriptions of the changes in the neurofibrils after tearing out the hypoglossus of rabbits. His records show changes from the forty-eighth hour up to thirty days, whereas our own preparations of the hypoglossal nucleus fail to show even at the end of the fifth day the changes he describes as having already taken place at the end of the thirty-sixth hour. We can corroborate his observation that only the anterior external group is affected, but the only alteration in the fibrils themselves seems to lie in a paler and more delicate stain. They no longer possess the dark, sharply differentiated outlines of the neighboring cells, and the contrast is quite marked. We are unable to see that the granulation and loss of structure, he so graphi-

cally describes, or a tendency of the fibrils to arrange themselves in bundles.

The Bielchowsky method, on the other hand, is much more logical in that it gives us a more constant stain of all the elements in the section, and the modifications have rendered it simple enough to permit most workers to become conversant with and rely on it. But here also there is need of much corroboration before the evidence can be accepted as final.

The new teachings ask us to imagine a fiber without a cell—a thing which we cannot do unless we give up the cellular theory.

Although there seems to be a necessity to modify the neuron theory, nothing has yet been done to cause it to be abandoned. In fact, some of the later work of Cajal, carried out according to his new method of staining, has strengthened the position of those who adhere to the neuron theory. For instance, Cajal and Retzius have both demonstrated the existence of a neurofibrillary network in the ganglion cells of vertebrates. Cajal maintains that these neurofibrils remain in the ganglion cells and their processes; they do not leave it as claimed by Apathy and Bethe, they do not emerge freely, they do not form connections with each other and accordingly they do not form a true network in the dotted substance, but merely an intimate interlacing. Cajal, Retzius and other investigators maintain that the neurofibrils in invertebrates belong to the cellular structure of the ganglion cells and their processes, being formed within them *in situ* instead of having migrated into them from without as described by Apathy and Bethe. If this is so, and at the present time it must be accepted, it tends materially to strengthen the neuron theory, for no proof has been furnished, apart from their mere existence of their extracellular appearance, and their seeming endlessness. That the neurofibrils are the actual and only conducting element of the nervous system has been assumed, but the assumption is based upon the correctness of the evidence furnished by Apathy, Bethe, *et al.*, and has been contradicted from most reliable sources.

Even though it is granted for the sake of argument that there is an intercommunication of the neurofibrils belonging to the motor and sensory system by means of networks in the cell-body, this is not adequate ground for asking us to abandon the neuron theory. There is no proof whatsoever that the fibrils have the function of conducting. That is an assumption just as the existence of a fibrillary acid by Bethe as the condition of nervous conduction is an assumption.

On the other hand, the neuron theory does not get all its support from histological study of vertebrates or invertebrates, by any means. As we shall point out later, it receives some of its strongest corroboration from embryology. But even though it were so dependent there would still be much histological evidence in support of it. For instance, the relation of the collaterals in the spinal cord, the free terminations of which can readily be demonstrated, the relation of the end-baskets around the Purkinje cells, and the granular cells of the cerebellum which Michotte (*Le Névraxe*, Vol. VI., No. 3) has particularly studied, many of which we have previously mentioned, and the results of study of the retina. Cajal has been able to demonstrate in the retina fibrillary network within the cell-body, also the anastomosis formation of the fibrils within the dendrites, but he was not able to see the anastomosis between two ganglion cells which Dogiel and Graef described.

One of the strongest supports of the neuron theory has been the teachings of embryology as set forth by His and his school. Those who oppose this theory look upon peripheral nerve fibers as the product of innumerable cells arranged one after another in chains which remain in fully developed nerves in the shape of Schwann's cells (Dorn, Apathy, Bethe, Schultze). But a recent work of R. G. Harrison of Baltimore (Sitzungsber. der Niederrhein. Ges. f. Natur. Heilk. zu Bonn, 1904), which has been received most favorably by embryologists and anatomists, gives the most unequivocal support to His' teachings that every nerve fiber is the outgrowth of an individual ganglion cell. Harrison shows, from many observations on the larvæ of amphibia that Schwann's cells, like the spinal ganglion cells, are of ectodermal origin and come from the so-called ganglion ledge of the neural canal. When this ganglion ledge is removed from the body at a certain stage of embryonal development and then the nerves develop in the normal way, it gives incontestable evidence that Schwann's cells as well as their cells of origin have no participation or significance in the formation of axis-cylinders. In other words, the peripheral spinal nerves may develop when the sheath-cells are entirely absent. This idea Harrison believes is substantiated by the fact that after complete extirpation of the ganglion ledge he has observed the development of naked fibers in the periphery.

His conclusions are: The axis-cylinders of motor nerves develop in a normal way in embryo frogs in which the development of Schwann's cells are prevented by cutting out early the ganglion ledge. The nerve consists in such cases of naked fibers which may be followed as such to the ventral portion of the thigh and tail muscles.

The sensory nerves of the tail in Triton larvæ of naked ramifying fibers, which, from their origin in the posterior cells, and the cells of the spinal ganglia to their ending, show no Schwann's cells. The latter are to be seen for the first time only after fibers have formed; they proceed gradually from the center toward the periphery, as is evident from a comparison of different stages, and also from direct observation of the fins of living frog-larvæ.

The Rohon-Beard's posterior cells of the frog embryo consist of early protoplasmic formations, which gradually stretch themselves under the skin to nerve fibers. The termination of nerve fibers so constituted consists of a thickening with fine pseudo podii prolongations. The nerve fibers are first of all simple, later they intertwine and eventually through interlacing with neighboring cells constitute a plexus. From the beginning to the end there are no Schwann's cells in these nerves. From which it appears that nerve fibers come exclusively from nerve cells.

Carrying the experiments a step further, Harrison excised in young embryo of *Rana sylvatica* and *Rana palustra* the ventral portion of the neural tubes from the cells of which develop the neuraxons of the spinal motor nerves. He left the neural ledge from which develop the spinal ganglia and sheath-cells intact. The result was that the latter developed normally, but of the former not a trace. Thus he proved incontestably, and in a way reflecting the greatest credit upon his insight and ingenuity, that the motor neuraxons are processes of the anterior horn-cells, and that the sheath-cells cannot by themselves originate these fibers.

The one thing that is needed by the opponents of the neuron theory is to show the transition of a sensory, centripetal impulse, to a motor centrifugal tract without the intermediation of a ganglion cell. If they could do that their claims would be estab-

lished. Whether they first go in or come out of the cell, whether the elementary trellis formation is originally extracellular or intracellular, whether the fibrils are at all interrupted at Ranvier's nodes, or whether there is a free peripheral termination, are all matters of trivial importance compared with this, for then the neuron theory would lose its applicability and usefulness to the problem of physiology and histology.

THE LENHARTZ TREATMENT OF GASTRIC ULCER AT THE EPPENDORFER KRANKENHAUS.

By J. VICTOR HABERMAN, A.B., M.D.,

HAMBURG, GERMANY.

Much is being said at present in German professional circles about the Lenhartz treatment of ulcus ventriculi, which, though employed at Eppendorf for some years, is comparatively new to the medical world, and radical enough to make it a subject for discussion, especially in view of the fact that the results attained at Eppendorf and reports of trials at other German hospitals proclaim it not only theoretically sane, but remarkably efficacious in practice.

The dietary treatment generally adhered to in this condition follows the plan based upon the work of Cruveilhier, Ziemssen-Leube, and Fleiner, with slight modifications in various hands, and consists in giving the stomach at first complete rest, allowing nothing per os save the sucking of ice, especially after a hematemesis, and furnishing nourishment by means of rich nutrient enemata. After several days a milk diet is substituted, with strict insistence on small quantities at short and regular intervals—allowing only after the second or third week 250 gm. as the maximum for every two to three hours—and this course is continued for from four to six weeks. Occasionally other fluid foods are permitted, some white meat after the fourth week, red meat in the sixth, and finally, and with care, the gradual addition of vegetables.

At the Congress for Internal Medicine at Wiesbaden, in 1901, Professor Lenhartz strongly protested against this "starvation regimen," and suggested a concentrated egg-albumin diet as a more rational method in the treatment of a gastric ulcer; for probably the chief cause of its persistence is the hyperchlorhydria almost invariably present, and, as Fleischer has pointed out experimentally and Riegel substantiated clinically, egg albumin is the most efficient food that will "bind" HCl, and thus neutralize the existing hyperacidity. In the hyperacidity occurring in nervous disorders a rich albuminous diet has long since been found the most serviceable plan of medication. And similar to the gastric disorders of neurological subjects is that in chlorotic girls: the epigastric distress, the sour regurgitation, the feeling of pressure and pain after eating, and the hyperchlorhydria are here also almost invariably present. We are sometimes undecided whether the hyperacidity pure and simple or an ulcer not yet advanced to a bleeding stage lies behind the trouble. Indeed, not only have these symptoms led to the diagnosis of gastric ulcer, but only too frequently has a chlorotic condition been the precursor of such. Here, too, the same indications hold good, and, in fact, the treatment of chlorosis by means of such a diet, together with the administration of iron, has met with excellent results, and is the one employed at Eppendorf.

From observations made in an extensive practice at Eppendorf (where 10,000 and some odd number of patients were admitted on the medical side in 1905) Lenhartz concluded that many cases of gastric ulcer do not definitely improve, or do so but very slowly, under the method of retrenched milk feeding, that the high acidity is not measurably lessened, and preeminently this: that if patients are brought into the hospital in a poor physical condition consequent upon one or more hemorrhages, often, indeed, in collapse, the "starvation treatment"—the ice and nutrient enemata and insufficient milk feeding following—not only maintains the patient in his wretched anemic state, but may even drag him into serious inanition; and such an undermined constitution hardly favors the speedy healing of an ulcer. Moreover, frequent nutrient enemata excite the gastrointestinal tract into peristaltic activity, and may thus induce renewed bleeding; besides very little nutriment is, after all, obtainable. On the other hand, should more milk be given per os, merely enough to preserve the body weight—three liters for an adult—would overfill the stomach and stretch its walls, thus preventing a contraction of the ulcer and again offering the danger of renewed bleeding. Professor Lenhartz therefore sought another dietary treatment, one that would especially combat the hyperchlorhydria and reinforce the enfeebled and anemic state of the patient, for such reinforcement is imperative in the severe cases, particularly when hemorrhage has occurred; and so the concentrated egg-albumin diet was tried. In case after case the effect proved so gratifying that this method became the routine hospital treatment. The result of such treatment is that the sour regurgitation subsides, the vomiting immediately ceases, the pain and distress after eating disappears within a few hours to a few days, and, finally, an increase in the body weight is manifest as early as the first week. Besides, the improvement is comparatively rapid, so that the patient can be dismissed as cured within a briefer time than formerly.

The following is the tabulated management at the hospital: Absolute rest in bed for at least four weeks. All mental excitement to be avoided. An icebag is placed upon the stomach, and kept there almost continuously for two weeks. This prevents gaseous distention, prompts contraction of the stomach walls, thus tending to obviate hemorrhage, and eases the pain when present. On the first day, even where a hematemesis has occurred, the patient receives between 200 and 300 c.c. of iced milk, given in spoonfuls, and two to four beaten eggs. At the same time bismuth subnitrate is given twice or thrice a day, 2.0 gm. at a dose, and is continued for ten days. The eggs are beaten up entire (with a little sugar), and the cup containing them is placed in a dish filled with ice, so that they remain cold. Sometimes a little wine is added. This food at once "binds" the supersecreted acid, and therefore mitigates the pain rapidly and causes the vomiting, often quite troublesome, to cease. The allowance of milk is increased 100 c.c. daily, and at the same time one additional egg is given, so that at the end of the first week the patient is receiving 800 c.c. of milk and six to eight eggs. Both these foods are now continued in the same amount per day for another week. For reasons given above, no more than one liter of milk a day is allowed at any time.

Beside milk and eggs some raw chopped meat is given from the fourth to the eighth day on,

usually the sixth: 35 gm. per day, in small divided doses (easily stirred up with the eggs or given alone), the day after 70 gm., and later possibly more if well digested. The patient is now able to take some rice or "griesbrei" well cooked and a little zwieback (softened). In the third week quite a mixed diet is tolerated, the meat being now given well cooked or lightly broiled. All heavy foods are, of course, interdicted as well as vegetables with husks, etc., and those tending to produce flatulence. At the same time the patient is given strict orders to masticate his food thoroughly. The accompanying chart will give the daily quantities at a glance:

Days after last Hematemesis	1	2	3	4	5	6	7	8	9	10	11	12	13	14	
Eggs	2	3	4	5	6	7	8	8	8	8	8	8	8	8	1 egg = 73 calories
	Beaten						4 beaten raw and 4 cooked								
Sugar to eggs			20	20	30	30	40	40	50	50	50	50	50	50	1000 sugar = 3830
Milk	200	300	400	500	600	700	800	900	1000	1000	1000	1000	1000	1000	1000 milk = 670
	To be given iced and a spoonful at a time.														
Raw chopped meat						35	70	70	70	70	70	70	70	70	1000 = 980
Milk-rice							100	100	200	200	300	300	300	300	1000 = 2450
Zwieback								1 pce.	2 pcs.	2	3	3	4	5	1000 = 3320
Raw ham										50	50	50	50	50	1000 = 3790
Butter										20	40	40	40	40	1000 = 7560
Calories	280	420	637	777	955	1135	1588	1721	2138	2478	2941	2941	3007	3073	

The bowels are not to be moved, both in order to avoid any peristaltic irritation and to permit the reabsorption of blood that may have passed into the intestine. In fact, one need pay absolutely no attention to constipation in the first week, nor in many cases even to the end of the second. After the second week the bowels are moved with small glycerin injections, or warm water, and after the third week this is done daily if a movement does not occur spontaneously. After this one tries to control the bowels by means of the food, and by having the patient go to stool regularly. For the anemia iron is given in the form of a soft preparation of Blaud's pills, the formula for sixty pills being: Sulphate of iron, 10.0; calcined magnesia, 1.75; glycerin, thirty drops. Two pills are given two to three times a day. These pills are given as early as the sixth, eighth, or tenth day of treatment, according to need, administered at first in a macerated condition. In severe cases arsenic is also given in the form of pills, each containing 0.001 gm. of arsenous acid. These pills are given in gradually increasing doses, three for three days, four for four days, up to seven for seven days, then decreasing again six for six days, etc. After the tenth day and to the sixth week bismuth compositum is substituted for the subnitricum and given t. i. d. before meals. The patient is usually allowed up on the twenty-eighth day and is dismissed in the sixth to tenth week.

By this method all patients have been treated in the Eppendorfer Krankenhaus for some five or more years, the treatment being at all times begun at once. Before the Lenhartz method was employed the records of 100 cases showed a recurrence of hemorrhage in 20 per cent. of patients. In a series of 135 cases with one or more hematemeses on or just prior to admission, such recurrence was noticed in but 8 per cent. of patients, three of whom had at first been in other hands. Among the 135 cases of Lenhartz there were three deaths, one due to severe anemia (the blood examination showing but 17 per cent. of hemoglobin on admission), one on the fifteenth day of treatment, due to femoral thrombosis and pulmonary emboli, and one on the twenty-seventh day, the autopsy disclosing five ulcers, one having eroded a duodenal vessel, thus occasioning profuse bleeding. This patient had had many hemorrhages before entering. Of the remaining cases the severest gave the most gratifying results. Those whose blood on admission contained but 35 per cent. of hemoglobin or under showed an average weekly increase of 7.7 per cent.; those having between 35 and 60 per cent., an average weekly increase of 6.34 per cent. In twenty-five cases under my own observation during four months there was an average weekly increase in weight of 1.15 kilos. The majority of patients were dismissed as cured before the eighth week. In no case was it manifest that any unfavorable effects were produced by the treatment.

It is interesting to notice that in the entire series no case of perforating peritonitis occurred. On the other hand, one case that during a strict Leube cure developed obvious symptoms of threatening perforation improved immediately when the Lenhartz treatment was instituted; and this case I shall record in full, as it illustrates unusually well the results obtained in a serious instance by both the Leube and Lenhartz management.

Emma L., twenty years of age, taken in charge March 15. She gave a history of epigastric pain for four weeks, a slight bloody emesis on March 3, a more profuse hemorrhage on March 4, and a very severe hematemesis on March 5. The anemia was extreme.

March 5 and 6, abstinence; 7, four saline enemata of 100 gm. each; evening, hematemesis; 8, two nutrient enemata of 100 gm. each; 9, three nutrient enemata of 100 gm. each; 10 to 13, three nutrient enemata of 100 gm. each; 14, three nutrient enemata of 100 gm. and fifteen teaspoonfuls iced milk; 15, three nutrient enemata of 100 gm. and twenty teaspoonfuls iced milk; 16, three nutrient enemata of 100 gm., five teaspoonfuls, and fifteen tablespoonfuls; in the evening there was hematemesis; 17, two nutrient enemata of 100 gm.; 18, three nutrient enemata of 100 gm.; in the evening, hematemesis again; 19, one nutrient enema of 100 gm., 300 gm. saline enema, and 100 gm. gelatin injection; 20, three nutrient enemata of 100 gm.; 21, enema of 500 gm.; 22, enema of 500 gm.; 23 until April 1, daily nutrient enemata of 600 gm. On March 27 there was repeated vomiting.

April 2, enema of 600 gm. One teaspoonful of iced milk every hour; hemoglobin, 40 per cent. From this date until April 10 nutrient enemata of from 600 down to 400 gm. were given, and, in addition, milk, at first in teaspoonful, later in tablespoonful doses every half hour. On April

11, two liters of milk was given, the enemata being stopped. The following day three liters of milk was given; April 13, two and three-fourths liters of milk, with bouillon and chicken soup; 14 and 15, two and three-fourths liters of milk, bouillon with egg, and chicken soup.

On April 16 she was placed in charge of Professor Lenhartz. On the same morning she had vomited several times, had severe gastralgia, and was exquisitely sensitive to pressure in the pyloric region. The abdomen was tense and slightly distended. Symptoms of collapse, with pulse 144 and temperature 38.5° C. (101.3° F. The application of ice-bags and administration of opium were at once prescribed.

April 17, signs of peritonitic irrigation were less apparent; 200 cm. of iced milk given spoonfulwise, and the yolk of two eggs; 18, patient very weak; about 600 gm. iced milk given per spoonful in twenty-four hours; also the beaten yolk of three eggs; 19 and 20, four eggs (entire); no pain; 21, four eggs and some chopped meat. On the following days the same diet was given, with the gradual addition of white bread, finely cut chicken, meat, and mashed potatoes. May 1, a normal strengthening diet; 12, out of bed part of the day; 18, hemoglobin 74 per cent. June 4, has gained 22 1-2 pounds; since April 30, hemoglobin 92 per cent.; discharged as cured.

Thus far Minkowski, Alb. Fraenkel (Urban-Berlin), and Senator have acknowledged the excellence of the Lenhartz treatment, the last named, however, suggesting some modifications.

THE TREATMENT OF STAMMERING.

By ELMER L. KENYON, A.B., M.D.,

CHICAGO.

Through the agency of the speech apparatus, the action of the mechanism of thought is paralleled by the action of a peripheral mechanism of bone, cartilage, and muscle. Thought is an intricate and rapid process of mind activity in which ideas are built up through the employment of words. The intricacies, precisions, and smoothness of flow of words in thought must be reflected in the rapid, intricate, and smooth production of articulate sounds in speech.

The speech mechanism is a contrivance by which a walled-in column of air may be quickly set in motion by compression upon its closed end, while at the same instant its outward movement is impeded in a definite manner at certain points in the course of its passage. This retardation of the outwardly forced air is brought about both in the larynx by the coaptation of the vocal bands, and in the mouth by various approximations of the teeth, the lips, the tongue, and the palate. Each one of these retarding positions produces its own characteristic elemental sound, and all of them together are responsible for the various elemental sounds of the language. The exact manner of production of one of these sounds is, for example, this: Nerve commands having been dispatched simultaneously to each of the groups of muscles concerned, the chest responds by contracting upon the inner end of the air column, the larynx assumes a definite position, the vocal cords coapt, the soft palate closes the mouth cavity off from the nasal space, and the tongue meets the palate in a definite place and manner. In the production of these complicated movements each organ of the speech mechanism must act in instant harmony with the corresponding movements occurring in each one of the other organs concerned in the production of the particular sound. It is important to recall also that this whole process goes on without conscious direction—that is, automatically. In carrying on the speech function an exceedingly intimate association of action between the groups of muscles of the speech series is required. When a nerve command is sent out to one group a similar command is also dispatched to each of the others, and all are thus caused to act simultaneously in mutual harmony. Let there be any cause, however, for imperfection or hesitation in the action of any one group, and the smooth train of relationship of all the groups is disturbed and the function for which the combined action exists is imperfectly performed.

Here lies the key to the explanation of the disorder of speech in question. Founded usually upon a nervous constitution somewhat easily disconcerted, stammering is a functional disturbance of the smoothness of action natural to the complicated nervomuscular speech mechanism. It is manifested by a failure in the perfect coordination between two or more of the several muscular organs involved. Most often the laryngeal sound lags behind, or else does not come out vigorously and distinctly enough. This results in a wavering, a hesitation. In the blind efforts of the patient to bring about harmony, a struggle, with or without the reproduction of an elemental sound, occurs. There are various sorts of efforts made and various degrees of intensity in the struggle. Following backwards this difficulty in the production of the laryngeal sound we find it usually depending upon a deficiency in the compressive action of the chest, or else in imperfect methods of breath control. Moreover, muscular spasm comes to enter more or less into most instances of hesitation. In some, especially in those of long standing, the spasm becomes severe and prolonged, even blocking wholly for a moment the action of the speech mechanism. This severity of spasm arises from the misdirection of the sufferer's efforts for relief, by which he blindly causes certain muscles habitually to be surcharged with nervous energy.

The peripheral organs of speech of the stammerer are not impaired in any manner peculiar to this class of sufferers. But peripheral abnormalities may help to aggravate the disorder when already engrafted. And with young children in whom there exists a neurotic basis for stammering such peripheral abnormalities may be the determining factor in setting going the slight imperfections of coordination which are to result in the development of a stammering habit. The disturbances capable of interfering with the chain of nervous discharges necessary for the production of this complicated automatic nervomuscular act are often also of an obscure character. It is to be remembered that, forming the basis for a large majority of these cases, we have to reckon with a nervous organization which is more readily disconcerted than that of the wholly normal subject. It is certain that suggestion is in this connection of great importance. That feeling of social apprehension common to sensitive young persons leads always to self-consciousness; and self-consciousness directed towards a subconscious physiologic function is often capable of producing disturbance. Witness the lack of control in walking of an unaccustomed person as he crosses the stage before an audience.

It is intended that these brief remarks upon the nature of stammering shall be scarcely more than suggestive. Coming to sum them up, we are, for the purposes of this paper, to bear in mind the subconscious control and action of the speech mechanism,

the functional character of the disorder and its usual basis in an easily perverted nervous organization, its possible incitation by physical abnormalities affecting the action of the peripheral organs, the tendency of the trouble to become more and more firmly engrafted as time elapses, and, we should add, the helplessness of the sufferer (barring exceptional cases) to master his disorder. This helplessness is a corollary to the subconscious production of speech. Knowing almost nothing of the manner of operation of his speech organs, the sufferer himself alone must work blindly and therefore usually unsuccessfully for his own relief.

In meeting the problem of treating stammering three main ideas are to be advanced: First, education, that the patient may consciously learn how to handle his speech apparatus; second, discipline, that he may overcome a firmly rooted and stubborn habit; and, third, correction of general organic disability, and of peripheral abnormalities, in order that the delicate mechanism of speech may not be physically interfered with. The last of these considerations we shall pass over lightly, as bearing rather upon individual cases than upon the general problem of treating stammering. It may be said as a general proposition that if abnormalities are present in the region of the tongue, palate, pharynx, nose, or larynx, capable directly or indirectly of retarding the free movement of the organs concerned in the production of speech, these certainly should if possible be eliminated. Moreover, the daily maintenance of the full physical vigor, aside from its direct effect upon the tone of the nervous and muscular structures, may prove to be the turning factor in the maintenance of the firmness and persistence which is usually essential for complete success in gaining control of the refractory speech mechanism.

Taking up the main considerations to be developed in discussing the treatment of stammering, those of education and discipline, we must at the beginning bear in mind the helpless ignorance of our patient concerning the technique of speech production. We can expect him to do nothing rightly for the correction of his disorder until he knows what he must do in order to handle his speech apparatus. We, therefore, at once make him a student of normal speech from the standpoint of the technique of its production. In the adult patient it is remarkable how much of the confusing mystery and seeming complexity of speech is thereby at once done away with, and how quickly the patient is able to apply this knowledge to the actual operation of his speech apparatus.

The "discipline" of our patient goes on coincidently with his "education." His new knowledge concerning speech production should at once be put into practice. In order to accomplish this the speech apparatus of the patient is immediately severed, so far as can be, from the control of the subconscious centers and placed in charge of the superimposed conscious mentality. Speech for our pupil is no longer an automatic process, but a function governed in detail by the consciousness and the will. The speech organs hereafter during his training are to act exactly and only as the will directs. Bearing in mind the commonness and importance of defection in the chest action, the patient is to be given eventually as ready control of the muscles of the chest for compressing the air column as of those, for instance, which open and close the fist. The enlargement of the chest capacity by training is often important; and the control of the breathing in order to insure a supply of air adequate for speech purposes at each moment must in many cases receive especial attention.

Our patient must learn to handle consciously the speech mechanism, chest, larynx, and throat, as a single machine, instantly and accurately. He is to be taught the manner of action of the articulating organs of the mouth and of the larynx in the production of each of the elemental physiological sounds. In conjunction with a well-controlled chest action, he should practise these sounds until they are thoroughly understood and easily produced. Simple combinations of such sounds are to be dwelt upon in great variety. His new conscious speech is to be built from the standpoint of and in harmony with the natural workings of the speech mechanism. Although this apparatus constructs words from the physiological elements, it makes the syllable its foundation-steps of progress. For this reason and because the syllable is simpler and more readily grasped than the word, the clear division of all words into physiological syllables is to be insisted on. Our aim should be to have the patient gain a full and ready conscious control of the speech apparatus. To this end he is set definite, conscious tasks, each having reference to the demands of normal speech and to his own peculiar needs. Accurate, forceful enunciation of the elemental physiological sounds, of simple combinations of these sounds, and of the syllables of words, demanding as it does definite brief placing of the organs of speech, is admirably adapted to the training and discipline which is our aim. The nervous apparatus and the muscular mechanisms must both act instantly to a definite simple purpose over which there can be exercised positive, unhesitating control. The nervous energy is to be directed where it is needed rather than where it was formerly wrongly sent. Each muscle group is to act in exact harmony with the other muscle groups. The peculiarities of the individual will require special adaptations in his training. The patient, for example, whose stammering is largely dependent upon a nervous overrapidity of utterance must have his "time sense" with reference to speech, as Dr. Makuen puts it, especially trained. In cases of severe muscular spasm particular attention towards bringing about a diffusion of the nervous impulse which has become overconcentrated in the spasm-involved muscles must be carried out.

"The stammerer," says Alexander Melville Bell, "has to take his speech to pieces as a watchmaker does a watch, and examine all the cogs, and pins, and pivots of its mechanism; then, having discovered and corrected the defects of the separate parts of the machine, he must proceed carefully to replace them, one by one, in natural order, adjusting each to easy action before he passes to the next."

In the course of time the patient has ceased to stammer. He has gained control of his speech mechanism and directs it correctly in detail as a conscious process. He understands what he must do in order to speak correctly and he does those things. Ignorant automatic stammering speech has given place to intelligent, conscious, normal speech. But the fight is even now only well under way. Through the conscious correct action of the muscles of speech the discipline of the subconscious nervous structures must go on until they can be freely entrusted to assume control. Until his conscious correct speech has by repetition and persistence completed the cycle and itself become automatic the patient is liable upon occasions (and they will grow in frequency) to be diverted by his thought, relax his conscious control and relapse at least partially into his long-established stammering habits. Great persistence in conscious control is an

all-important necessity, albeit one that patients are prone not to realize fully.

It will be universally agreed that a firmly rooted habit of any sort is not easy of eradication. It will be also agreed that the firmness of purpose demanded for the eradication of any habit, a firmness often to be exercised through a long period and under difficult circumstances, would be found lacking in a great many persons. The stammerer is no exception to this rule. In many cases we are obliged to realize that the patient would rather stammer than not, or, in other words, that he would rather stammer than carry out the fight necessary for his release. And here enters the temperament of the sufferer to aid or to hinder. The forceless, the vacillating, he who temperamentally drifts with the currents of life, who, instead of overcoming tasks permits tasks to overcome him, will be a much harder problem than the one who by temperament courageously fights his way through every difficulty. The latter will, under guidance, sometimes recover normal speech with remarkable quickness; the former may require much encouragement for months or even years. It will be seen that the tactful resourcefulness and practical psychological insight of the director has unending opportunity for occupation in the course of his labors with the various types of the disorder and with the various temperaments of the sufferers.

The beginning of training should be made as early as the discovery of the fault, that the habit feature may be as lightly grounded as possible. It is much to be deprecated that the highest possible usefulness of the physician, the forestalling of disaster, is almost never exercised in these cases. If a tendency to stammering shows itself in the young child, let it be assumed unhesitatingly that the utmost danger of the continued development of the disorder exists, and let the physician proceed accordingly. Thus we may usually avoid untold mental suffering, not to speak of expense and often of blighted worldly hopes. In caring for stammerers of immature age we should apply the principles already laid down, but in a manner simplified to meet the reduced intelligence of the patient. It may be necessary in the very young child chiefly to guide the little chap gently, but persistently and always without excitement, into a slower and more distinct and more forcible manner of speech; and also so far as possible to lead him out of his excitable periods. But even in children as young as three or four years it is feasible and desirable to enter upon a simplified course of training upon the general lines already laid down.

The factors which bear towards a less hopeful prognosis may be stated as follows: The instances in which the disorder is most firmly rooted in the nervous structures are least hopeful, some of these being quite incapable of recovery; such are often the hereditary cases. Habitual severe spasms render the case much more difficult. The older the patient the more firmly is the habit rooted and consequently the harder the cure. Extreme weakness of will, or of persistence, as well as extreme indifference, constitute, unless they can be controlled, almost hopeless mental states. Finally, circumstances interfering with an efficient course of training (as, for example, the necessity of continually overtaxing mind and body in earning a living, or unintelligent cooperation, or indifference, on the part of the parents) are unfavorable conditions sometimes hard to overcome. In actual experience the element of doubt most often arises from the difficulty of enforcing a sufficient degree of earnestness and persistence. In general, the majority are curable and nearly all can be much helped.*

THE STOMACH DOUCHE AND ITS APPLICATION.

By M. GROSS, M.D.,

NEW YORK.

The introduction of the stomach tube is indicated: (1) For diagnostic purposes, where in any case it is indispensable in order to permit of intelligent therapeutic procedure.

(2) For therapeutic purposes, to remove strongly tenaceous mucus in old, obstinate catarrhal inflammations of the mucous membrane of the stomach, such mucous being certainly apt to contribute to a disturbance of normal digestion. With this process may be combined the application of fluids, the chemical composition of which depends upon the effect it is intended to produce. Thus, alkaline solutions—aside from their emollient action—exercise an inhibitory effect upon the secretion; salt solutions are employed to increase secretion; weak silver solutions decrease abnormal acidity and are also used in certain hyperesthesias and in erosions. Bismuth, which is milder in action, is used for the same purpose.

(3) The stomach tube is further used in cases of serious disturbances of motility. Here the object is not only to remove food remnants, but also to exercise a purely mechanical effect upon the relaxed abdominal wall.

There is no doubt, however, that frequently we are able to overcome the above-named functional derangements by adhering to suitable diet, going through a mineral water cure, and prescribing correct medicinal treatment, so that only in a comparatively small number of cases the introduction of the stomach tube will prove indispensable. It is equally certain that frequently, even in old cases, a milder course of treatment will be found sufficient, provided the existing functional disturbances, permitting of such a course, have been clearly established.

On the other hand, there remain a series of cases, in which we are compelled to use the stomach tube for therapeutic purposes, and in these cases it will be found that only a few applications are required to lead to the desired end.

To recapitulate: The strict indications for the introduction of the stomach tube for therapeutic purposes are: (1) Acute toxic inflammations, intoxications, and ileus; (2) old mucous or non-mucous gastric inflammations; (3) a small number of sensitive stomach neuroses, hyperesthesias, chronic ulcerative affections, erosions; (4) anomalies of secretion, or chylorrhea; (5) disturbances of motility in both atonic and mechanical gastroectasia.

It is difficult to conceive how the stomach tube which is at present in general use, can produce satisfactory results for the purposes indicated. To meet these difficulties others have already suggested to let the patient lie down after the introduction of the fluid, so as to distribute the same equally over all the parts of the stomach; others again have tried to achieve the same result by shaking the entire

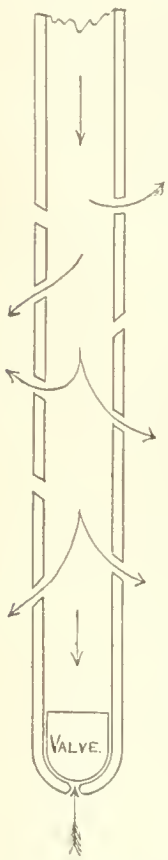
*The author wishes to acknowledge his indebtedness to many authorities, including particularly Merkel, Gutzmann, Kussmaul, Bell, Makuen, and Wyllie. He takes especial pleasure and satisfaction in publicly acknowledging his greatest indebtedness to Dr. G. Hudson Makuen of Philadelphia, whose patient, personal interest and guidance taken with his fine mastery of this subject, has piled up an indebtedness not easily to be repaid.

body of the patient—a manipulation as absurd as it is impracticable.

My contention is that only an empty stomach, readily accessible in all directions, can be thoroughly cleansed and be satisfactorily subjected to the influence of therapeutic measures.

For the purpose, then, of thoroughly removing mucus, food remnants, etc., of reaching every part of the cavity of the stomach, and of imparting tonic action to the musculature of the stomach wall in a number of cases, I exclusively employ the stomach douche, a description of which will follow. By this douche the entire inner surface of the stomach is irrigated by a fluid injected under exaggerated pressure.

In ordinary lavage the fluid injected affects only that part which is contiguous to the tube, thus either never reaching tenacious mucus at all, or only with insufficient pressure. This task, however, is accomplished by the douche. Besides, fluids introduced under exaggerated pressure tend to flow off rapidly. Thus, we have to deal not merely with simple syphon action, but with animating, irrigating spouts, which incite the reserve forces of the muscular apparatus to action, thereby contributing to an improved elasticity of the muscular layer.



Rosenheim's stomach douche does not fulfil these requirements, as I have tried to show in a former article.*

The tube which I have used during the last few years differs from an ordinary stomach tube only in that it is provided with an end opening (outlet aperture) instead of the ordinary lateral apertures, and a number of small, pinhead-size lateral holes (inlet openings), which perforate the walls of the tube in different directions.

As the fluid is injected under exaggerated pressure, the large aperture at the end tightly closes itself by a loose hard rubber valve being pressed against it, thereby absolutely deflecting the inflowing stream against the lateral apertures.

On lowering the head of the tube, the outflowing stream pushes the valve up, an operation which may be assisted by aspiration.

The tube, introduced to the length of about fifty centimeters, hangs freely in the cavity of the stomach and commands the entire field of operation. To reach every part of the stomach by the ordinary tube requires the complete filling of the stomach, which, aside from the extensive dilatation and involvement, is frequently a matter of impossibility on account of the vomiting which, according to individual idiosyncrasies, will occur sooner or later during the operation.

Einhorn's spray apparatus (which, by the way, is susceptible of simplification) may reach a large portion of the stomach, and may be suitable in cases where only small quantities of fluid require to be injected. The gaseous distention of the stomach which occurs in these cases, and which Riegel regards as an objection, rather proves an advantage, assisting as it does in the unfolding of the wall, thus rendering a large portion of its surface accessible to the spray.

The action of the stomach douche is thus mechanico-chemical, thermic, or both. The increased supply of fluid produces, in both nerves and muscles, a state of excitation, or internal massage; the direct and reflex irritation of the vasomotor nerves affects an improved circulation; the peristaltic motion is incited, and the smooth muscles respond more readily to tactile irritation. The sympathetic nerves and ganglia undergo direct excitation, causing a flow of secretion as well as reflex action on organic muscular fibers, and removing functional disturbances.

In order to increase the irritating effect upon the muscular fibers, I inject alternately warm and cold fluids, as the susceptibility of the nerves and muscles to the effect of cold in increased by a preceding injection of a warm substance.

DIPHTHERIA ANTITOXIN IN CHOREA.*

By B. F. HAMILTON, M.D.,

EMLENTON, PA.

About nine years ago I saw a case of diphtheria in a boy fifteen years of age. He had been suffering from an aggravated form of chorea for several months. I gave the boy full doses of diphtheritic antitoxin and opened the trachea, but he lived only a week. I noticed, however, that as soon as the antitoxin was given the choreic movements ceased and did not return. I made a mental note of this fact, and resolved to bear it in mind in the first case of intractable chorea that might come under my care. This opportunity never presented itself until quite recently. The history of the case is as follows:

A young man twenty years of age, of robust health, a night telegraph operator, had never been sick, but had become an inveterate tobacco smoker, and for the past year had not been getting nearly enough sleep. The family history is unusually good, except that an older brother has an involuntary muscular movement of the lower extremities when he attempts to walk. This came on after a severe illness in infancy, the nature of which I could not ascertain. His mind is also somewhat affected.

I was called to see this young man, first mentioned, December 15, 1905. He was suffering from an attack of subacute rheumatism affecting his hands and right side mostly. The temperature was very moderate, and all trouble seemed to subside in a week, and in ten days he reported for duty, but only for one night, as the rheumatism returned. I did not see him again until January 30, 1906. In the meantime he had been treated with various nostrums. He had at this time but little rheumatism, but was extremely nervous, and this condition, as I was informed by the family, was growing rapidly worse. His mind was quite unsettled also. I ordered him to bed at once and placed him under the care of a trained nurse, and began to give him full doses of the fluid extract of cimicifuga and Fowler's solution of arsenic. I increased the dose of the latter rapidly until twenty-five drops were taken three times a day, before any constitutional effects of the drug manifested themselves. The rheumatic symptoms subsided, but the chorea became rapidly worse, so that by February 15 his hands had to be tied together, and his feet and limbs

*Read before the Venango (Pa.) Medical Society, March 20, 1906.

had to be confined, and at times it took the combined efforts of two attendants to keep him in bed and prevent him from injuring himself. At this time it took as much as ninety grains each of chloral hydrate and bromide of potassium in divided doses during a night to procure a few hours' sleep; or, which acted rather better, forty grains each of sulphonal and trional. The delirium, which at first was moderate, was now a violent mania. It was evident that the man could not survive long under these conditions. On February 17, at 8 o'clock A. M., I gave him three thousand units Alexandris of diphtheritic antitoxin; at 12 M. a decided reaction had come on, temperature 102°; by 5 o'clock P. M. this had subsided, and the choreic symptoms were so much relieved that all restraint could be removed; delirium the same. Half the former dose of the hypnotics above mentioned procured a good rest the following night. By 8 o'clock A. M., February 18, there still being some choreic movements, I gave two thousand units of antitoxin serum; in four hours there was some reaction; temperature, 100°. By the evening of this day all irregular muscular movements had subsided, and at this writing (March 20) have not returned. The arsenic and cimicifuga were discontinued when the serum treatment was begun. Bromide of strontium with strychnine and general tonic treatment have been continued; all hypnotics were left off three or four days after the chorea had subsided. The mental condition is improving, but not yet normal. The patient eats and sleeps well.

So far as I know this is the first case of chorea treated by diphtheritic antitoxin, and I wish to call the attention of the profession to it, not to promulgate any theory, but to induce others to try it, and report the results.

I think a physician feels as helpless in the presence of a case of this distressing malady as under any other circumstance. He is bound to tell his patient that, with rest and seclusion, he will likely recover, but he can't tell when; that drugs are generally useful under these circumstances.

It is little wonder that these cases generally fall into the hands of charlatans, and the quack remedy that happens to be in use when nature is about to effect a cure gets the credit.

REICHENHALL, BAVARIA; A CLIMATIC RESORT.

By L. GRUENWALD, M.D.,

MUNICH, BAVARIA.

On the occasion of a visit from an American colleague it was vividly brought to my mind how little the famous resort "Bad Reichenhall," with its world-wide reputation, is visited by American travelers and health-seekers. To draw the attention of larger circles to the place, its natural advantages and its medical institutions, is the object of this paper.

Reichenhall is situated very near to two places much frequented by globe-trotters, viz., Munich and Salzburg, in a wide valley surrounded by high mountains, which offer a panorama of exquisite beauty and protect the whole valley against winds and storms, producing at the same time stronger insolation and higher temperature. Reichenhall is by these favorable conditions the warmest place in Bavaria proper, and strongly contrasts with Munich. Its climate in summer is less adapted for the vigorously healthy, who seek exercise and excitement, but it has no equal for convalescents and patients with affections of the mucous membranes, who find there an air of rare mildness and an equable temperature.

It is surprising that this most important natural factor, the climate, began to be appreciated only after patients had already for fifty years made use of the evaporation of the salt-water, supplied by the natural saline springs and forced to considerable height by large pumps in the Gradirhaus. Whilst at that period these inhalations were considered the principal therapeutic factor, we have learned to-day to pay more attention to the effect of the salubrious climate, which is a particular attribute of the place and cannot be enjoyed elsewhere.

In addition to these natural advantages Reichenhall has, like other resorts, a number of medical appliances and institutions, of which I shall enumerate only the principal ones.

One of the most prominent features is the drinking of whey, made of the milk of cows and goats, whose main value, besides its high degree of albumin—91 to 93 per cent.—seems to consist in the large proportion of potassium and phosphate salts in soluble form up to 0.9 per cent. Its effect is often increased by a decoction of genuine mountain herb, relieving dyspepsia.

From the mountain fir needles is obtained the renowned "Latschen oil," an aromatic oil, used pure or suspended by warm or cold inhalations.

The inhalations of Latschen oil as well as of other remedies may be called a specialty of Reichenhall, and greater and more practical institutions for vaporization of all kinds cannot be found elsewhere. The various forms of steam inhalations can be taken, if desired, in separate cabinets, but the majority of men and women take them in a large room, where they are covered by rubber cloths and sit or walk and breathe the medicated air. Adjoining the Inhalatorium is the pneumatic cabinet, whose improvement and perfection is due to the efforts of a deceased physician of Reichenhall, the son of the famous Liebig, the father of organic chemistry. The buildings for the use of condensed air are most extensive and comfortable, and are used with excellent results in cases of emphysema, chronic catarrh of the bronchi, atelectasis, and old pleuritic adhesions, being in this respect on a par with the effect of the inhalations in catarrhal conditions of the mucous membranes.

The capacity of the pneumatic cabinets is so large that 198 persons can make use of them at the same time.

Tuberculous patients are not admitted. For these and other seriously afflicted ones ample provision is made as to rooms, resting places in the gardens, verandas and the Liegecur, where they can have the unlimited use of fresh air.

Modern hydrotherapy is administered by baths of natural salt water of different concentration and temperature, to which department the physicians of the place have always paid great attention.

Additional features are a large drinking hall with a bar, furnishing all European mineral waters, kefyr, etc., a lignosulfite inhalatorium for consumption and especially purulent bronchitis, baths with Latschen oil, turf, fango, carbonic and electric baths for patients with heart disease, who are coming in increasing numbers, and a Terraincur after Oertel, extending over 200 kilometers.

But in conclusion I must again emphasize the wonderful tonic air and climate, which attracted over 30,000 people last year, the bracing effects of which are well worth a fair trial by travelers from the Western Hemisphere.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, June 16, 1906.

THE BOSTON MEETING OF THE A. M. A.

THE fifty-seventh annual meeting of the American Medical Association, held last week in Boston, will be memorable for the good work of the various local committees having charge of the arrangements. The program was carried out exactly as planned, without a hitch. Some complaint was made of the strict insistence upon the rule that admission to the meetings and receptions should be given only to registered members of the Association, but with an attendance of 4,500 members the press would have been intolerable had outsiders been admitted without badges or other credentials. Even with this precaution some of the receptions were uncomfortably crowded.

The scientific work of the meeting, so far as can be judged from the very full reports of the four chief sections which the readers of the MEDICAL RECORD have had presented to them, was quite up to the average of such assemblages. The association is, however, becoming so large that the number of papers presented in the various sections is too great to permit of their being assimilated by the hearers or profitably discussed. If the programs continue to grow it may be necessary to adopt the plan of the Association of American Physicians, according to which papers are read only in abstract—a good way for expediting business but not favorable to scientific calm and deliberation.

This meeting had promised to be politically more interesting than some of its recent predecessors, for it was rumored that a strenuous effort would be made to dismiss the secretary-editor. So great has become the dissatisfaction with his administration that this endeavor might have been successful had the general body any voice in the management of the Association, but as the society is ruled by the House of Delegates, whose members are appointed before the meeting each year by the State societies and not by the Association itself, the change of dynasty was not effected. The feeling of opposition among the members was indeed so strong that the retiring president deemed it wise to speak of it, to assure the delegates that everything was as it should be, and to avow that he personally knew nothing of the existence of any inner ring or clique. That assurance was, of course, unnecessary, for if there were an inner circle of "bosses" such an ephemeral officer as the president would not be likely to be admitted to its councils. Another evidence of the general dissatisfaction with the management of the Association was the resolution presented in the House of Delegates calling for the appointment of a committee to look into the affairs of the treasurer and secretary. Drs. Billings and Simmons must now regret the shortsightedness of their friends in tabling this resolution, for they will have to be investigated some day and the sooner the disagreeable job is over the better. As Dr. Walker of Detroit stated in introducing his resolution, the criticism of the management has been so bitter because the majority of the members do not understand the intricacies of the business of the Association; the object of the proposed investigation was therefore to clear the officers of unjust suspicion and to demonstrate to all that they had acted solely in the interests of the Association, as they understood them, uninfluenced by motives of self-seeking. The unwise tabling of these resolutions will defer what the unhappy officers might resent as the indignity of an investigation, but it will, on the other hand, strengthen the suspicion in the minds of many that certain things may have been done which would not bear the light of an investigating committee's report. So far from quieting suspicion this evading the issue will be almost certain to increase it. As the preamble to Dr. Walker's resolution read: "because of these facts, there has arisen the sentiment which bids fair to become disagreeably large, unless the cause upon which it feeds be removed, viz., ignorance of the real truth," but the only way of making the real truth known has been stopped by the friends of the accused. These two officials are now in the unenviable position of serving a body, a large minority, if not the majority, of the members of which look upon them with distrust, yet their foolish friends refuse to permit an investigation which they must surely know is the only means of restoring confidence in their integrity. The opposition to an investigation could not have been on account of the constitution of the committee named in the resolution, for the Association could trust such men as Lydston and Graham of Chicago, Wiggin of New York, Cordier of Kansas City, and Eve of Nashville, to do their work conscientiously and make a report on the facts as they found them, free from any taint of prejudice or favoritism. For the sake of the Association as well as of the officers mentioned, it is a great pity this well-intentioned endeavor to get at the truth and make it known was suppressed.

The selection of Atlantic City as the place of meeting in 1907 was not unexpected. This popular resort is a favorite convention city for medical societies, rivaling Washington in this respect, and it is apparently becoming the summer capital of the Association. No better place for the June meeting of such a large body exists. It is near the three great medical centers of the East, its hotel accommodations are more than ample, it is readily accessible from all parts of the country, and its bracing sea air acts as a grateful tonic to the members from the interior, jaded by a winter of arduous professional work. It was a much better choice for a summer meeting than that of Chicago, the only other place considered, would have been.

THE NOSE IN ITS RELATION TO THE SEXUAL ORGANS.

The apparently close relation between the nose and the sexual organs has often been commented upon. Even among the ancients the influence of certain odors on the sexual sense was a matter of common knowledge, and this phenomenon, together with a number of others which have also long been recognized, has during recent years been subjected to scientific test and investigation. One observer has pointed out the existence of a "nasal dysmenorrhea" and has shown that its symptoms may be made to disappear by appropriate treatment applied to the nose. The possibility of a motor instead of a sensory reflex being produced by the irritation of an inflamed and hypertrophied nasal mucous membrane is well shown in cases in which uterine contractions have followed the application of the faradic current to the former, and abortion after galvanocaustic treatment of the inferior turbinates is not unknown. It might be expected that sooner or later the thought would occur to someone to apply this knowledge for clinical purposes and that when the proper indications were present uterine contractions could be excited by local stimulation of certain areas in the nasal mucosa.

In order to test the value of such procedures an investigation of this character has been conducted by Jerusalem and Falkner (*Wiener klinische Wochenschrift*, 1906, No. 15). Their observations were made in cases of prolonged but uncomplicated labors, in inevitable abortion, and when induction of labor was necessary. The following modes of applying the stimulus were made use of: Massage of the so-called genital spot in the nose with an ordinary probe, the application of the faradic current to the same area, and electrolysis of the inferior turbinate by the galvanic current. A considerable number of patients were experimented upon, but the results of the investigation, though interesting, are by no means conclusive or satisfactory. It seems that uterine contractions could be promptly elicited in this manner in women who were previously afflicted with dysmenorrhea, but in normal cases the procedure failed entirely. The writers are in fact forced to admit that stimulation of the nose in the manner described does not compare in efficiency or certainty with other well-known methods of exciting uterine contractions. Even if the latter appeared they were far too weak to result in the expulsion of the fetus. The only apparent value of the procedure is in cases in which it is merely desired to hasten labor rather than to bring it to a sudden termination.

The uncertain character of the results obtained will scarcely warrant the adoption of any of these procedures as therapeutic aids to labor, but there is another aspect of the subject which would seem to be of more positive value. This is in reference to the possibility of influencing the severity of the labor pains through the medium of the nose. As already stated there are two areas in the nose which become hyperemic and swollen during the menstrual period. It has also been found that in certain forms of dysmenorrhea of the nervous type, in which mechanical factors can be entirely excluded, cocainization of these "genital spots" affords well-marked relief from symptoms. Closer examination shows that the pains in the hypogastrium are apparently lessened when the application is made to the inferior turbinate and those in the back when the tubercle of the septum is thus treated. As the act of labor is considered by many to be entirely analogous to menstruation, it would seem that certain features connected with this process could be similarly affected through the nose. It is claimed, and this is supported by observation, that perfectly normal physiological labor should be quite free from pain and that the uterine contractions give rise to this sensation only when an obstruction is to be overcome. A certain degree of mechanical resistance obtains in every labor, but this does not apply during the early stages unless dystocia in some form or other is present. Thus labor may and often does go on to complete dilatation of the os without any complaint of pain. But there are very many parturient women, one may almost say a majority, who experience pain during the early stages, and among these may be found some who suffer acutely. The latter usually give a history of previous menstrual disturbances and in addition they will present the nasal lesion already referred to. The application of cocaine to the nasal genital areas in thirty-one out of forty cases observed by the writers was followed by a marked alleviation of the physical pain connected with the process of labor, although the expulsive effects were not diminished. The influence of suggestion in these patients must, of course, be kept in mind, although there was no evidence of such in the cases related.

Another symptom for which nasal cocainization was tried were the puerperal after-pains and here, where the mechanical factor could be practically excluded, a single application was usually found sufficient to dispel every trace of pain. It may be that the method will be found useful in instances such as those described and also in those in which the special indication would appear to be the existence in a woman of dysmenorrhea previous to the time of her pregnancy. Here it appeared that the acute suffering coincident with the stage of dilatation during labor could be alleviated to some extent at least.

THE CORSET QUESTION.

The artillery of the hygienists has already many times been leveled at various features in the feminine wardrobe which appear inexpedient to the cold eye of reason, however much they may appeal to the esthetic sense. The circular garter, open-work stocking, high-heeled and unduly acuminate shoe, and decolleté bodice have all been subjected to criticism and efforts at abolition, but man, mere man, even when dressed with the brief authority of a medical title, can effect but little in matters such as these. Even the corset question, although settled long ago from the standpoint of hygiene, is still *in statu quo* so far as womankind is concerned. For one short period early in the nineteenth century the corset was laid aside, but this was in obedience to the dictates of fashion and not through a sense of its physiological undesirability, so that when the mood had passed the waist was once more constricted. During comparatively recent times a very strong anti-corset propaganda has been carried on in Germany, with some success, we believe, but no one who has viewed the very ungraceful so-called *Reform-*

kleid which the disciples of the health movement offer as a substitute for the more conventional garb can help feeling that it will take a few eons to get people sufficiently used to it to change their standards of what is attractive in feminine dress.

The feature on which physiologists are apt to lay greatest stress in the corset question is the assumed interference with abdominal respiration which it involves, and although some authorities such as Boerhave, Hermann, and Du Bois-Reymond have maintained that the costal type of respiration is a feminine trait which is quite independent of the manner of dress, many others refer it directly to the use of the corset and the support of clothing by constricting bands about the waist. Among the latter is Lange of Munich (*Münchener medizinische Wochenschrift*, March 27, 1906), who ascribes the feminine "waist" to an interference with the development of the lower thorax caused by these factors during the years of active growth at about the period of puberty, the time when corset wearing is usually begun. His assertions are founded on a large series of life-size tracings of the trunk contours made during a period of years from the bodies of growing girls, which show that, whereas the hips and shoulders increase rapidly in size during the second decade, the waist enlarges to a very much less degree. Through the deficient oxygenation entailed by the costal type of respiration the tendency to chlorosis among young girls is explained, while the absence of the diaphragmatic massage which should normally accompany respiration leads to disorders of the stomach and liver. The greater prevalence of gallstone disease among women is but one of the conditions referable to the reduced activity of the biliary circulation in the liver which follows this fixation of the diaphragm, and movable kidney, enteroptosis, and pelvic displacements are other penalties the risk of which must be incurred by the possessor of a modish figure. Lange believes that if the corset is to be abolished the weakened condition of the dorsal musculature of those who have worn it must first be corrected by the use of suitable gymnastic exercises, and that this is particularly necessary in growing girls who are compelled to spend many hours a day sitting at school desks. A further essential is the adoption of a mode of dress which will relieve the waist of all constricting bands, but without falling into the error of the present "reform dress," in which the weight is borne almost entirely by the shoulders. This is to be effected by having the garments cling closely enough to the trunk to cause them to be to a considerable extent supported by friction. He illustrates various plans of accomplishing this, which appear excellent in principle though their feasibility must be left to the judgment of those concerned.

Appendicitis or Colitis.

A dispatch to *The Herald* of June 10 from Paris states that the subject of appendicitis has again come up for discussion before the Academy of Medicine in that city. Dieulafoy recently asserted that too many operations were performed for appendicitis and he deplored the tendency among surgeons to cut into the abdomen whenever there were symptoms of trouble in the right inguinal fossa, saying that the appendix was often removed when the patient was in reality suffering from colitis. This point was brought out several years ago in a discussion before the Practitioners' Society of this city and reported in the Medical Record of April 19, 1902. Referring to a case in which colitis and appendicitis coexisted, Dr. Beverley Robinson said that colitis might closely simulate disease of the appendix, for the pain might become localized over the appendical region and there might be increased resistance of the abdominal walls over the same region; then the presence of nausea or vomiting, high temperature, and quickened pulse and respiration would complete the resemblance to an acute appendicitis. Cases are on record in which the removal of an apparently healthy appendix has cured the colitis giving rise to these symptoms, apparently indicating that, although no gross lesions were present, some abnormal condition existed in the appendix, causing the inflammation in the typhlocolon. On the other hand, removal of the appendix may fail utterly to relieve the symptoms complained of, indicating that the disease was located in the typhlocolon as well as in the appendix. Treatment of the colitis in the first place might well have obviated the necessity of operation in such cases; and further, as Robinson has suggested, keeping the colon clean and healthy would no doubt reduce the number of cases of appendicitis. After all that has been written and talked on this subject, it is evident that there is still something to be learned in relation to the appendix vermiformis and its troubles.

The Therapeutic Value of Mastication.

It has long been recognized that the oral cavity constitutes an important factor in the physiology of digestion, and this importance is increased by the knowledge now so universally prevalent, that many chronic diseases are directly dependent upon autointoxication originating in the intestinal tract. The part which the mouth and its accessory structures play in digestion is in fact of equal value with that assumed by the remaining portions of the alimentary canal, and this is of particular significance because it is here that the only part of the process resides which is under voluntary control. The oral cavity is concerned with the mechanical disintegration of the food, it regulates the temperature of the latter and provides an admixture of saliva which, aside from its lubricating functions, affords a means by which the organs of taste may be excited and the digestion of the carbohydrates begun. Pavlav has pointed out, the sensation of palatability conveyed by this means has an important psychical effect on the secretion of the gastric juice and, in addition, the peripheral stimulation of the gustatory nerve increases the potential energy of the entire nervous system. Monteouis and Pascault (*Journal des Praticiens*, No. 3, 1906), following Fletcher and Chittenden in their modification of Cornaro's practice, believe that this knowledge can be made of great practical value in the treatment of certain diseased conditions. Thorough mastication it is quite evident will serve to make even small quantities of food more efficient and sustaining. In addition to this, the assimilation of otherwise indigestible material is favored and the remaining portions of the alimentary tract are relieved of a certain amount of labor. Systematic mastication, therefore, they regard as of particular value in dyspepsia and autointoxication; arthritis and neurasthenias of various types, which are believed to depend on the latter, will consequently be especially benefited. Even when

the diet is limited to fluids, the suggestion also holds good in a way, for in this case it is advised that the nutriment be taken in small quantities at a time, in order to gain the same advantages in the way of gradual introduction into the stomach and mixture with saliva as would otherwise be produced by the act of chewing.

News of the Week.

The American Medical Editors' Association.—The thirty-eighth annual meeting of this association was held in Boston, on June 4, under the presidency of Dr. Henry Waldo Coe of Portland, Ore. Dr. Frank P. Foster of New York City read a paper on "The Repeater in Medical Literature," in which he advocated concerted action on the part of medical editors to prevent attempts at simultaneous publication of the same article in several different journals. Dr. W. C. Abbott of Chicago made a plea on behalf of the advertiser of proprietary preparations, in which he decried ill-advised criticism of all advertisers indiscriminately and called upon all fair-minded journals to support the honest advertiser. If this were done there would result good for the worthy advertiser and condemnation and disaster for the fraud. Dr. Kenneth W. Millican of St. Louis dealt with the subject, saying that what should be insisted on in the advertising world was honesty, and that there was no sound reason why physicians should oppose advertising of that sort. Papers were also presented by Drs. James E. Pilcher, William J. Robinson, T. D. Crothers, John Punton, and Charles Wood Fassett. Officers were elected as follows: *President,* Dr. James Evelyn Pilcher of Carlisle, Pa.; *First Vice-President,* Dr. Frank P. Foster of New York; *Second Vice-President,* Dr. Charles F. Taylor of Philadelphia; *Secretary and Treasurer,* Dr. Joseph MacDonald, Jr., of New York.

American Medical Association; Officers of Sections.—The following officers were elected in the various sections:

Medicine—Chairman, Dr. Thomas H. Coleman of Augusta, Ga.; *Secretary,* Dr. Joseph L. Miller of Chicago; *Delegate,* Dr. Nathaniel B. Potter of New York.

Obstetrics and Diseases of Women—Chairman, Dr. J. Wesley Bovée of Washington, D. C.; *Vice-Chairman,* Dr. Edward Reynolds of Boston; *Secretary,* Dr. W. P. Manton of Detroit; *Delegate,* Dr. Walter B. Dorsett of St. Louis.

Hygiene and Sanitary Science—Chairman, Dr. Prince A. Morrow of New York City; *Secretary,* Dr. Elmer E. Hegg of Seattle, Wash.; *Delegate,* Dr. W. Lewis of Chicago.

Diseases of Children—Chairman, Dr. J. Ross Snyder of Birmingham, Ala.; *Secretary,* Dr. George Wentworth of Chicago; *Delegate,* Dr. T. W. Southworth of New York.

Pathology and Physiology—Chairman, Dr. W. L. Bierring of Iowa City, Iowa; *Secretary,* Dr. W. B. Cannon of Boston; *Delegate,* Dr. W. S. Hall of Chicago.

Laryngology and Otology—Chairman, Dr. S. M. Snow of Philadelphia; *Vice-Chairman,* Dr. Philip Hammond of Boston; *Secretary,* Dr. W. Sohier Bryant of New York; *Delegate,* Dr. Otto F. Freir of Chicago.

Ophthalmology—Chairman, Dr. G. C. Savage of Nashville, Tenn.; *Vice-Chairman,* Dr. A. A. Hubbell of Buffalo; *Secretary,* Dr. A. E. Bulson, Jr., of Fort Wayne, Ind.; *Delegate,* Dr. S. D. Pisley of Philadelphia.

Pharmacology and Therapeutics—Chairman, Dr. H. C. Wood, Jr., of Philadelphia; *Vice-Chairman,* Dr. H. R. Slack of Atlanta, Ga.; *Secretary,* Dr. C. S. M. Hallberg of Chicago; *Delegate,* Dr. S. Solis-Cohen of Philadelphia.

Stomatology—Chairman, Dr. Schamberg of Philadelphia; *Vice-Chairman,* Dr. Branigan of Boston; *Secretary,* Dr. Eugene S. Talbot; *Delegate,* Dr. G. V. I. Brown of Milwaukee.

The Army Medical Bill.—The following resolution was offered by Dr. James Evelyn Pilcher, seconded by Dr. Henry O. Marcy, and unanimously carried, at the annual banquet of the American Medical Editors' Association, June 4, 1906:

Resolved: That the American Medical Editors' Association telegraph to the speaker of the House of Representatives that only the passage of the bill to reorganize the medical department of the army can save this country from disgrace in the eyes of the world and avoid a mortality in peace and war which shall put the entire nation to shame, and that as citizens and representatives of the medical press of the United States we urge that this bill in question be brought to passage and without delay.

Civil Service Examinations.—The State Civil Service Commission will hold examinations in all parts of the State June 30, 1906, for the following positions: Health Officer, Town of Minerva, Essex County; Orderly, Erie County Hospital, $540 and maintenance; Physician, State Hospitals and Institutions, $900 to $1,200 and maintenance; Pupil Nurse, Erie County Hospital. The last day for filing applications for these positions is June 25. The Commission has been unable to secure a sufficient number of eligibles for several of these positions, and qualified applicants have an excellent chance of appointment. Full information and application forms for any of the examinations may be obtained by addressing Mr. Charles S. Fowler, the Chief Examiner of the Commission at Albany. The United States Civil Service Commission announces the postponement to July 5-6, 1906 (in view of the small number of applications filed), of the examination scheduled for June 6-7 to secure eligibles from which to make certification to fill at least two vacancies, at $600 per annum each, with maintenance, in the position of medical interne, Government Hospital for the Insane, Washington, D. C., and vacancies as they may occur in any branch of the service requiring similar qualifications. The Department states that it reserves the right to continue or terminate appointment at the end of one year, or to promote the appointee at the expiration of that length of service. The United States Civil Service Commission also announces an examination on July 5-6, 1906, to secure eligibles from which to make certification to fill vacancies in the position of hospital interne (male) under the Isthmian Canal Commission, on the Isthmus of Panama, as they may occur. As an insufficient number of eligibles to meet the needs of the service resulted from the examination held on December 6-7, 1905, for this position, qualified persons are urged to enter this examination. Men only will be admitted to the examination, for which two days will be required. Each applicant for the Isthmian Canal Service will be required to submit to the examiner, on the day he is examined, a recent photograph of himself, taken within three years, which will be filed with his examination papers, as a means of identification in case he receives appointment. An unmounted photograph is preferred. The date, place, and name of examination, the examination number, the competitor's name, and the year in which the photograph was taken should be

indicated on the photograph. Age limit, twenty to thirty years on the date of the examination; salary, $100 per month, with quarters, but without board and washing. Only graduates of reputable medical schools having not less than a three years' course will be admitted to this examination. Applicants for either position should apply to the United States Civil Service Commission, Washington, D. C., for application Form 1312.

The New Bellevue Hospital Plans.—The State Board of Charities, through Deputy Attorney-General Graham, on June 9 made application before Justice Betts in Special Term for a peremptory writ of mandamus, directed to the trustees of Bellevue and Allied Hospitals, compelling them to submit their plans for hospital construction and alteration to the State board for approval. It was stated that the purpose of the provision for supervision by the State Board of Charities was to enable it to make suggestions as to changes and improvements in the plans looking to greater safety of the inmates and to see that modern improvements and conveniences were secured. Prior to the separation of Bellevue Hospital from the jurisdiction of the Commissioner of Charities these plans had always been submitted to the State Board, and the Commissioner of Charities still continued to submit plans for the buildings remaining under his jurisdiction. The hospital authorities, through an Assistant Corporation Counsel, opposed the application.

Meat Inspection in this State.—The New York State Health Department on June 5 issued an order directing local health officers to inspect immediately all slaughter houses and packing plants in the State. A resolution providing for the appointment of a committee of aldermen to investigate the conditions of the slaughter and packing houses in this city has been referred by the board to the Committee on Rules.

Denaturized Alcohol Bill Signed.—The President on June 8 signed the denaturized alcohol bill which provides that alcohol for use in the arts or industries and made unfit for drinking purposes shall be free from the internal revenue tax.

No Free State Antitoxin in New Jersey.—The New Jersey State Board of Health's bill providing for the manufacture and free distribution of antitoxin was vetoed on June 8 by Governor Stokes, on the ground that as some municipalities already supplied free antitoxin it would be unfair to these to use State moneys to furnish antitoxin to other communities that were less liberal.

United Hebrew Charities in Need.—The directors of this organization have announced that they will be obliged to terminate the work of the society on August 10 unless a deficit of $140,000 is made good before that date. The organization has been working on the East Side for thirty years and is spending now about $300,000 a year. The organization has 30,000 applications a year for help, and deals with 10,000 Jewish families annually.

To Increase New York City's Hospital Facilities.—The Board of Health has authorized Commissioner Darlington to ask the Board of Estimate for an appropriation of $1,000,000 to continue the additions being made to the contagious disease hospitals on North Brother Island, at the foot of East Sixteenth street, and on Kingston avenue, Brooklyn.

Yellow Fever at Havana.—That the recent outbreak of yellow fever near Havana has not been gotten altogether under control is shown by the development of another case on June 6 in the city itself. It is supposed that the patient became infected at Bolondron.

Hospital Carnival.—Beginning June 6 a ten days' carnival was held at East Orange in aid of the New Jersey Orthopedic Hospital and Dispensary of Orange.

Decrease in Mortality Rate in Chicago.—During the week ended May 26, 1906, there were seventy-two fewer deaths in Chicago than during the previous week. The 580 deaths reported represent an annual rate of 14.76 per 1,000 of population, a reduction of a little more than 11 per cent. from that of the preceding week, but still an excess of 24 per cent. over the corresponding week of last year. During the above week there were forty-five fewer deaths among children under five years of age, and fifteen fewer among persons over sixty years.

American Physicians in Japan.—Deputy Consul-General McLean of Yokohama has published a statement intended to discourage any emigration of American physicians to Japan. The consul says that the foreign community of less than three thousand persons is already well supplied with European and American physicians, and that the Japanese prefer medical men of their own nationality. All practising physicians in Japan are required to have government licenses, and it takes a foreigner about six months to obtain one, even if his credentials are good.

Testimonial to Dr. Bass.—On May 31 a banquet was given by the physicians of Lowell, Mass., to commemorate the fiftieth anniversary of the entrance into the practice of medicine of Dr. William E. Bass, the oldest practitioner in the city. An antique hall clock was presented to Dr. Bass as a remembrance of the occasion.

A New Quarantine Station.—Surgeon-General Wyman has obtained permission for the United States Public Health and Marine Hospital Service to establish quarantine and disinfecting stations at St. Lucia and Barbadoes. This is done so that vessels which have been passed at these ports may be allowed to enter the port of New Orleans without the customary period of detention.

To Fight Scarlet Fever in Chicago.—The Finance Committee of the Chicago City Council has granted an emergency appropriation of $10,000 to combat the present epidemic of scarlet fever.

American Academy of Medicine.—At the thirty-first annual meeting of this society held in Boston on June 2 and 4, under the presidency of Dr. D. C. Hawley of Burlington, Vt., the following officers were elected: *President*, Dr. Casey A. Wood of Chicago; *Vice-Presidents*, Drs. W. L. Estes of South Bethlehem, Pa., James A. Spalding of Portland, Me., Woods Hutchinson of Redlands, Cal., and Guy Hinsdale of Hot Springs, Va.; *Secretary and Treasurer*, Dr. Charles McIntire of Easton, Pa.; *Assistant Secretary*, Dr. Alexander R. Craig of Columbia, Pa.

Chicago Society of Social Hygiene.—A number of physicians, clergymen, and business men met in Chicago on May 28 and organized a Chicago Society of Social Hygiene. The object of this society is to combat the social evils of Chicago in a systematic way. Dr. Wm. T. Belfield was made temporary president, and Mr. Wm. Hallam was made temporary secretary.

North American Association of French-Speaking Physicians.—The third Congress of this association will be held at Trois-Rivières, Canada, on June 26, 27, and 28, 1906. The various French

medical societies of Canada and the United States have appointed delegates, and official representatives will also be present from France and the French medical societies. Among the latter will be Dr. H. Triboulet of Paris, who will deliver an address on alcoholism, Professor Proust, who will be the official delegate of the University of Paris, and Dr. Foveau de Courmelles, vice-president of the French Society for Hygiene. The subjects for especial consideration before the Congress will be: Alcoholism, The Hygiene of Infancy, and Tuberculosis. The president of the association is Dr. L. P. Normand of Trois-Rivières, and the secretary is Dr. C. N. De Blois of Trois-Rivières.

Obituary Notes.—Dr. Robert S. Ives of New Haven died of appendicitis on June 8, at the age of sixty-four years. He was a native of New Haven and was graduated from Yale College in 1864. He received his medical degree from the College of Physicians and Surgeons in New York in 1867. Dr. Ives left a son and a daughter. His wife died about eight years ago. He was the son of Dr. Levi Ives, long one of the leading obstetricians in New Haven; a grandson of Dr. Robert S. Ives, who was instrumental in founding the Yale Medical School; and the great-grandson of Dr. Eli Ives, a celebrated physician of his day and a surgeon in the Revolutionary War.

Dr. Hall Curtis, a retired physician of Boston, died on June 2 at his summer home in Beverley Farms at the age of seventy-one years. He was a graduate of Harvard University in the class of 1854.

Dr. James W. Duprée of Baton Rouge, La., died on May 25 in Cincinnati, O., at the age of sixty-five years. He received his medical education in the New Orleans School of Medicine and served as surgeon through the Civil War. He began the practice of medicine in Baton Rouge in 1867 and had been a prominent figure in medical circles for many years. He was president of the Louisiana State Board of Health, and for many terms was president of the Baton Rouge Board of Health. He had held the Chair of Anatomy, Physiology, and Hygiene in the Louisiana State University, and served in the State legislature for four years. He was appointed Surgeon-General of the Louisiana State Militia with the rank of brigadier-general. In 1880 he was elected president of the Louisiana State Medical Society.

Dr. T. R. Watkins of Memphis, Tenn., died on May 31, at the age of sixty-five years. He had served in the Confederate Army and had taken a prominent part in combating the various epidemics of yellow fever that have visited Memphis.

Dr. Frederick W. Deichman of Bristol, Conn., died on June 6, at the age of fifty-nine years. He was born in Germany and served as surgeon through the Franco-Prussian War. He received a medical degree from the New York University Medical School in 1877.

Dr. Wm. Jacoby of Mankato, Minn., died on May 31, at the age of sixty-eight years. He was a native of Indiana and received his medical education at the Western Reserve College at Columbus, O. He had practised in Mankato thirty-five years.

Dr. King R. Cutler of Houston, Texas, died on May 31, at the age of fifty-five years. Dr. Cutler went to Houston from Corpus Christi six years ago.

Dr. Donald McLean Barstow of this city, son of Dr. J. W. Barstow, died suddenly at Portland, Me., on June 9, at the age of forty years. He was graduated from the Medical Department of Columbia University (College of Physicians and Surgeons) in the class of 1892.

Obituary.

MARY PUTNAM JACOBI, M.D.,

NEW YORK.

Dr. Mary Putnam Jacobi died at her residence in this city on June 10, after a long and trying illness. She was a daughter of the late George Palmer Putnam, the founder of the New York publishing house of that name, and was born in London, August 31, 1842. She early conceived the ambition to become a physician, and in 1861 entered the Woman's Medical College of Philadelphia, having already been graduated as Doctor of Pharmacy in New York. After passing a year as interne in the New England Hospital in Boston, and two years in private practice in New York, she went to Paris in 1866 and entered the École de Médecine. She was the first woman ever admitted to this school, though Dr. Elizabeth Garrett Anderson of London, who entered later than she did, took a shorter course and so was graduated in 1870, a year before her. While in Paris Dr. Putnam was a regular correspondent of this journal. In a magazine article on "Women as Physicians," published in 1868, it was stated: "Miss Mary C. Putnam, who graduated in 1864, is now in Paris pursuing her studies. She was the first woman admitted to visit the School of Medicine in this city, and has recently, after a brilliant examination, been admitted as a student. She is the 'P. C. M.' correspondent of the New York Medical Record, who sends that journal such racy and graphic accounts of the medical world in Paris." She took her degree of M.D. in 1871, receiving the second prize for her graduation thesis.

On returning to this country she resumed practice in New York and at once won recognition from her male colleagues as a physician of great attainments. She was the first woman member of the New York Academy of Medicine and was the first woman ever sent as a delegate to the Medical Society of the State of New York. She was for ten years a professor in the Woman's Medical College of the New York Infirmary, and later a professor at the New York Post-Graduate Medical School and Hospital; she was physician to the out-patient department of Mount Sinai Hospital and was also attending physician to St. Mark's Hospital. In 1873 she married Dr. Abraham Jacobi of this city. In 1874 she founded and was elected first president of the Association for the Advancement of the Medical Education of Women. In 1894 she took up the gage in behalf of the ballot for women and delivered a memorable speech in Albany that year in support of a woman suffrage amendment to the State constitution. But her labors for her sex were not confined to public acts and speeches, and many women living to-day, in and out of the medical profession, will cherish the name of Mary Putnam Jacobi in grateful remembrance as that of a wise counsellor, a helper in the time of need, and one upon whom a sister's weight could rest when in distress and weary of the buffeting of the world, and of its temptations as well.

Dr. Putnam Jacobi was a woman of great mental grasp, of superior intellectual abilities broadened by a lifetime of serious study. She was a good writer and would doubtless have made a name for herself in general literature had she abandoned medicine for that field, as she was at one time early in her career tempted to do. Among her non-medical writings were "The Value of Life," a reply to Mallock's "Is Life Worth Living?", "From Massachusetts to Turkey," "Studies in Primary Education," and "Common Sense Applied to Woman Suffrage." In 1876

she won the Boylston prize at Harvard for an essay entitled "The Question of Rest for Women During Menstruation." In an article on the history of medical women in this country forming a chapter in "Woman's Work in America," published in 1891, there is a list of over forty titles of papers on medical subjects contributed by Dr. Putnam Jacobi to various periodicals and encyclopedic text-books.

(From Our Special Correspondent.)

DEVELOPMENT OF THE NERVOUS SYSTEM—STRUCTURE OF THE RED BLOOD CORPUSCLES—ACTION OF RADIUM ON THE EYE—THE PANCREAS AND FAT NECROSIS—PROTOZOAN DISEASES—INTESTINAL SURGERY—CONGENITAL DISLOCATION OF THE HIP—THE TREATMENT OF MYOPIA.

LISBON, April 29, 1906.

RAMON Y CAJAL of Madrid spoke on the histogenesis of the nervous system, basing his conclusions on work done by means of his reduced silver method. He found that in the embryo of the chick and other animals the axis cylinders preserve perfect independence in the course of their development, and concluded that there was no reason for abandoning the monogenetic theory of His. He considered that the neuron theory received additional support through these observations.

Albrecht of Frankfort discussed the composition of the red blood corpuscles. He said that the uppermost layer of the erythrocytes in vertebrates consisted of a lipoid substance (lecithin) which was particularly prominent among the mammals. This body had a particular affinity for oxygen, with which it could combine and in this way take part in the formation of hemoglobin. It could also unite with substances dissolved in the blood serum. The interior of the erythrocytes was composed of a more or less homogeneous fluid holding hemoglobin in solution. In order for the latter to be set free, destruction of the lipoid envelope and alterations in the inner fluid was necessary. The nucleus of the red cells probably took part in the formation of the lecithin and perhaps also in the production of hemoglobin.

Birch-Hirschfeld of Leipzig read a paper on the physiological and pathological action of radium on the tissues in general and on the eye in particular. He first gave a general review of what was known concerning the action of radium on the tissues and then took up its application to the tissues of the eye. As a result of what had so far been observed, it was not possible to expect much from the use of radium in ophthalmology. On the contrary, the development of conjunctivitis, ulcerative keratitis, or retinitis through the radium was to be dreaded. In trachoma a beneficial action was noted, but this was purely temporary. Further investigations in this field might yield more promising results, but for the present were not to be advised on account of the dangers involved.

Chiari of Prague took for his subject the pancreas and fat necrosis. He said that numerous observations had established the fact that necroses of fatty tissues were caused by the pancreatic juice through its proteolytic and lipolytic ferments. Studies in this connection had also shown that pancreatic juice brought about these changes outside of the pancreas as well. The question now arose how the pancreatic juice found an exit from the gland, and it appeared that the proteolytic ferment could dissolve pancreatic tissue itself. There was therefore autodigestion of the pancreas *intra vitam*. Autodigestion of the pancreas was accordingly to be regarded as a disease *sui generis*. The acute or hemorrhagic and gangrenous inflammations of the pancreas and pancreatic apoplexy were forms of autodigestion, caused either by trauma, local disturbances of circulation, interference with the excretion of the juice, or the effect of a "kinase." The treatment was purely surgical.

Laveran of Paris spoke of protective inoculations against protozoan diseases. He said that immunity produced through vaccination was closely allied to natural immunity and suggested the question whether the protozoan diseases such as malaria, pyroplasmosis and trypanosomiasis brought about an immunity or not. It was known that one attack of malaria did not confer immunity against subsequent infections, but Koch, who had observed the frequency of this disease among the native children in Java and German New Guinea and the resistance to infection manifested by the adults, concluded that the natives did acquire a form of immunity against the disease. In reality this immunity was only relative, however, and therefore one could not expect to protect human beings against the disease through the inoculation of a weakened virus, and all practical attempts in this direction had been without results. The only efficient protection was to be obtained through the prophylactic use of quinine. On the other hand, inoculation had been found very serviceable as a protective measure against Texas fever. The attempts of this sort in trypanosomiasis had so far not been very encouraging. Serum treatment had been found unavailing, and it was extremely difficult to obtain attenuated virus.

Varoncellos of Lisbon discussed gastroenterostomy and intestinal anastomoses in general. He said that gastroenterostomy was the most important measure to be considered in cases of stenosis of the pylorus or in those in which the symptoms of beginning stenosis were present. In cases of malignant stenosis gastroenterostomy should be done if extirpation was not possible. This could, however, always be effected if there were no adhesions, particularly posteriorly. In benign stenosis, gastroenterostomy was much to be preferred to all other procedures, such as pyloroplasty, for example. The speaker preferred von Hacker's method of posterior gastroenterostomy and always used sutures rather than the button, as the advantages of the latter did not outweigh its drawbacks. The speaker also condemned all procedures for this purpose accompanied by crushing, as he considered primary union of the cut edges of intestine and stomach by suture as essential. Intestinal anastomosis was of use principally in stenotic conditions of various sorts.

Kirmisson of Paris presented his views on the treatment of congenital dislocation of the hip. He said that, although the bloodless operation did not produce very satisfactory anatomical conditions, the functional results were very good. The figures published by different operators varied widely, however, from 20 to 85 per cent. of successes. The speaker agreed with Lorenz in thinking that 52 per cent. might be taken as a fair average. In future it was desirable to speak of successful reductions only when the head of the bone had been placed in its socket, presented the normal relation to the femoral artery, and was freely movable. In reference to the prognosis of bilateral dislocation it might be said that the result was never the same on the two sides, the one joint always proving to be less efficient than the other. In general, the rule might be stated that the age between three and five years was the most favorable for treatment. He preferred the gentle methods, like those of Pavi, to the more energetic procedures, and employed Lorenz's principle of operating in two stages. If no success followed repeated gentle attempts the bloody operation should be resorted to, and in carrying this out it was essential to secure adequate excavation of the acetabulum. In cases in which the age of the patient or the degree of deformity rendered the radical treatment impossible subtrochanteric osteotomy was a useful substitute.

Lorenz of Vienna, in speaking on the same subject, said that in spite of all the suggestions that had been made by others he still considered that the method he had described ten years ago was the best. For older children it was preferable to employ extension with preliminary abduction to the angle of 90°, and even more in some cases. In very young children abduction to 90° could easily be effected, but there was also a strong tendency to relapse. To correct this tendency it was necessary to use a high heel under the unaffected limb and during the night to provide some form of apparatus for maintaining the abduction. In older children the danger of relapse was slighter, but the correction was more difficult to effect. If difficulties were encountered, such as danger of fracture or unfavorable conditions about the joint, intertrochanteric osteotomy of the femur was the preferable procedure. From the practical standpoint the following groups of results could be distinguished: (1) Absolute cure both functionally and anatomically could be effected in about 50 per cent. of the cases. (2) In the greater proportion of the remaining 50 per cent. it was possible to secure an advantageous position of the head of the femur, especially if the musculature could be made efficient. (3) Only very few cases did not show a favorable result, but even in these the functional capacity of the limb could be increased by the treatment.

Hess of Würzburg discussed myopia and its treatment. His studies on the mechanism of accommodation had shown that even when the function was used to its maximum no increase of intraocular tension was produced, whereas the tension was markedly augmented through every contraction of the outer eye muscles. In consequence there was no physiological basis for the view that close work produced an increase in myopia through elevation of the intraocular tension, and therefore there was no objection to full correction of the myopia. Hess believed that the statements that strong lenses were injurious could not be substantiated, and he said that he had seen glasses of 20-23 diopters worn long periods of time without injury. When the stronger lenses were used even a slight error in centering them and in their distance from the eye might have a very marked influence

on the effect of the lenses. It was often observed that myopic patients were not able to use strong glasses that had been prescribed for them elsewhere, but that they were glad to use equally strong lenses selected according to Hess's rules. There was little divergence of opinion in regard to the treatment of myopia of 3-6 D., but in cases in which the error was only ½D. Hess did not employ the full correction because such patients could read well with only slight correction. In conclusion he said that the operative treatment of myopia was to be condemned.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—KING'S COLLEGE HOSPITAL—ELIZABETHAN FÊTE—CHARING CROSS HOSPITAL—MR. WHITELAW REID'S SPEECH—PROF. KOCHER ON GRAVES' DISEASE—LISTER INSTITUTE—"SWEATED INDUSTRIES" EXHIBITION—CHARGE OF NEGLIGENCE—ANTI-VACS IN PARLIAMENT.

LONDON, May 25, 1906.

THE General Medical Council opened its summer session on Tuesday. The President, Dr. Donald McAlister, perpetuates the example of his predecessors by delivering superfluous addresses. He opened this session by informing the councillors what every one of them knew, that the Act of 1886 has now been applied to the Empire of Japan, full details as to the curriculum and examinations of the Imperial University having been supplied through the foreign office. He ventured to say the council would probably consider the conditions amply sufficient to guarantee the efficiency of the Bachelors and Doctors of Medicine of Japan. All information went to show that our allies had wisely provided for medical education, and this explained the unparalleled efficiency and success of their military medical service in the recent war.

The president went on to say that two bills had been prepared for submission to parliament this session. One was to prohibit medical practice by companies, the other a similar dental restrictive measure. Considering that the pharmacists have lost their bill protecting them from companies' encroachments, I am afraid the two proposals of this council will be equally unsuccessful. The president said some of the disciplinary cases would bring home to the council the gravity of the situation arising from the unrestrictive exercise of the skilled professions by joint-stock companies. But it is not so much to the council this must be brought home as to parliament and the public. The council may do something to place obstacles in the way of the companies, and so may the existing law as to frauds and conspiracy. But will they? Experience proves that the only way of safe-guarding the public against ingenious evasions of the law is rigidly to enforce its provisions and where it is weak to strengthen it.

With regard to the University of Wales the president stated that the executive committee had considered the proposed supplementary charter giving power to grant medical degrees to graduates in arts and science and gave no objection to it. If the charter be obtained an act of parliament would be required to make the degrees registrable. There can be no doubt that the University of Wales would exact a high standard for its degrees but it would be well if it admitted only those candidates qualified to practise. If all the universities would join to effect this a good medical reform would be secured.

Nova Scotia is seeking reciprocity in recognizing medical qualifications, and the requisite order in council has been issued. The information required to decide what qualifications in Nova Scotia comply with the conditions demanded for registration. The matter cannot be settled this session.

It was decided to reduce the number of the committee on penal cases. The name of John Bate Bawden was removed from the register for acting on a society that canvassed for patients. The Glasgow University's degree in public health was recognized for registration. Yesterday the council resolved that the pharmacy bill as amended in the House of Lords (which allows companies to act as pharmacists) is fraught with obvious and extreme danger to the public, and that it would be inimical to the public interest to confer the privileges and powers of the sight testing (opticians') bill on persons other than those qualified in medicine and surgery.

King's College Hospital has basked in the smiles of society this week by reason of a great Elizabethan fête held under Royal patronage in the hall and grounds of Lincoln's Inn, lent for the occasion. No trouble was spared by the organizers to accomplish their purpose, which was to provide the most successful fête of the season for the benefit of the hospital's removal fund.

You know that a new site has been provided in South London by the generosity of the Hon. W. F. D. Smith. This site is twelve acres in extent and the design is to increase the number of beds in the new hospital to 600, for which subscriptions are coming in, though more slowly than is needed to meet the cost of building and up-keep.

H. R. H. Princess Christian opened the fair on Wednesday, the Lord Mayor the next day, and your ambassador to-day; all circles of metropolitan society put in an appearance. The stall-holders in the great hall included all ranks of the peerage from duchesses downward. The "Boke of ye Fayre" contains over 250 portraits of patrons, with literary and art contributions. In the grounds flowers and farm produce were to be bought at "the old Cross of Enfield," and the cup that cheers could be had at the "old Rye House," served by ladies connected with the medical staff. But the most striking view was on the terrace, where there was a realistic reproduction of Cheapside in the time of Queen Elizabeth, at which Countess Roberts, Lady Methuen, Lady Peel, and other ladies of rank, dressed in Elizabethan costume, presided as saleswomen. One stall, named after Sir Walter Raleigh and devoted to the sale of the weed, was presided over by Miss Ellen Terry and other famous actresses. In a specially erected theater some entertainment or other was kept going; on the first day an original travesty written by Mr. W. S. Gilbert, who took a part in it; on the other days, plays by Mr. Nigel and Mr. Cutter, besides dancing, lightning portraits, strolling minstrels, and the other attractions for a most elaborate fancy fair, among which I must name pavement sketches by Mr. Wylli, A.R.A., got up as a beggar with a wooden leg, and cat sketches by Mr. Louis Wain. With all this "society" seems satisfied and delighted. I hope it will prove a good thing for the removal fund, but what a pity it is people should want to bargain even for their help to charities. It would be so much easier to give the money spent on this Elizabethan fête—curious and interesting as it is. I cannot report the total returns, as the fête only closes to-night, but I hear that the first days were financially successful.

Your ambassador presided on Wednesday evening at a festival dinner in aid of Charing Cross Hospital. In the excellent little speech he made on the occasion, Mr. Whitelaw Reid said it always seemed to him a beautiful trait of the English character and of the character of all English-speaking people that they maintained such magnificent hospital systems and that largely by voluntary contributions. It was a direct link between the man who gave and the man who needed, and it seemed to him a priceless link to bind all together. Then, he continued, there was a poverty with London hospitals at the present time and he was informed that not more than one-tenth of well-to-do London householders contributed to hospital funds. But it was the interest of the well-to-do citizen to see that his hospital system was in good condition. Otherwise he had no security for the safety of his wife and children. The great progress which had been made in medical science was almost entirely dependent on the assistance given to the medical profession by hospitals. Charing Cross Hospital demanded support. Situated in the heart of the metropolis where street accidents and emergencies were numerous, during the past year it received 2,465 in-patients. Of 20,500 out-patients more than half were cases of accident or emergency.

At the close of the dinner contributions were announced amounting to £12,257.

The *Conversazione* of the Medical Society on Monday was a great success. The chief attraction was the oration delivered by Prof. Kocher of Berne on the Pathology of the Thyroid Gland. He exhibited a table of 165 cases on which he had operated. He divided them into three series: The first comprised ten cases of struma vasculosa, which began with Graves' disease, all ten being cured by operation. His second series consisted of sixty cases, described as a mild form of Basedow's disease developing on a preexistent goiter. He said forty-nine of these were cured and two others greatly ameliorated. His third series consisted of 106 cases of typical Graves' or Basedow's disease. Like so many continentals, he generally used the latter term, though he did acknowledge Graves. Of these 106 cases sixty-two he reported as cured, nine greatly ameliorated, seventeen others in a lesser degree ameliorated, and there were nine deaths. He had not lost a case when it was operated on early enough, and he thought a cure was always to be anticipated in such cases, but he enjoined a rather protracted preparatory medical treatment. A course of several weeks of iodide of potassium in small doses or of phosphoric acid with bodily and mental rest should precede the operation, which should be done in stages. Prof. Kocher does not like the term exophthalmic goiter, as it

specifies the least constant of the three conditions. He suggested "heart goiter" as a substitute.

On the proposition of Sir Victor Horsley a vote of thanks was carried by acclamation.

The authorities of the Lister Institute of Preventive Medicine have made liberal arrangements for the accommodation on their premises of the Professor of Protozoology recently appointed by the University of London, an assistant, and six research students. Three laboratories will be placed at his disposal with the use of the library and a lecture theater. The Institute will further provide a sum of £250 for equipment, together with annual grants for the salary of the assistant, apparatus, and up-keep, amounting in the first instance to £150.

An exhibition of "Sweated Industries" has been organized by the *Daily News*, and the revelations are calculated to give the visitors heartaches. It seems terrible to see women and girls showing the manner in which they earn a penny an hour and to be assured that some toil for seventeen hours a day to make 12s. or 14s. a week. It is difficult, no doubt, to cope with home labor compared with that in factories, but our politicians would be better employed in thinking out such problems than in pandering to the trades unionists and encouraging picketing, which often means violence as well as robbery.

Dr. Fenton of Chelsea Hospital for Women and his former house surgeon have had to defend an action for negligence based on the assertion of a patient who had been successfully operated on that she was not told when leaving that she must return to the hospital in two months to have an instrument removed which was therefore left for eighteen months. Evidence was given that she was told to attend as an out-patient two months later, and that the routine of the hospital would prevent her from leaving without that explicit direction. The jury returned a verdict for the doctors, adding that in such cases written instructions should be given. The judge said he thought the suggestion a very wise one, among other reasons for the protection of the hospital in case of such questions arising.

Mr. Burns, as president of the Local Government Board, has been a good deal heckled by the anti-vacs in the House, but so far has maintained his position. To one tiresome questioner who repeated part of his query of the previous day he retorted, "I am not now answering yesterday's questions." The war minister was also questioned about the statistics of deaths from smallpox in the armies in Egypt and India during twenty years—1881 to 1900—compared with those in Leicester during the same period. Mr Haldane professed not to see the use of procuring those statistics, but if the figures for 1901-4 were of any use to the questioner they were—for the Indian and Egyptian troops 163 admissions to hospital for smallpox with twenty-one deaths—for Leicester, 740 admissions, with thirty deaths.

A DEVICE FURTHERING THE TECHNIQUE IN RADICAL OPERATIONS FOR CANCER.

To the Editor of the Medical Record:

Sir:—While the cause of cancer remains an open question, any procedure having in view the localization of the byproducts of the growth must be worthy of consideration. In breast amputations for malignant tumor, for example, wide dissection is the present rule of practice, and it is regarding the care of the discharge in cases of malignancy presenting ulcerous fungoid growths that the procedure I present is intended. The device applies to any form of open-surface cancer and consists in a sealing up of the ulcer with wax or paraffin as a preliminary to the subsequent incision for removal of the growth. The method is as follows: After the ordinary preparation of the case, the assistant nurse or the operator with temporarily gloved hands is to dry carefully the ulcerous mass. Melted paraffin or beeswax is to be freely poured over the open surface. Carried out under anesthesia, as the patient lies upon the table, the final cleansing of the area affected is not interfered with. Cooling and solidification taking place quickly, "cancer juice" and fungous granules are kept confined within the mass, thus insuring against the escape or later transfer by contamination of the surgeon's fingers to the operative wound.

Frederic Griffith, M.D.

New York.

A Hitherto Disregarded Source of Pentosuria.—Von Jaksch points out that the ingestion of large quantities of fruit juices may give rise to pentosuria, and advises practitioners never to omit the fermentation test in cases that give a positive Trommer's or Nylander's test. Urine containing pentose is not fermented by yeast, but gives an osazon with phenylhydrazin.—*Centralblatt für innere Medizin.*

Progress of Medical Science.

New York Medical Journal, June 2, 1906.

Do Central Tracts of the Nervous System Regenerate?—L. Pierce Clark submits the following conclusions in answer to the query of his paper: (1) Animal experiments fail to provide conclusive data that central tracts of the nervous system ever regenerate so that the former function is restored. In warm-blooded animals, and in the human species in particular, an abortive attempt on the part of the cord to regenerate is largely if not solely confined to fibers of undoubted peripheral type. (2) Histological analysis of cases of hemisection, compression paraplegia, and myelitis, and the like destructive lesions of the cord fails to show positive evidence that actual structural regeneration of axis cylinders ever occurs in the central nerve tracts of the human spinal cord. In case of complete division of the brain and spinal tracts there is simply degeneration, followed by sclerosis. (3) A most acceptable reason for nonregeneration of such tracts is shown in that the compressed nerve fibers do not possess a neurilemma sheath, from which nerve regeneration mainly if not solely occurs. This lack in cord and brain tracts, in contrast to the regenerating peripheral nerves, is due possibly to a difference of embryological origin for these two structures of the nervous system. (4) The cases cited by Stewart and Hart (quoted in the paper) for cord regeneration either do not fulfill the conditions of test, being merely hemisections, or, the evidences for regeneration are not definite or convincing. The two suture cases reported by Stewart and Hart and Fowler are good illustrations of this type. (5) In cases of complete transverse division of the cord there is no sufficient justification either from experimental or clinical data to warrant suture of the spinal cord in an attempt to cure the defect.

Acute Abdominal Symptoms from Chronic Conditions.—F. D. Donoghue gives the detailed history of two cases. Case 1 was that of a boy of nine years with a sarcoma of the transverse mesocolon and growing into the stomach with many metastases in glands and liver. Operation was followed by general sarcomatosis with death in four and a half months. During the course of the disease, pain, emaciation, and anemia were wanting, and as far as known there had been no continued fever. The first symptoms were abdominal pain and soreness, and when the boy was first seen a few days later a tumor was located in the epigastrium. The case shows that sarcoma of the mesenteric or retroperitoneal glands does not give the classical symptoms usually ascribed to sarcoma of the intestinal tract. Case 2 was that of an ovarian tumor in a girl of twelve with torsion of the pedicle, giving symptoms strongly suggestive of appendicitis. Operation in this case was followed by recovery.

Diagnosis of Tabes in the Preataxic Stage.—A. D. Young would first take the age of the patient into account. Tabes usually begins between twenty-five and fifty, the most common period for specific infection. When children present the disease, it is the result of inherited syphilis. The most common symptom during the preataxic stage is loss of the patellar reflex. Hardly less constant are the lancinating pains. Another symptom of importance at this period is the Argyll-Robertson pupil. Toward the later stage of this period comes the static ataxia. Incidents in the course of the disease are symptoms referable to the bladder, rectum, and sexual functions. Finally the author considers nerve atrophy, which he maintains is probably more common than statistics would indicate, and is sometimes the earliest sign. It may appears years before the ataxia, and can often be detected long before the vision begins to fail. When suspicion is aroused the eye fundus should be carefully examined, and if optic nerve atrophy is present, this fact should be given considerable weight in arriving at a diagnosis. Blindness usually supervenes in about three years.

Journal of the American Medical Association, June 9, 1906.

The Cause of the Heart-Beat.—W. H. Howell gives an elaborate historical review of facts and theories as to the causes and mechanism of the heart-beat, and critically discusses the factors in the problem. From this study of the data so far as known, he concludes that the myogenic theory is the most probable of any that have been offered so far. It does not explain satisfactorily, however, the phenomenon of the coordination of the heart-beat which can be disturbed by puncture of a particular region in the ventricular septum, although

this is not better explained on the neurogenic theory. As regards the further deeper question of the initial cause of the heart-beat, the most hopeful line of investigation has been that of late years, dealing with the action of the inorganic constituents of the blood on the heart-beat. He objects to being quoted as holding that the calcium ions constitute the inner stimulus; the rôle of the calcium and sodium salts, according to the provisional hypothesis he has chosen to guide his investigations, consists in replacing the potassium and converting a part of the store of stable, energy-producing material in the normal heart into an unstable easily dissociable compound, thus producing the contraction. This hypothesis, as he shows more in detail, accounts for some of the most characteristic features of the heart-beat. Whether it or any other of those proposed be correct, we may congratulate ourselves on the acquisition of the knowledge gained by the labors of the experimental physiologists of the last quarter of a century, that the inorganic salts of the blood and lymph play an essential rôle in the production of the heart-beat.

Artificial Gastric Ulcer.—F. B. Turck gives a history of experiments by himself and others on the induction of artificial ulcer of the stomach. He notes particularly the failure of local irritation by mustard oil injections to produce ulcer and his success in a few instances in producing peptic ulcer in guinea-pigs by long-continued close confinement without exercise and with limited light and ventilation. These few successes suggested the possibility of systemic conditions being important factors, and that alterations in the toxic state of the alimentary canal with consequent change in the blood might play some part. Experiments were begun with *Bacillus coli communis* because it is an organism found abundantly in the intestines and which flourishes in catarrhal and atonic states of the stomach. Although no difference could be detected, morphologically or culturally, between strains isolated from the stools of normal individuals and those from cases of gastric ulcer on account of there being a possible difference in their pathology the latter were selected, and the toxin of *B. coli* being intracellular, suggested the use of killed as well as living cultures. In the earlier experiments the bacteria were introduced directly into the circulation, but in the later ones they were fed by the mouth, thus approaching more nearly the natural conditions. Meat extractives were fed in some cases, as it was observed that *B. coli* grew most abundantly in media containing meat extractives. Positive results were obtained in every experiment in which cultures of *B. coli* were fed to dogs, the number and extent of the ulcers varying from a few ulcers in the duodenum to numerous typical peptic ulcers of the stomach. In order to ascertain the percentage of gastric ulcer in dogs not experimented with, the stomach and intestines of 189 healthy dogs killed at the dog pound and of 82 dogs dying from disease, injury, poisoning, etc., were systematically examined. In no case was a peptic ulcer found, and it appears, therefore, that the percentage of its occurrence must be very small. Turck thinks that a dual condition is indicated in the production and persistence of these ulcers; a toxic condition overcoming natural resistance and possibly some chemical substances formed within the alimentary tract which when absorbed may neutralize the protective bodies in the blood and tissues, resulting in autocytolysis. We have in these results, the author holds, a positive etiological factor of gastric ulcer, and have now a firm basis for the unraveling of the finer or underlying etiology of peptic ulcer.

Trypsin in Malignant Growths.—W. A. Pusey has followed the suggestion of Beard of Edinburgh, and tested the effect of trypsin on seven cases of inoperable carcinoma and one of inoperable sarcoma. In some cases the injection caused little pain and no subsequent irritation, in others abscesses formed discharging, when opened, a thick, sticky, almost transparent serous fluid containing broken-down cheesy masses and leaving unhealthy appearing sinuses, sometimes idolent and slow to heal. Local accidental infection, Pusey thinks, could be excluded, as strict asepsis was employed. In one case of circumscribed carcinoma in the pectoral muscle, distinct benefit followed the injections. After the opening and discharge of the abscess the growth disappeared as if digested and the opening is now almost healed. In the other cases Pusey believes the injections did harm. In several instances after large injections, patients had chills. There were no other immediate constitutional effects, but in all patients who have had numerous injections, cachexia has developed and failure has been more rapid than before. Unless there was prospect of destroying a localized mass by a few injections, as in the one case mentioned, he would not now feel justified in using the remedy.

The Lancet, May 26, 1906.

Saline Injections in Cholera.—F. C. McCombie records a mortality of 23.8 per cent. out of 105 cases, although four of the cases subsequently died, two from dysentery and two from tetanus. Other and usual remedies were administered, but if reaction did not appear, saline injections were given in the usual manner (105-110°), but in the subcutaneous tissues over the axillæ breasts, and epigastrium. The resulting swellings were firmly rubbed to promote absorption. The solution was used freely, some patients receiving as much as nine pints. The author declares that previously unfavorable results from this method have been due to insufficient quantities of fluid injected. With ordinary antiseptic precautions he had only a few cases of abscess following injection and unfortunately three of tetanus, but each of these had septic wounds elsewhere at the time which would have provided a suitable nidus for the *Bacillus tetani*. One patient died on the fourth day after receiving his injection; he had sores due to scabies. One woman had ulcers on her leg and died three weeks after her cholera treatment, whilst the third, with an ulcer of the vulva, succumbed to lockjaw after seventeen days.

The Immediate Treatment of Extensive Wounds on Field Service.—C. A. Gill comments on the lessons taught by the recent wars in South Africa and the far East. He declares that the problem of field surgery is reduced practically to (1) arresting hemorrhage, (2) preventing shock, and (3) preventing sepsis. He maintains that the medical officers should always carry a freshly made morphine solution instead of tablets. The soldier's water bottle provides for the establishment of an antiseptic solution, and he himself has a first field dressing. The Japanese soldier carries also his own antiseptic tablets. The routine to be followed may be thus summarized: (1) The immediate application of an antiseptic lotion to a large wound. (2) The provision of the necessary antiseptic, the addition of tabloids of perchloride of mercury to the first field dressing packet, is suggested. (3) Following the first dressing a period of rest may be allowed which is highly convenient to the medical staff and conducive to the wellbeing of the patient. (4) Removal by ambulance transport to field hospital where operation may be undertaken on a patient whose vital powers have largely recovered from the shock consequent on his wounds.

Hematoma of the Ovary and Certain Other Closely Allied Conditions.—Clinical histories of eight cases are given by H. W. Wilson. All were operated on and all recovered. The author divides these cases into two groups: First, bleeding into a preexisting cavity and second, bleeding into the ovarian stroma. Such accidents occur in young women whose pelvic organs are at the height of their functional activity and whose tissues are exceedingly well nourished. In some instances there is a condition of old salpingo-oophoritis. It may be that the tough and thickened peritoneum on the ovarian surface prevents the intraperitoneal rupture of the follicle. Several blood cysts may thus form. Accidents are naturally more liable to occur at or about the menstrual period. Certain diagnosis is almost impossible. The two cardinal symptoms are abdominal pains and uterine hemorrhage. Vomiting and collapse may follow. The shock in cases without intraperitoneal hemorrhage is very profound and out of proportion to the severity of the actual lesion. Pelvic examination is unsatisfactory on account of abdominal rigidity. The slight cases may clear up in a short time under complete rest; but cases with pronounced symptoms call, of course, for immediate laparotomy.

British Medical Journal, May 26, 1906.

Heterochromia Iridis.—Referring to a case recently reported, R. H. Wellington explains the condition by stating that the *substantia propria* which is the ground substance of the iris has many connective-tissue corpuscles found in it, many of which contain, except in albinos and blue eyes, yellowish-brown pigment granules. The color of the iris varies according to the number of these pigmented connective tissue cells and to the amount of the pigment granules present in them. The posterior layer of the *substantia propria* is made up of polyhedral cells filled with dark pigment granules, except in albinos, where there are no pigment granules. Now, in blue eyes this posterior layer is the only pigmented part of the iris, and this is also the case in all newborn children; hence, we are all born with blue eyes. Such an iris appears blue because its dull tissue is

viewed on dark ground—that is, on the pigmental epithelium of the posterior surface. It appears, therefore, that if no pigment is in the eye at all, then the child is born an albino; if the pigment is limited to the posterior layer of the epithelium, as it is at the birth of us all, it gives the blue eye; and finally, if pigment is ultimately deposited in the anterior layer, it changes the eye from a blue one to the various shades we see from day to day, depending upon the amount of pigment deposited here as in other parts of the body. In heterochromia iridis there is a local deposit of pigment instead of uniformity throughout the iris. W. C. Louter also refers to this abnormality, and gives brief notes of nine cases coming under his own observation. None of the patients complained of any visual disturbances.

Very Early Conditions of Cancer of the Tongue.—H. T. Butlin gives the notes of seven cases, in which four distinct conditions were recognizable in the early stages of the disease. These are described as follows: (1) A flat very slightly raised smooth, red plaque feeling like a thin piece of gristle in the surface of the tongue, not thicker than an ordinary copper coin, looking and feeling very much like the ordinary primary specific lesion; (2) a white warty growth not ulcerated and scarcely indurated at its base; (3) a slight thickening and hardening of a leukoplakic area, rather distinguishable to feel than to sight, possibly an earlier stage of (1) and (4) a nodular plaque, red, and commencing to ulcerate, with indrawing of the surrounding tissues. In general, the author says that he has been in the habit of apportioning three stages to the development of the large majority of cases of cancer of the tongue. First of all we have predisposing conditions such as leukoplakia, ichthyosis, chronic superficial glossitis, which may exist for many years without the occurrence of cancer; but which undoubtedly render the individual much more liable to cancer than are individuals in whom the tongue is healthy. Then there ensues precancerous states as warty growths, thick plaques, sore places, which are not actually cancerous, but which inevitably proceed to cancer unless they are completely removed or destroyed. Finally we have actual cancer in one of its various forms, when it is obvious to an educated surgeon, and ought to excite suspicion in the minds of persons who are not experts. A colored plate and some section photographs accompany the paper.

Early Recognition of Cancer of the Breast.—G. L. Cheatle describes his method of examining the breast in a suspicious case, calling attention to methods of palpation and to the significance of retraction of the skin, flattening of a part or of the whole of the normal curve of the gland, the presence of enlarged glands in the axillary and supraclavicular regions, and retraction of the nipple and hemorrhage therefrom. A series of photomicrographs illustrates varieties of tissue found in operation. Some of the specimens removed may be of doubtful nature. We may find an epithelial activity, cells undergoing a somatic metosis. The condition suggests an early stage of cancer, but in reality it is not, although the author believes that this change in the alveoli which may become filled with papillomata may form one of the sources of origin of the so-called "duct cancer." The papillomatous changes above referred to may be much in evidence, but are occasionally found in women who have complained of no mammary symptoms whatever. Lymphocytes and plasma cells around the margin of the part removed for microscopic diagnosis are of value as indicating cancer only when they are seen in overwhelming numbers and crowding into and among the cells of the obvious lesion. We may overlook cancer, mistaking epithelial cells of the disease which have been so altered by inflammatory and toxic changes that they resemble connective tissue or inflammatory cells. Sometimes there are unusual changes in the staining properties and size of the fibrous tissue portions. Finally there is the early condition of cancer itself. Its microscopical appearance fortunately, as a general rule, is unmistakable, the epithelial cells invade the breast and the fat in its immediate vicinity, although their invasion is not advanced enough to produce retraction of the skin or to flatten the normal curve. The author's course in a doubtful case is as follows: An elliptical shaped piece of skin is mapped out, measuring three inches at its widest point, which is immediately over the suspected area. This piece is left untouched, but the skin around it is undercut in all directions, and that half of the breast which contains the suspected area is excised, together with the underlying part of the fascia covering the pectoralis major, and the elliptical piece of skin comes away undisturbed, with the parts thus removed The resulting cavity is then soaked with a 1 to 500 watery solution of perchloride of mercury, the wound is sewn up and temporarily covered over with a layer of gauze during the macroscopical examination of the suspected area, and if cancer is evident, gloves and instruments are changed and the breast at once removed.

Propagated Cancer.—E. F. Bashford contributes an illustrated paper on this subject. His experiments illustrate the identity of the sporadic malignant new growths of the mouse in all their anatomical features with those of man and the reproduction of the gross morbid anatomy of malignant disease as met with in the human subject in the artificially-propagated cancer of the mouse. Although malignant new growths are far from rare in these animals, he has found it difficult, in fact, exceptional, to obtain a growth which can be propagated with certainty in a large number of animals for long periods. The tumors which result from the subcutaneous implantation of cellular grafts in mice are usually of an irregularly rounded form, and show but little tendency to infiltrate deeply into the subjacent tissues. They are, however, highly malignant. Metastasis follows the development of experimental tumors in the subcutaneous tissues, peritoneum, and other localities. Microscopical emboli of cancer cells are very frequent in animals whose lungs appear to the naked eye free from secondary deposits, but enormous metastases replacing almost the entire respiratory area are not infrequent when animals are allowed to live for a longer time. The author's experiments give conclusive evidence that a specific cachexia or symptomatology do not exist in mice. He declares that it is certain that the early diagnosis of cancer and its successful treatment depend, not on insistence on the search for supposed early symptoms of the disease, but on the recognition by the practitioner of the absence of symptoms apart from an anatomical lesion of minute dimensions.

Berliner klinische Wochenschrift, May 21, 1906.

A New Method of Catgut Sterilization.—Karewski says that in spite of the very considerable number of methods which have been devised for sterilizing catgut no procedure has yet been perfected by means of which it is possible to secure an altogether satisfactory product. He states that after a great deal of experiment the following plan of preparation has been elaborated in his clinic. The object was to prepare the catgut without the use of any antiseptic or the addition of any substances likely to prove irritating to the tissues, and without impairing its tensile strength and elasticity. It was, furthermore, to be preserved in such a container as to make sterilization of this possible by boiling, and permitting division of the catgut into lengths as required without handling with the fingers. The method is described as follows: The catgut is boiled first in glycerin, after which it is soaked in ether and alcohol. It is then placed in glass tubes having a constriction at one end through which one end of the thread is passed and knotted. The tubes and their contents are sterilized by being subjected for twenty-five minutes to the vapor of 70 per cent. alcohol at a temperature of 70°C., a suitable autoclave for this purpose being described. The tubes are sealed at one end and are then filled in vacuo with absolute alcohol containing 1-3 per cent. of glycerin; after which the other end is also sealed, and the tube is heated again during one hour at a temperature of 103°C. Catgut prepared in this way is absolutely sterile, as was demonstrated by a very extensive series of bacteriological tests, and keeps indefinitely without impairment of its physical properties. Before use the tubes may be sterilized if it is desired by boiling in soda solution for a short time, without injury to the catgut. The author details at length the numerous advantages which, he believes, pertain to this method of sterilization. When the catgut is to be used the tube is broken at the constricted portion and the knotted end remaining in the smaller fragment enables any desired quantity to be withdrawn without subjecting the unused portion to any external contact. What is left in the container may be kept sterile by immersing the tube in 70 per cent. alcohol.

Münchener medizinische Wochenschrift, May 22, 1906.

The Diagnosis of Congenital Stenosis of the Small Intestine.—Walz describes a case of atresia of the duodenum combined with horseshoe kidney. He concludes that the occurrence of such deformities is due to a developmental defect as shown in this case by the presence of the abnormality of the kidney. A feature of importance from the diagnostic standpoint is that even in complete atresia of the duodenum meconium may be passed. The addition of constituents of the liquor

amnii is not necessary for the formation of yellow meconium. In every case of persistent vomiting of the new born the author considers that a microscopical examination of the meconium should be carried out as the operative treatment of intestinal atresia has a favorable outlook only if the diagnosis is made early. If there is no spontaneous passage of meconium the effort should be made to obtain some by a rectal irrigation. If no lanugo hairs are present in the meconium the conclusion is justified that a complete intestinal occlusion arising before the fifth month of development, must exist. This diagnosis is corroborated by the absence of squamous epithelium and fat droplets from the meconium.

Criminal Abortion.—Schickele says that this practice is becoming more and more common in Germany, and describes a number of illustrative cases to show some of the methods of instrumental abortion employed. In order to determine whether the abortion is a criminal or a natural one, he says that it is of importance to examine the external and internal genitals for fresh lacerations or other evidences of trauma. If the fetus is expelled without hemorrhage and without pain the induction of criminal abortion should be suspected. If the fetus presents injuries such as would be effected by the introduction of instruments into the uterus the nature of the abortion is revealed. The occurrence of severe infection immediately or shortly after a miscarriage is also strong evidence in favor of the assumption of an illegal manipulation. The author discusses the conditions which lead to the commission of this offense, and states that it should not be as harshly judged as is usually done.

The Treatment of Acute Otitis Media.—Scheibe presents an analysis of the etiology and therapeutic results obtained in a series of 527 cases of otitis media observed in private practice. The treatment employed may be summarized as follows: Acute middle ear disease without perforation is first treated either with the catheter or with the Politzer method. If the mastoid is sensitive the ice bag is applied. In addition rest and abstinence from alcohol are prescribed, and if there is an acute nasopharyngitis this also is treated. If the pain increases and there is bulging of the drum membrane, increasing tenderness over the mastoid, or fever with diminution in hearing, paracentesis is practised. If discharge is present the meatus is daily washed, irrigated with warm 4 per cent. boracic acid solution, Politzer's method is used and the meatus is insufflated with boric acid powder and is plugged with cotton. The ordinary systemic measures are also taken, and if there is evidence of involvement of the mastoid, as is shown by swelling behind the ear or bulging of the posterior wall of the meatus, the process is opened. The paper also contains a detailed analysis of the different groups of cases encountered.

Deutsche medizinische Wochenschrift, May 24, 1906.

Internal Hemorrhage Following Ectopic Gestation.—Busalla in discussing this subject states that the rapid diminution in the volume of circulating blood attending abdominal hemorrhage is accompanied by a prompt fall in blood pressure with all of its consequences. As a result the cerebral terminations of the cardiac accelerator nerve are stimulated and the heart action becomes rapid. The small size of the pulse, the facial pallor, the coldness of the extremities, and the fainting are other manifestations due to the reduction in the volume of the circulating blood. The vomiting and abdominal pain are caused by the peritoneal irritation induced by the shed blood. This sequence of events does not always follow, however, and occasionally the diagnosis must be made in spite of a pulse that appears incompatible with concealed hemorrhage. The author describes a case of this nature in which, although the other symptoms strongly suggested rupture of an ectopic gestation, the pulse was regular, soft, moderately full and only 56 to the minute. In spite of this condition of the pulse a laparotomy was performed and a ruptured tube with about two liters of partly fluid blood free in the abdominal cavity were found. The patient made an uneventful recovery, the pulse going as high as 104 on the day after the operation, but after that remaining between 60 and 70.

Operation in Barlow's Disease.—Riese advocates operative treatment of the subperiosteal hemorrhages that form so conspicuous a feature of this condition. Although surgical intervention has been considered dangerous in this disease on account of the risk of secondary hemorrhage, the author does not consider that this possibility involves very grave hazard. He recommends incision through the soft parts and periosteum about the affected extremities of the bones in order to secure free drainage. He describes a case in which this procedure was carried out with great success, and states that he has used it in other instances with equally satisfactory results. Moderately free incision followed by drainage is to be preferred to simple aspiration. Surgery is to be recommended only in the graver cases, however, as the less severe forms of the disease promptly respond to suitable dietetic treatment.

The Pancreas and Diabetes.—Herxheimer expresses the following view in regard to diabetes, and particularly concerning the participation of the islands of Langerhans in the causation of the disease. The cells of the pancreatic acini in addition to the external secretion produce another substance controlling carbohydrate metabolism. The islands are formed from the parenchyma cells and gradually lose their connection with the external secretion. They are particularly active, however, in producing the internal secretion, a function for which they are well adapted through their richness in capillaries. In diabetes there is impairment of function of both components of the pancreas, but the impairment of function of the islands is of the greater importance. The new formation of the cell islands in diabetes therefore represents a regenerative process of the highest order. It is still impossible to determine exactly what type of injuries affect the pancreas in this way, but in part of the cases, at least, arteriosclerosis, especially of the capillaries of the cell islands, may be at the bottom of the process.

French and Italian Journals.

Tuberculous Appendicitis.—Gabriel Hérisson in speaking of the diagnosis of this affection states that in the majority of cases it is difficult and sometimes clinically impossible. Aside from those cases of appendicitis which are never detected until autopsy, the writer believes that ordinarily the clinician makes a diagnosis of appendicitis not recognizing the tuberculous nature of the trouble which the miscroscope alone reveals. However, there are a number of symptoms and etiological conditions, which, if carefully observed and judiciously interpreted, may lead to an exact diagnosis. Diarrhea is common in tuberculous appendicitis, but exceptional in simple appendicitis. This symptom is not constant, but when it is present it is of the greatest value. The presence of inguinal ganglia is of only slight value. Far more important is the induration of the cecoappendicular ganglia. Frequent relapses, especially when they are separated by incomplete remissions without entire subsidence of the phenomena, are far more characteristic of tuberculous appendicitis than of ordinary appendicitis. The personal and family history of the patient should be considered. The method of serodiagnosis is valuable. The prognosis of tuberculous appendicitis is doubly grave, for not only the disturbance of the appendix itself has to be considered, but also its tuberculous nature.—*Gazette des Hôpitaux, Civils et Militaires*, April 14, 1906.

Arterial Poisons and the Etiology of Atheroma and Arteriosclerosis.—Maurice Loeper states that atheroma and arteriosclerosis may be considered clinically as the result of slow or prolonged toxic irritations of arterial tissues. Recent investigators who have conducted experiments on some of the lower animals, have isolated from the supposed poisons substances with an action especially sclerosing or inflammatory, and others with a veritably calcifying action. The first lead to the formation of sclerous endarteritis, the second group cause lesions of calcification very analogous to certain alterations of the middle coat of the human artery. Future investigations will show if there are two groups of different causes to be considered in the double process of human arteriosclerosis and atheroma.—*La Presse Médicale*, April 14, 1906.

Affections of the Skin Most Often Associated with Syphilis.—Thibierge speaks of certain cutaneous affections which tend to confuse the diagnosis of syphilis. Pityriasis rossa often appears coincidently with the secondary lesions of syphilis and resembles roseola. In such cases other specific lesions should be searched for, especially those of the mucous membrane. Various forms of erythema are observed principally in changing seasons in young subjects. These lesions may or may not be accompanied by infiltration and exudation; they may vary from a simple red spot to erythema bullosum. The preceding history of the patient must be investigated. Finally the itch sometimes appears in these cases, and former evidences of syphilitic infection must be carefully searched for.—*Journal de Médecine de Paris*, April 15, 1906.

Book Reviews.

Histological Studies on the Localization of Cerebral Function. By Alfred W. Campbell, M.D., Pathologist to the Asylums Board in the County of Lancaster. Published by aid of a subsidy from the Royal Society of London. Cambridge: The University Press, 1905.

Of this magnificent and scholarly work, which represents a large expenditure of well-directed energy and time, we cannot in the space at our disposal give anything like an adequate notice. The scope of the book is best indicated by the titles of the various chapters: 1, material and methods of examination; 2, general remarks on cell lamination and the arrangement of nerve fibers in the cerebral cortex; 3, the precentral or motor area; 4, the postcentral or sensory area and the intermediate postcentral area; 5, the visuosensory and visuo-psychic areas; 6, the temporal lobe and the auditory areas; 7, the limbic lobe; 8, the parietal area; 9, the intermediate precentral area; 10, the frontal and prefrontal areas; 11, the island of Reil.

The material, on which the author's studies are based, was derived from three sources: The normal human; this consisted of three cerebral hemispheres completely examined for fibers only, and two hemispheres partially examined for nerve fibers and nerve cells. 2. The normal comparative; this consisted of the right cerebral hemisphere of a chimpanzee, completely examined for nerve fibers and partially investigated for nerve cells; the left hemisphere of another chimpanzee, completely examined for fibers only; and the right hemisphere of an orang, completely examined for fibers only. 3. The pathological; this consisted of two brains from cases of amyotrophic lateral sclerosis, seven from cases of amputation of one or other extremity, three from cases of tabes dorsalis, and one from a case of old-standing capsular lesion; and the occipital lobe was examined in two cases of old standing blindness. An Addendum contains the result of further investigations on the brains of the cat, the dog, and the pig. At the end of each chapter there is a valuable summary, which will be appreciated by those who have not the time or the inclination to follow the author through the many histological details with which the book naturally abounds. There is also a list of bibliographical references at the end of the chapters; and the volume closes with a complete index of authors and subjects. The book is exceedingly readable, the author's claims are modestly put forth and are more than substantiated, and due recognition is given to the work of colleagues and previous observers.

The Diseases of Infancy and Childhood; Designed for the use of Students and Practitioners of Medicine. By Henry Koplik, M.D., Attending Physician to the Mount Sinai Hospital; Formerly Attending Physician to the Good Samaritan Dispensary, New York; Ex-President of the American Pediatric Society; Member of the Association of American Physicians, and of the New York Academy of Medicine. Second Edition, Thoroughly Revised and Enlarged. New York and Philadelphia: Lea Brothers & Co., 1906.

In this new edition of Koplik's "Diseases of Infancy and Childhood" the general plan of the original work remains unchanged; but the various sections have been revised and some of them have been entirely rewritten. This latter is particularly apparent in those parts of the book devoted to the subjects of Infant Feeding and the Diseases of the Newborn. The section dealing with Infant Feeding covers the ground very fully, and is one of the most valuable chapters in the book. The author gives his own experience, and also describes other methods. Milk analysis, pasteurization, sterilization, food preparations, composition of various infant foods, maternal nursing, selection of a wet nurse, mixed feeding, artificial feeding of infants, all receive careful and minute attention. The physiology and pathology of the newborn is treated with more thoroughness than is customary in text-books; and the chapter on the diseases of the newborn is very satisfactory and will well repay perusal by students and practitioners. The book is both readable and practical, and it reflects the large personal experience of the author. Many new illustrations have been added to this edition, which is larger than its predecessor by some two hundred pages. The author's plan, as stated in the preface, was to present a succinct reflection of the pediatric practice and knowledge of the day; in this he has been eminently successful.

Die Orthodiagraphie. Ein Lehrbuch für Aerzte. Mit 75 Abbildungen und 3 Tafeln. Von Dr. Karl Francke, Specialarzt für innere Leiden in München. München: J. F. Lehmann's Verlag, 1906.

Orthodiagraphy and orthodiaphotography are the somewhat ponderous terms used by Prof. F. Moritz of Giessen to designate his method of mensuration of the internal organs, particularly those of the thorax, by means of a special application of the *x*-rays. The rather difficult technique of the process is well set forth by Dr. Francke in this brochure of 100 pages, which also contains numerous reproductions of records and tabulations obtained by the author. The subject is of much interest, and while it is not likely, for the present at least, that the method will attain great popularity, it promises to be of value for the purposes of scientific medical research.

Outlines of Medical Diagnosis. Prepared for the use of Students at the Harvard Medical School, Boston. Fourth Edition. Boston: F. H. Thomas Co., 1906.

This little book consists of about thirty pages, and contains a good outline of the chief methods of medical diagnosis. The beginner must have some plan by which to work; and this pamphlet will keep him from serious omissions, and at the same time make his procedures methodical and therefore of value to himself and also to his patients.

Indigestion; an Elementary Study of Its Causes and Treatment. By Fernandez Clarke, L.S.A. Lond., L.R.C.P., Lond., M.R.C.S. Eng., etc., etc. New York: William Wood and Company, 1906.

This little book contains a brief and elementary account of the subject of indigestion. The physiology of digestion is first reviewed; then the various causes of indigestion are considered; and in the concluding chapter the author shows how impossible it is to treat all cases of indigestion by any given fixed rule. There are also chapters on anemia and constipation.

Manuel Pratique pour le Choix des Verres de Lunettes et l'Examen de la Vision, par le Docteur Scrini, Ancien Chef de Clinique Ophthalmologique à la Faculté de Paris, Lauréat de l'Academie de Médicin, Membre de la Société de Thérapeutique, et le Docteur Fortin, Médecin Oculiste. Paris: Vigot Frères, 1906.

This little volume of 228 pages is divided into six chapters, of which the first is devoted to a description of the properties of lenses and the materials of which they are made. The second chapter takes up the consideration of physiological optics. The third treats of the determination of ametropia. The fourth describes binocular vision. The fifth takes up the consideration of the writing of prescriptions for glasses for the correction of the various errors of refraction, and the sixth describes the mountings employed. There are twenty-four figures in the text. The subject is treated briefly and masterfully, but in an elementary manner.

Nouveau Traité de Médecine et de Thérapeutique, publié en fascicules sous la direction de MM. P. Brouardel et A. Gilbert, professeurs à la Faculté de Médecine de Paris. Maladies de la Bouche, du Pharynx, et de l'Œsophage par les Drs. G. Roque et L. Galliard. Paris; J. B. Baillière et Fils, 1906.

This volume of Brouardel and Gilbert's New System of Medicine and Therapeutics deals with the upper part of the digestive tract. There are chapters on diseases of the mouth, including the various forms of stomatitis, gangrene, and aphtha. On diseases of the tongue there are three sections dealing respectively with geographical tongue, black tongue, and leukoplakia. Diseases of the pharynx cover about one hundred and forty pages, and are thoroughly discussed; this is by far the longest portion of the book. The concluding fifty pages of the volume are devoted to diseases of the esophagus; one section being on the various parasitic diseases which can affect the esophagus. The general plan of the work is similar to that of the previous volumes of the series which have been already noticed in the pages of the Medical Record; and the present volume is up to the same high standard as its predecessors.

The World's Anatomists. Concise Biographies of Anatomic Masters from 300 B.C. to the Present Time, Whose Names Have Adorned the Literature of the Medical Profession. By G. W. H. Kemper, M.D., Professor of the History of Medicine in the Medical College of Indiana, Indianapolis, Ind. Revised and Enlarged from the Original Publication in the Medical Book News. With Eleven Illustrations, Nine of which are Portraits. Philadelphia: P. Blakiston's Son & Co., 1905.

Captious critics might complain that in a list of 245 anatomists the names of Poirier, Cunningham, Huntington, Zuckerkandl, Toldt, and Ramon y Cajal might well be included; that in a series of biographies of anatomists such men as Henry Gray, Joseph Hyrtl, and Quain deserve more than the mere mention of the dates of their birth and death; that Kölliker has been dead long enough to make the statement that he is "still living" inexcusable, etc. But if allowance is made for inconsistencies of this sort the present pamphlet may be found of use where larger works of reference are not available.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-seventh Annual Meeting, Held in Boston, June 5, 6, 7, and 8, 1906.

(Special Report to the MEDICAL RECORD.)

DR. LEWIS MCMURTRY OF LOUISVILLE, KY., IN THE CHAIR.

(*Continued from page 956.*)

HOUSE OF DELEGATES.

Proposed Investigation of the Treasurer and Editor.—Dr. H. O. WALKER of Detroit, referring to the great dissatisfaction felt and expressed by so many members with the management of the affairs of the Association, offered a resolution that a committee of five be appointed to investigate the management of the Association, and the way in which its *Journal* was conducted, to go over the business accounts, and in other ways to ascertain and report upon all the facts which were now unknown or not understood by the great body of members of the Association. That the distrust of those who managed the affairs of the Association was felt by a large and increasing number of the members was evidenced, he said, by the fact that the retiring president, in his address, found it necessary to express his disbelief in the existence of a "ring" having the Association under its control. A motion to lay the resolution on the table was carried.

The Journal and the Postal Laws.—A resolution was passed to the effect that a portion of the dues of each member of the Association be set aside as a subscription to the *Journal*, so that the postal laws might in future be complied with.

The Annual Orations.—It was voted that hereafter the orators in medicine, surgery, and State medicine be selected by the Sections on Medicine, Surgery, and Hygiene respectively, instead of being appointed by the House of Delegates.

Resolution of Thanks.—Resolutions were passed in appreciation of the hospitality shown to the members and guests of the Association by the local physicians, and of thanks for the admirable work done by all those who had had to do with the arrangements for the week's program. A resolution of thanks to the Council on Pharmacy and Chemistry was also voted.

Officers.—The election of officers resulted in the choice of the following: *President*, Dr. Joseph D. Bryant of New York; *Vice-Presidents*, Drs. Herbert L. Burrell of Boston, Andrew C. Smith of Portland, Ore., E. S. Fairchild of Des Moines, Iowa, and W. S. Foster of Pittsburg, Pa.; *Treasurer*, Dr. Frank Billings of Chicago; *Secretary*, Dr. George H. Simmons of Chicago; *Trustees*, Drs. M. L. Harris of Chicago, W. H. Welch of Baltimore, Md., and Miles M. Porter of Fort Wayne, Ind. Atlantic City was chosen as the place of meeting in June, 1907.

SECTION ON DISEASES OF CHILDREN.

First Day—Tuesday, June 5.

Address of Welcome.—Dr. THOMAS MORGAN ROTCH of Boston delivered the Address of Welcome, referring to the early history of the Section, recounting some of the problems in the treatment of diseases of children which had been solved and mentioning others which still claim the close attention of the pediatrist. He extended a graceful and cordial welcome to the members to Boston.

The Pediatric Outlook.—Dr. W. C. HOLLOPETER of Philadelphia, chairman, delivered an address with this title, mentioning some of the barriers against professional progress which had been overcome, such as the treatment of the dread diphtheria, the exanthemata, and other infectious diseases. The increased knowledge of food modifications was mentioned as an important advance, with the enlarged appreciation among the laity of the laws of personal and domestic hygiene. He thought the offer of the Mayor of Huddersfield, England, to give prizes to mothers for yearling babies as an incentive to keep their infants alive, would be of little value without further effort for the betterment of the nation. Life with health was to be regarded as a boon accomplishment rather than the mere maintenance of life. The author felt that there was no more vital touch to national life and spirit than that given by the citizen in the devotion of his life work to the welfare of the child. A problem yet to be solved was the education for maternity. A maternal mind previously prepared in hygienic instruction was considered of much value. Careless medical inspection of houses and schools and public institutions, it was felt, led to a false sense of security; but so long as politics remain on a low plane, so long will crime and graft crush out young life. Great emphasis was laid upon the necessity for *clean*, not sterilized or pasteurized milk. The great possibilities in the proper care of defectives were outlined. Extended reference was made to the argument of Mr. Havelock Ellis for placing matrimony upon a scientific basis. Mr. Ellis states that investigations show that there are certain definite matrimonial tendencies; that like are attracted rather than unlike, and that "while some kinds of people tend to be married with special frequency, other kinds tend to be left unmarried." Dr. Hollopeter regarded the argument of Mr. Ellis for the betterment of the race through the eugenic selection of parents sufficiently forceful, but confessed to a feeling that humanity was not prepared for the departure.

Injuries to the Child's Head During Labor.—Dr. B. SACHS of New York City presented this communication, speaking of his efforts through many years to enlist the interest of the obstetrician and of the general practitioner in the injuries which the child's brain was apt to sustain during parturition and of his belief that there are innumerable imbeciles, paralytics and epileptics in the world to-day who might have been normal individuals had they been given a "square deal" at the time of birth. He had observed that a very considerable number of the cases of infantile cerebral paralysis were either first born children or such who had been born after prolonged, often dry labor. Statistics of several hundred of such cases showed less harm by instrumental delivery than by prolonged labor, although unskillful instrumental delivery had been a frequent cause of trouble. If physicians were more confident of the safety of the forceps and of their own skill to apply the same, protracted labor would not be as powerful an etiological factor as at the present time. A word of warning was given to the obstetrician, that other things being equal, and above all, the life of the mother not being in danger, it was wise to curtail the period of labor as much as possible and not wait until the child's heart action became feeble. Reference was made to Cushing's recent suggestion of opening the skull in severe cases of meningeal hemorrhage at birth and washing out of the blood clots. In three of five children so operated upon by Dr. Cushing cure was effected so far as Dr. Sachs knew. Such a daring procedure, however, would apply to relatively few of the cases. He believed that dependence must be placed wholly either upon prophylactic measures or upon more skillful manipulation of labor on the part of the obstetrician. While not suggesting a modification of the rules of the obstetrician Dr. Sachs felt that the medical men in attendance at confinements had for years followed a policy of indifference toward the welfare of the child, allowing too many children to be born into the world after labor unnecessarily prolonged and in conditions of distinct disadvantage to them and to society for the entire period of their natural lives.

Dr. EFFIE DAVIS of Chicago thought rather that injuries to the child's head during labor were due more frequently to the use of forceps than to prolonged labor. As a much more satisfactory plan than the use of the forceps she sug-

gested the regulation of the size of the child, particularly in patients of the higher classes who had plenty of leisure.

Dr. C. G. Kerley of New York City believed there were more of the cases mentioned by Dr. Sachs than there should be. He agreed with the view that the accidents were due to compression in prolonged labor rather than to actual injury from the forceps. In his observations degeneracy in the parents had not been a factor in the injuries.

Dr. Gilbert of Louisville had found of value the method of inducing labor, especially in primiparas, two or three weeks prior to the full term. He employed a tampon soaked in glycerin solution and never introduced an instrument into the uterine cavity for this purpose.

Dr. J. C. Cook of Chicago believed that in the majority of cases of injury at birth the cause was either prenatal or postnatal.

Dr. Sachs in closing emphasized his reason for introducing the subject, which was to get the influence of the members of the Section in furthering the cause of regarding the child at birth as well as the mother.

Heredity and Environment as Factors in the Life and Diseases of Children.—Dr. C. F. Wahrer of Fort Madison, Iowa, referred to the authority of Genesis that every living thing, whether it be plant or animal, should produce offspring after its own kind, thus establishing the law of heredity, and at the same time forming abundant proof for those who believe in the so-called bathmic evolution. While no one, he takes it, from scientist down to the most ignorant casualist denied the matter of heredity, yet many biologists as well as psychologists had devised different and even antagonistic theories to account for heredity and its correlative factor, environment. According to Weismann only inherent qualities can be transmitted to offspring; acquired characteristics not being transmissible. According to Darwin, the transmission of acquired as well as inherent qualities is possible. The views of other philosophers were given. Reference was made to the fact of the practice of circumcision among the Jews for thousands of years but that no Jewish boys are born without their foreskins. Shepherds had amputated the tails of all lambs for centuries innumerable, but to-day no bob-tailed sheep are born. Per contra, Brown-Sequard created artificial epilepsy in guinea-pigs and saw epilepsy develop in the offspring, even to the third generation. The question is raised, are diseases, like certain traits, inherited, that is, transmitted from ancestor to posterity? If so, have these diseases always existed in this particular tribe or family, or were they first acquired and then transmitted? If the latter, how can Weismann be right? Despite the dictum of Weismann Dr. Wahrer regarded the consensus of opinion of philosopher, philanthropist and statesman, of scientist and sage to be against him as far as the practical results of education and training were concerned. This being the fact, pediatrists were encouraged in combating diseases in children and in preventing disease tendencies of the mind and body. The conduct of society to all its members Dr. Wahrer felt could never be placed upon permanent bases without regard being paid to what science teaches upon the fundamental problems of inheritance.

Dr. Rhoads of Pittsburg remarked that the subject of transmission from parent to child was one which had been studied for hundreds of years, and that at present little more was known than at the beginning of the researches.

Dr. Hansell of Ohio thought that in the question of heredity and environment the fact was lost sight of that heredity is slow in action, environment rapid; for instance, in the careful selection of seed corn which has taken years to develop, if the corn be placed in poor soil or, in other words, poor environment, it will not produce a well-covered cob, and if successively planted in poor soil, all the good gained by heredity will disappear. The same law would work out in animal life; for instance, a horse used for breeding horses of great speed will, if put in the plough, lose the ability to produce offspring capable of racing.

Dr. Gilbert of Louisville said he believed that the fact of accidents to the fetus in *utero* from impressions made upon the mother, or even from traumatisms, was well established.

Dr. Robbins of Ohio stated his belief that if Jesus Christ had left one drop of His blood in the human race he would believe that one person might be superior to another; since He did not, Dr. Robbins believed that environment was the important factor in the development of the race as it is to-day.

Dr. Keyser of Boston referred to the settlers of New Zealand and Australia who were convicts. The character of the present inhabitants he thought was an evidence of the possibilities of environment.

Hemorrhage in the Newborn.—Dr. H. McClanahan of Omaha gave a review of the literature pertaining to hemorrhage in the newborn. That the hemorrhage is due to a specific condition he thought entirely probable. The important principles of treatment he considered to be to control the hemorrhage and to aid the nutrition of the child, and to maintain body heat. The details of treatment were given in reports of cases. Five cases of cephalohematoma were reported under the head of traumatic hemorrhage. The diagnosis is usually simple and is made upon the location of the tumor, the bony ring that forms around the periphery of the mass, and the absence of pulsation. The report was appended of one case of hemorrhage of the lungs in the newborn.

Dr. I. A. Abt of Chicago felt that hereditary syphilis was a factor in the hemorrhages of the newborn; also infection of the ordinary pathogenic microorganisms, the streptococcus, the staphylococcus, or even the colon bacillus, might in a large number of cases be the etiological factor.

Blood Cultures in Children and their Significance.—Drs. Thomas Morgan Rotch and Harry Chamberlain Low of Boston contributed this paper. The points treated were: (1) Blood cultures in the living, a modern and important diagnostic measure; (2) difficulties of technique in children; (3) character of cases where blood cultures would be of value in children; (4) illustrative cases.

Dr. E. E. Graham of Philadelphia thought the blood cultures often of distinctive value, whether or not a special organism were found. If the case were suspected of being tuberculous, it was possible to find the tubercle bacillus, but not finding it did not prove that the case was not tuberculous. Many cases of concealed pneumonia were immediately cleared up by the finding of the pneumococcus.

Second Day—Wednesday, June 6.

Bacteriological and Blood Findings in Thirty-Six Cases of Bowel Infection in Infants.—Dr. J. C. Cook of Chicago said that the work was taken up with the hope of obtaining findings pointing to the relation of the condition of the blood, the enlargement of the glands and spleen, and the bacterial and metabolic intoxications. An accompanying chart showed the most important data in each case. The cases were arranged with regard to the red blood count, the highest to the lowest, that being the most logical order upon which to make comparisons. In every case of examination of the blood, including a count of the red and white cells, a differential count of the white cells and a hemoglobin test were made. In cases in which a general infection was suspected cultures from the blood were made. Microscopical examinations from the stools and throat were recorded upon another chart. Of the physical findings only the enlarged glands and spleen were recorded. In the cases of anemia the red blood counts varied from 8,850,000 to 3,256,000; and the white count from 6,600 to 53,000. The differential counts of white cells were as follows: Small lympho-

cytes, 4-77; large lymphocytes, 6-56; neutrophiles, 8-87; eosinophiles, 0-10. The hemoglobin ranged between 45 and 100; the color index between 1.5 and .4. The logical conclusion regarding the variation of the red count was that there was a concentration of the blood in those cases showing clinical aspects of anemia and high red counts. To the author the significance of the blood examination was that in those cases presenting the clinical aspect of an anemia and a high or even normal red blood count, there was concentration of the blood pointing to the lack of sufficient ingestion of fluids or to a depletion of the system from vomiting or from diarrhea, and indicating a high concentration of toxic substance.

Dr. J. L. Morse was impressed with the record of the high blood count and questioned the explanation given by Dr. Cook. A more reasonable explanation to him was the fact that in all conditions of malnutrition there was a contraction of the superficial capillaries and a concentration of the blood in the central circulation, so that the red count taken from the ear or finger did not give a true picture. The changed blood count in anemias was known to be due not to the anemia but to the disturbed nutrition which was the cause of the anemia.

Dr. A. H. Wentworth of Boston thought there must be some error in the red blood counts, and inquired whether all were made by the same person.

Dr. Cook in closing thought the criticism of Dr. Morse just, and one probably throwing some light upon the question. Replying to Dr. Wentworth, he said all the counts were made by the same man, and that the facts were true as stated. He thought the great concentration of the blood explained the fact that as many of these patients died of toxemia from concentration of the blood as from actual exhaustion.

The Utility of Saline Solutions in the Treatment of Febrile States.—Dr J. Madison Taylor of Philadelphia read this paper, relating his further experiences and conviction on the practical use of saline solutions in all fever states. Fever being a protective process in great measure, the aim should be to conserve to the uttermost the autoprotective forces of the organism to which Sajous gave particular emphasis in 1903. The way to do this was said to be to begin the use of saline solution as early as possible, continuing it throughout the fever, until a general diet permitted the normal intake of salines to be resumed. He reiterated his opinion expressed in connection with pneumonia, and added further testimony, giving a number of cases of extreme severity treated in this way. Dr. Taylor said that his method was to give all such febrile cases freely to drink of the physiological salt solution a half hour before each feeding every three hours. In this way the organism was fortified through the enhancement of the action of the ductless glands to form antibodies and furnish the equivalent of antitoxic sera.

Case of Meningitis with Isolation of Bacillus Diphtheriæ from the Cerebrospinal Fluid.—Dr. A. C. Cotton of Chicago offered this volunteer paper describing a case reported from the Pathological Laboratory of Cook County Hospital by Dr. Joseph Morrell and Herman E. Wolf. The organism was isolated at two spinal punctures and again at the postmortem, as also from the throat. The organism was described morphologically and as to culture characteristics, in which it agreed with *B. diphtheriæ*. Lesions were produced in guinea-pigs quite typical for *B. diphtheriæ*, with which it also agreed in its ability to ferment certain sugars.

A Further Contribution to the Study of the Stools in Starch-fed Infants.—Drs. C. G. Kerley and H. N. Mason of New York presented this paper, which was based upon the result of observations in sixty children, 324 stool examinations having been made in infants varying in age from a few days to one year, undertaken to ascertain something definite relative to the starch digestion capacity of children of different ages. Barley flour was used, which was boiled one hour and a half; the cereal water was used both as a diluent to the milk food and as a milk substitute. In thirty-three children the stool examinations were persistently negative to starch. Of these twenty-two were between six and twelve months, eleven being under six months. Seven cases were persistently positive, showing starch at each examination. The stools in the remaining twenty children showed sometimes positive, sometimes negative. Eight of these were positive in the majority of examinations and are recorded as showing a positive tendency. Twelve were negative in the majority of the examinations and are recorded as showing a negative tendency. Among the sixty cases forty-one showed a good starch capacity, nineteen a poor or indifferent starch capacity. That some of the starch might have undergone fermentation in the intestines, but that it was of no great moment, was explained by the author. The influences of feces bacteria acting as an enzyme was also brought out in the paper.

Dr. G. R. Pisek of New York said that Dr. Kerley had proven his case by clinical facts. He thought all were ready to dilute the milk with cereals as soon as they could feel sure that the starch would be taken care of.

Dr. Thomas W. Southworth thought the paper would remove the question of doubt of starch digestion by infants. A point of interest to him was the length of time—an hour and a half—that the cereal was cooked. To increase the time of cooking these starch preparations he thought was the present tendency.

Dr. T. W. Kilmer of New York thought there should be no age limit in regard to the starch feeding; this was also true of the quantity of milk an infant should take, and in regard to its clothing.

Dr. J. B. Learned of Northampton, Mass., spoke in favor of giving whole milk to infants and referred to a case in his own family in which this had been done successfully.

Sodium Citrate in Infant Feeding.—Dr. A. C. Cotton of Chicago in presenting this paper remarked incidentally that the infant deprived of the breast must, in relation to his feeding, be regarded as a pathological problem. The important question in feeding cow's milk was how to increase the proteids and maintain unimpaired digestion. He was convinced that sodium citrate, through its inhibition of dense coagulation of cow's milk in the presence of acid and rennin ferment, was valuable in this respect. In the last two years he had used it in more than fifty cases in hospital and private practice. A report of eight cases by Dr. J. D. Merrill and the history of twenty-nine cases of Dr. Vanderslice were also referred to; in these the results were satisfactory. In the employment of the method an aqueous solution was ordered containing from one to five grains to the dram. A quantity of this solution was furnished the mother or the nurse, with instructions to add to the baby's bottle immediately before feeding enough of the solution to represent from one to three grains of the citrate to each ounce of milk in the feeding mixture. An indication for the increase of the sodium citrate, in some cases to as high as three grains to the ounce of milk, was vomiting of curds or the appearance of curds in the stools, care being taken to exclude indigestion from excess or intolerance of fats. The duration of the exhibition of the sodium citrate varied in individual cases. No case of citrated milk feeding had been brought to the operator's attention in which the results were unsatisfactory. The method especially commended itself to the author in dispensary practice where the mother's demand for "medicine" for her baby's dyspepsia might be met by the standard solution of sodium citrate to be administered in the bottle of feeding mixture.

The Trend of Pediatric Opinion Concerning the Artificial Feeding of Infants.—Dr. Thomas S. Southworth of New York in this paper said that the spirit of inquiry was now engaged in testing the principles upon which artificial feeding rested. Only milk formed the soft solids necessary to develop the stomach, and all methods of

feeding or any recipe had the common purpose of making the infant digest enough of the casein of cows' milk to thrive. Whether all the starch granules in a cereal diluent were digested was not as important as the latter's mechanical effect upon the curd and the presence of the important absorbable vegetable proteids which it contained. We had ceased to add alkalis upon general but vague or unknown principles. Lime water added to fresh milk changed its normal constituent bicaseinate of calcium into caseinate of calcium, which was no longer coagulable by rennet. The usual 5 to 10 per cent. of lime water rendered noncoagulable but small quantities of milk. As the strength of the milk mixture was increased more and more coagulable casein was present. Other alkalis, such as sodium carbonate, potassium carbonate, or magnesium hydroxide, also altered the digestive properties of milk and probably formed caseinates of calcium and sodium of calcium and potassium and of calcium and magnesium. Bicarbonate of sodium was usually added in such quantity that its uncombined surplus could be used as an antacid in the stomach, and it had a valuable field in neutralizing abnormal acids in vomiting cases. When the usual alkalis were added to milk, acids restored the coagulability by rennet, but citrate of sodium decalcified the casein so that rennet would not thereafter coagulate it, and only compounds of casein (not of paracasein) could be found with acid. This difference accounted for its usefulness in selected cases. Prof. W. B. Cannon's recent work upon intestinal processes threw light upon the formation of the small isolated fecal masses which make up certain infants' stools, and in other ways explained the injurious effect of flatulent destruction of the intestines. Percentage feeding and milk modification far surpassed in scope and elasticity previous efforts at artificial feeding, but would never be as free from danger as good breast milk. Parents and physicians using infants' food should comprehend their composition and their dangers. The pure milk movement was one of the great life-saving agencies of recent years, but pasteurization was still advisable in hot weather. Even ignorant mothers could be taught to modify milk with very simple apparatus. "Top-milks" were better and their fat contents were less variable than cream and milk mixtures. Evidences of proteid indigestion were more readily grasped than those of too high fat. Spitting up, the "scrambled egg" stool, fat constipation, the passage of mucus, and refusal to take a proper quantity from the bottle were some of the signs. The use of a few stock formulæ designed for certain ages meant many failures. Only a clear idea of the purposes subscribed by the different elements of the food and the indications for varying them would solve difficulties as they arose. The infant previously fed with condensed milk, infants' foods, or unsuccessful mixtures must first have its digestion for casein (or fat) trained with weaker formulæ. The stool, the weight chart, and the infant must be considered together when subsequent changes were made in the formulæ. Level fat and proteids (*i.e.* mixtures made from plain milk) were often better borne in cases of malnutrition and by sick infants with fever. A large proportion of the failures arose, despite suitable formulæ, from neglect of well-established rules governing the proper intervals and the quantity at each feeding. It was especially common to overfeed undersized infants.

Whole Milk vs. Laboratory Milk.—Dr. Alexander McAlister of Camden, N. J., in this paper contended that laboratory milk was ideal in theory, but for clinical and economical reasons practical only in selected cases for temporary use. Infants requiring substitute feeding and who came to the attention of physicians were abnormal and always difficult cases. Functional and perhaps organic disease he believed was already a complicating factor. The virile, life-quickening qualities which gave to milk its freshness and sweetness were said to be not present in laboratory milk, nor in sterilized or pasteurized milk, and must be rated in this respect with old, stale, and decomposed milk. Fresh milk, he said, was a vital fluid like live blood. The vital principles therein gave it distinct germicidal power, as shown by the researches of Freudenreich. This he considered essential in an ideal and practical substitute infant food. He thought too little attention had been directed to securing the benefits of this native virility in cow's milk. Increased attention to rapid transit and the introduction of laboratory methods in the handling of milk, he thought, were making infant feeding in cities less difficult each year; facilities were not wanting for a milk supply 100 per cent. better than that now provided. When such was demanded he believed that it would be forthcoming.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Second Day—Wednesday, June 6.

Pathology of Uterine Cancer.—Dr. Thomas S. Cullen of Baltimore went very briefly into the pathology of uterine cancer, dividing the disease in (1) squamous cell cancer of the cervix, (2) adenocarcinoma of the cervix, (3) adenocarcinoma of the body. Squamous cell carcinoma of the cervix usually extended by continuity to the body and out into the parametrial fat. It also extended out into the vaginal wall. The lymph glands of the parametrium and the iliac glands are involved in early metastases. The same group of glands were involved in adenocarcinoma of the cervix, which spread rapidly. Adenocarcinoma of the body, however, usually grew slowly, gradually infiltrating the uterine walls and forming metastases in the lumbar glands. The inguinal lymph glands showed metastases when the uterine cornua were involved. Adenocarcinoma of the cervix was the most dangerous form, next squamous cell carcinoma of the cervix, adenocarcinoma of the body, on the other hand, being most amenable to treatment.

The Operative Treatment of Cancer of the Cervix.—Dr. Emil Ries of Chicago read this paper, in which he held that the rational operative treatment of cancer of the cervix was the outcome of the conception of the pathology of the condition. Every case should be subjected to the double test of a confirmation of the diagnosis by microscopical examination, and observation of the patient for at least five years after operation. Pathological examination was not sufficiently applied to cancer of the cervix. Investigation of cancer in general and of the cervix in particular had shown that cancer was not confined to the area of patent involvement, but had outposts which must be removed as far as possible. This could not always be done completely. The disease, though originally circumscribed, was rarely seen in that stage; it followed the lymphatics, and the size of the original growth was no criterion as to the advancement of the disease. Following this belief, he held that operative treatment should extend to the lymphatics and surrounding connective tissue. It was recognized that recurrence depended not only upon contamination at the time of operation, but on the possible invasion of more or less distant organs related physiologically to the original seat of the disease. If this were true of the lymphatics, early removal of these lymphatics would give an additional chance of cure. He reported eight cases treated by his method, two of which died on the table; the remaining five were alive to-day, after five years. Four of the surviving cases were free from cancer; one had cancer of the breast, which, in view of the fact that the two cancers were different, he was inclined to believe was a new growth.

The Present Status and Future Prospects of Operative Treatment of Cancer of the Uterus.—Dr. Alfons von Rosthorn of Heidelberg, Germany, read this paper, in which he outlined the advantages, disadvantages, and future outlook of the abdominal operation for cancer of the uterus. His work up to the present time had of necessity been confined to the advanced cases which would not have been satisfactory in their results by any method of treatment. The mortality, therefore, had been high. He hoped that future work could be done in earlier cases, and believed that it was along this line that progress would be

made in future. Cancer of the womb began as an absolutely local affection, in some forms remaining so for a long time without showing a tendency to spread. In cases which were still sharply localized the cancer could be eradicated and thus permanently cured. Absolute cure by operation by removal of the affected organ could be assured only when the disease was confined to the organ in question. As soon as the disease, even as microscopically demonstrated, had tended beyond the organ originally affected recurrence was inevitable. These extensions could not be recognized by clinical examination unless palpable, hence the tendency of surgeons to remove as much as possible of adjacent tissue. The removal of the lymphatics in the vicinity came to be considered a necessity. Gynecologists were slow to recognize this necessity. The abdominal operation must be looked upon as the most rational procedure, since it corresponded more nearly with recognized surgical principles of the day. Its opponents had contended that it was essentially more dangerous to the individual than the vaginal operation. This could not be definitely determined until more cases had been reported.

Dr. James W. Ross of Toronto, Canada, said, in opening the discussion, that after all little progress had been made in the study of cancer and its treatment. Despite early diagnosis and removal, the cancer would recur in many instances. Results from the simpler operations had been disappointing in many cases, and he believed results from the more radical and more dangerous procedures would prove proportionately disappointing.

Dr. Rosenthal of Fort Wayne, Ind., said the fact that carcinomatous tissue should be treated as suppurative tissue would be treated would give the preference to the abdominal method of procedure advocated by Dr. Von Rosthorn.

Dr. Noble of Philadelphia said that the radical operation was the logical one. The choice of operation decided upon *a priori* grounds would at once point to this; but various facts tended to prevent his adherence to Dr. Von Rosthorn's teaching. He had adopted the method when it was first introduced into this country by Clark, but experience had taught him that it was a serious operation with high mortality and frequent recurrence. He had abandoned the procedure. He abandoned the operation for the further reason that it did not accomplish what it started out to do, viz., to remove all the tissues. He had adopted a modified operation.

Dr. Bovée of Washington said he combined several methods, removing the lymphatics from the pelvis, removing practically the whole of the vagina, and pushing the specimen down through the vulva. He did not believe vaginal hysterectomy to be advisable in any case of cancer of the uterus which had passed beyond the early stage. In more advanced cases abdominal hysterectomy should be performed. He resorted to galvano-cauterization in cases in which he was not fairly confident of eradication of the disease.

Dr. Clark of Philadelphia said that while he had formerly advocated the radical operation he now restricted it, believing that in extensive extirpation of glands less was gained than lost.

Dr. Massey of Philadelphia protested against curettage as a preparatory method of treatment. He believed that in the few minutes elapsing between the wound of the cancer and the removal of the growth the veins and lymphatics might aspirate the juices of this wound and thus be responsible for the metastasis which resulted a few months later.

Dr. Cushing of Boston protested against the pessimism expressed by Dr. Ross. He had adopted the plan of opening the abdomen, tying off the vessels, then pulling the uterus down and removing it through the vagina.

Dr. Boldt of New York had known cures resulting from the vaginal operation with no recurrence for years. He cited such a case in which he had operated thirteen years before by vaginal hysterectomy. On account of pelvic pains and other symptoms he had, a short time ago, opened the abdomen, expecting to find recurrence; he was surprised to find absolutely no sign of recurrence. He deprecated too prolonged anesthesia as was practised in most American hospitals. All preliminary preparation should be carried out before beginning the anesthesia. He emphasized the possibility of ureteral necrosis following abdominal hysterectomy by citing three cases which he had had a short time ago. He called especial attention to the necessity of examining the patient at intervals of four weeks for two, three, or four years after operation.

Dr. Laura E. Branson of Iowa City said that theoretically carcinoma might be divided into local and general; practically this could not be done, because it was impossible to tell at what time the secondary deposits of metastasis may take place. Theoretically the patient might be told that the possibility was there would be no recurrence; practically this could not be done because of the secondary neoplasms which might already be developing. It was scarcely just, therefore, to claim that at any period the carcinomatous process was local or general.

Dr. Dührssen of Berlin had employed for several years his method of division of the levator ani, which he had found easier than abdominal hysterectomy. In cancer of the uterus complicating pregnancy he first performed vaginal cesarean section, then split the uterus in halves and did vaginal hysterectomy. Such patients could not stand the abdominal operation. In all other cases he advocated the abdominal method.

Dr. Carstens of Detroit said he confessed to pessimism regarding the radical operation.

Dr. Cullen of Baltimore said that Dr. Kelly and his associates had followed the development of the technic in the abdominal operation for removal of the uterus and all agreed that the abdominal operation was the one to perform. They believed it to be the most difficult operation, however, and should be the first of the day always.

Dr. Ries of Chicago said nothing was to be gained by reporting one successful case and saying nothing of the ninety-nine failures. From his knowledge of the pathology of cancer he thought vaginal hysterectomy in very few cases reached all the carcinomatous tissue.

Dr. von Rosthorn, in closing the discussion, said no progress would be made by holding to the old method, and made a plea for work along the newer lines of abdominal hysterectomy in both early and late cases.

The Preservation of the Functions of the Broad Ligaments in Pelvic Surgery.—Dr. E. C. Dudley of Chicago emphasized the advantages of utilizing the broad ligaments in supporting the uterus in procidentia. He called attention to the fact that prolapse of the uterus was incident to prolapse of the whole pelvic floor. When not only the uterus but the whole pelvic floor was prolapsed the uterosacral and round ligaments, even though shortened, did not give sufficient support.

Dr. Reynolds of Boston believed Dr. Dudley's operation as illustrated by the lantern pictures and his explanations would prove to be one of the lasting contributions to surgery.

Dr. Montgomery of Philadelphia said that this method of dealing with a condition that had long been a bugbear to gynecologists would prove to be a great advance.

Dr. Waldo of New York said that if the broad ligaments, when brought together as illustrated in the pictures, would hold, such an operation would cure the condition.

Dr. Tausig of St. Louis said that operations for prolapse compared with those for carcinoma, inasmuch as results could not be determined without waiting three, four, or five years. He believed, however, that the operation of using the broad ligaments instead of the uterosacral and round ligaments in supporting the uterus would prove a success.

Dr. Craig of Boston said that when this operation was accompanied by repair of all other injuries to the vagina it would in all probability make the function of the broad

ligaments permanently operative. The original causation of cystocele, with the downcome of the vaginal walls, originated in laceration of the perineum. The fact that the broad ligaments had once given way from the abnormal conditions below rendered it probable that they would do so again if these conditions were not removed. He considered Dr. Dudley's operation by far the best suggestion that had been made for dealing with those cases which had not come under observation early enough for other procedures.

The Conservative Surgery of the Ovaries.—Dr. Edward Reynolds of Boston read this paper. If cystic disease of one ovary existed it tended to appear in the other. If one ovary was affected it was conservative surgery to remove the affected one, leaving the other. If both were affected conservative surgery called for the removal of both, saving as much ovarian tissue as possible. Malignant neoplasms meant radical operation. After the childbearing age both ovaries should be removed if affected, the disadvantages of castration in such case being of minor importance as compared with the probability of second operation. Normal ovarian tissue could generally be found in benign tumors, and effort to preserve as much as possible of this normal tissue should be made. Ovarian tumors could conveniently be classified as cysts originating from the corporea lutea, dermoid cysts, Graafian cysts, and enlarged sclerotic ovaries. Cysts of the corporea lutea would slip out through an incision, leaving practically normal ovarian tissue. Dermoid cysts and the larger cysts of the Graafian follicles must usually be excised. Enlarged sclerotic ovaries may be treated by puncture and removal of the lining membrane, with or without suture; resection; bisection of the ovary and multiple puncture or resection; and scarification or multiple incisions of the surface.

The Present Status of Conservatism in the Surgical Treatment of Tubes and Ovaries.—Dr. J. E. Cannaday of Paint Creek, W. Va., read this paper, in which he gave briefly the teachings of some of the pioneers in gynecology, emphasized the rights of the patients concerned, and correlated the views of a number of the eminent gynecologists of this country. He dwelt upon the different ideas of what constitutes conservative work. He outlined the indications and arguments in favor of both removal and repair of diseased ovaries and tubes, giving the technic of and results of plastic repair work. Ovarian transplantation and its limitations were briefly mentioned. The symptoms following artificially produced menopause were enumerated, and the views of conservative writers on this subject given.

Dr. Polk of New York said the situation resolved itself into the question of how far one should go in the preservation of an ovary found upon laparotomy to be diseased. It was one of the most difficult conditions which confronted gynecologists up to the present time because no method had been devised for deciding the after-history of these growths. Inasmuch as it was not a matter of life and death, but rather one of function, the patient should be allowed to decide the question in large part. The question of conservatism so far as the ovary was concerned was in a far better way of being solved than that concerning the oviducts.

Dr. Morris of New York agreed with Dr. Polk that the patient should be considered in the decision as to the work to be done. In malignant cases the operator must act regardless of the patient's wishes. If there should be a question of doubt about the diagnosis a spot-diagnosis could be made from a frozen section. In gonococcus cases he tried to save a little of the ovary for purposes of internal secretion, although he believed gonococcal infection meant pretty complete loss of the oviducts. In tuberculous cases conservative surgery did not apply. He had gradually narrowed the field of ovarian grafting down to homoplastic grafting as heteroplastic grafting had not seemed successful because of the intolerance of the tissues of one animal organism for those of another. Lately, however, he had been able to report a successful case of heteroplastic grafting. He called attention to the interesting medicolegal questions which might arise in such a case as to who was the mother of the child resulting from such operation.

Dr. Lawrence of Columbus, Ohio, said his experience with the conservative treatment of tubes and ovaries had been far from satisfactory. He thought the pendulum had swung to the opposite extreme. True conservatism was that which subserves the interest of the patient.

Dr. Gordon of Maine called attention to the fact that pregnancy had occurred, in his own experience and that of others, after complete, or supposedly complete, removal of tubes and ovaries. A great deal of good as well as harm had resulted from conservative surgery of the ovaries and tubes.

Dr. Pantzer of Indianapolis referred to a case which he had reported two years ago, in which the condition of the ovaries theoretically excluded all forms of conservative treatment. The smaller ovary was removed for microscopical examination and the other was pared of its sclerotic coat. In fifteen months after the operation the patient became a mother.

Dr. Dorsey of St. Louis called attention to cystic ovaries, which could be successfully treated by resection. In such cases the patients went on to menopause without pain. He would not hesitate to slit the ovary to the hilum and scoop out the cysts.

Dr. Boldt of New York agreed with Dr. Polk in regard to leaving it to the patient whether or not some function should be preserved. He would consider it conservative surgery if in case of a large ovarian tumor part of the ovarian stroma was saved. In a case of pyosalpinx with macroscopically normal ovaries he would advocate exsection of the entire Fallopian tube and grafting of the ovary into the cornua of the uterus. So-called conservative surgery was sometimes fraught with disastrous results.

Dr. Reynolds agreed with Dr. Polk that inasmuch as conservation of the ovaries and tubes, with the chance of a second operation, concerned the life and function of the patient the question should be left to her. He considered pregnancy occurring after removal of tubes and ovaries due to the fact that such operation was not in reality complete.

Dr. Cannaday did not believe in leaving tubes which were the seat of infection, but only those in which infection had disappeared. Ectopic gestation, supposed to be due to destruction of the cilia in the tube, was disputed by Kelly, who held that inflammation did not destroy the cilia.

SECTION ON SURGERY AND ANATOMY.

First Day—Tuesday, June 5.

Address in Surgery.—Prof. F. Trendelenburg of Leipzig, Germany, delivered this address. He reviewed all the branches of surgery since the preantiseptic period, and discussed particularly the surgical treatment of puerperal pyemia, which, he said, should be similar to that employed in the treatment of pyemic sinus thrombosis following an otitis media, the conditions found in both condition, and the clinical history being practically analogous. A number of cases have been published, showing that ligature of the pelvic veins for chronic suppuration is a successful procedure. In the acute cases the prognosis is favorable only when an early operation is possible. Even in the presence of a thrombosis in the vena cava spontaneous recovery may follow. Complete obliteration of the lumen of the vein may be followed by the development of a sufficiently extensive collateral circulation. He had attempted ligation of the common iliac artery and the lower section of the vena cava. One patient lived six days and another thirteen days, but he did not advocate this procedure. In acute cases he strongly advocated the ligation of the ovarian and external iliac veins at an early period. He also considered the preferable method of exposing these veins.

Results of Partial Occlusion of Large Arteries.—Dr.

W. S. Halsted of Baltimore had during the past twenty months conducted a series of experiments on 100 dogs for the purpose of noting the effect of complete and incomplete occlusion of the abdominal and thoracic aorta by metal bands. He had found that the pressure below the band was lowered in proportion to the amount of the occlusion. The return to normal below the band was rapid but varied greatly in different dogs. Partially occluding bands produced, as a rule, no macroscopic change in the artery wall, even after seven or eight months, but under completely occluding bands the artery wall usually atrophied and in the course of several weeks or months was absorbed. Twice the portion of the arterial wall embraced by the band was converted into a solid cylinder of tissue. He considered this the ideal closure of an artery. One notable change was the unusual deposit of extradural fat about the spinal cord below the site of the constricting aortic band. He believed that lesions in the cord or the artificial anemia were responsible for this deposit. He thought this metal band might be extremely useful in occluding arteries above an aneurysm. The band was preferable to the silk or other ligature because it was not liable to cut through the vessel wall; it produced gradual occlusion; it could be removed, if necessary, without having in any way injured the vessel wall. Dr. Halsted had partially occluded the innominate once in the human subject and the carotid four times, successfully, with an aluminum band. In a case of large popliteal aneurysm he employed the band to occlude completely the femoral artery. He thought that partial occlusion might even, in rare instances, cure an aneurysm.

Treatment of Aneurysm by Intrasaccular Suture.—Dr. Rudolph Matas of New Orleans reviewed the operation described by him on former occasions and reported thirty-eight cases in proof that his method had not only stood the test of experience but that it would accomplish results with greater security and simplicity than any of the older methods hitherto employed. Of twenty-two cases of obliterative endoaneurysmorrhaphy and seven cases of restorative endoaneurysmorrhaphy there had been no relapses, although there had been two relapses out of five cases of reconstructive endoaneurysmorrhaphy or arterioplasty.

Dr. W. W. Keen of Philadelphia commended Dr. Matas' operation very highly. He also described a clamp that he had devised for producing partial occlusion of a vessel under graded pressure on the same principle, to a certain extent, as the metal bands employed by Halsted.

Dr. Willy Meyer of New York cited the case of a boy who had a traumatic aneurysm of the popliteal artery in which he employed Dr. Matas' method with excellent results.

Dr. R. C. McChord of Lebanon, Ky., also reported a similar case, as did also Drs. Stillman, White, and others.

Tumors of the Carotid Gland.—Dr. W. W. Keen of Philadelphia reported a case of this kind and gave a brief résumé of twenty-six other cases reported in the literature and two cases discovered post mortem. He reviewed the anatomy of the gland and the clinical history of the tumor. Of the twenty-seven cases cited there were twenty-six operations with seven deaths, a mortality of 27 per cent. He stated that unless serious functional disturbances arose operation was not indicated, except when there was unmistakable evidence that the tumor was undergoing rapid malignant changes.

Surgical Conception of Sigmoid Pathology.—Dr. H. D. Niles of Salt Lake City stated that chronic ulcer or its cicatrix was the cause of cancer of the bowel in 80 per cent. of all cases. Any rational treatment of sigmoid disease must be based on a correct perception of the anatomy, physiology, and pathology of that part of the bowel. To recognize and interrupt this process at the earliest possible moment and before irreparable damage had been done should be the aim of the physician. Pathology here passed from the medical to the surgical field when any ulceration or necrotic process starting in the mucosa extended to or included the peritoneum; whenever there was any evidence of mechanical obstruction, partial or complete, regardless of the cause; when a localized peritonitis existed that did not readily yield to simple measures directed to the suspected cause. The essential principle of treatment was rest. Just how this might be accomplished successfully could not be stated at this time.

Neoplasms of the Large Intestine.—Dr. A. F. Jonas of Omaha reported sixteen cases involving the colon and gave a brief description of the pathology from diagnostic points. He stated that in the diagnosis a careful study of the history was of first importance. Cramp-like pains, abdominal tenderness, palpable tumor, and obstruction of the bowel were also of importance, although the existence of these symptoms indicated only the presence of a lesion of some kind. Gurgling, distinguished by means of a stethoscope, especially after air had been injected into the rectum, was a valuable sign. He did not offer anything especially new, except a double loop ligature which he had employed for many years as an aid to suturing the bowel after resection of a part of the gut.

Dr. Dawbarn of New York advocated the use of a continuous suture, using a linen thread and the so-called morphine splint, checking all peristalsis until the union of the bowel was assured. He did not favor the use of the Murphy button or any other contrivance.

Dr. Dunsmoor of Minneapolis cited a case of ulcerative colitis in which he removed a large part of the colon down to the sigmoid flexure. He employed a button when making an anastomosis, except when he got below the small intestines; then he used the suture.

Dr. E. W. Andrews of Chicago believed in the efficacy of the Connell suture for intestinal anastomosis. He employed it not only for uniting the large and small intestine, but also in pylorectomy and gastroenterostomy.

Dr. Freeman of Denver called attention to the comparatively favorable prognosis of cancer of the sigmoid and cited a case in illustration, the patient being free from a recurrence eighteen months after removal of the growth.

Dr. McGlannan of Baltimore emphasized the occurrence of intermittent intestinal obstruction as a valuable diagnostic symptom of intestinal cancer.

Surgical Treatment of Femoral Hernia.—Dr. A. J. Ochsner of Chicago briefly reviewed the various operations now employed for the cure of femoral hernia and described a method devised by him which he used in all simple femoral hernias. It consisted in the removal of the hernial sac, the reduction of the stump within the peritoneal cavity, and the closure of the superficial wound. The hernial ring was left to close spontaneously.

Silver Wire Filigree Work.—Dr. Willard Bartlett of St. Louis reported 22 cases in which the method previously described by him had been employed with most excellent results. Of the 22 cases four terminated fatally, but from causes not connected with the operation or the implantation of the filigree. The patients lived six months, three months, ten days, and two days respectively. The method was employed in clean cases and in pus cases; it had withstood the test of pregnancy once, of tremendous ascitic accumulations in two instances; it had not interfered with the growth and development of the abdominal walls in small children, and was used twice as a prophylactic measure in cases where there seemed to be a possibility of a hernia developing. In no case did the filigree fail to perform its functions. It did not need a clean wound for its bed.

Dr. Tuttle of Cambridge had employed silver wire in fifteen cases of ventral hernia following appendicitis, in umbilical hernia and inguinal hernia, but in every instance he had later to extract the broken pieces of the wire. He was convinced that silver wire was acted on by the body juices in the same manner as any other suture material, perhaps not quite so rapidly.

Dr. Ferguson of Chicago was impressed with Dr. Ochsner's operation for femoral hernia and stated that if the

results were always as good as Ochsner stated, he, too, would employ the method. Thus far he had never seen a recurrence of a femoral hernia operated on by the radical method. He made his incision above Poupart's ligament and parallel with it and dissected out the hernia from below. He never tied off the sac without first opening it.

Dr. Dawbarn of New York saw no advantage in doing away with the sac which was a living and useful tissue. He thought it wise after dissecting it loose to carry out the Macewen method. He also described his method of operating.

Second Day—Wednesday, June 6.

Cause and Diagnosis of Gastric and Duodenal Ulcer. Dr. Frank Billings of Chicago discussed, briefly, the current theories as to the causation of ulcer, its clinical history and differential diagnosis. He said that when the classical symptoms were present the diagnosis could be made easily, but when the symptoms were not clear the diagnosis might be difficult.

Medical Treatment of Gastric and Duodenal Ulcer.—Dr. Alexander Lambert of New York stated that the first essential in the treatment of this condition was complete rest, both for the body and the stomach. This meant rest in bed and rectal feeding followed by continued rest in bed and a milk diet. The length of time necessary to remain in bed varied from a week or two in the acute cases to several weeks in the acute exacerbations of chronic ulcer. The method of feeding was described in detail. Gastric feeding should be begun before the rectum grew intolerant, and as gastric feeding was increased, rectal feeding should be decreased. Massage and a non-irritating form of iron should also be prescribed. After the patient was up and around and returned to his duties, his feeding must be supervised carefully. The bismuth cure and the olive-oil cure were also worthy of mention in the treatment of ulcer. Excellent results had been obtained by the use of a mixture of chalk, talcum, and magnesium, and by that of insoluble carbonate of lime instead of the bismuth. He stated that until the best operation and its technique were more generally agreed on, and there were published more statistics of end-results of operations, physicians could not enthusiastically adopt a surgical point of view. At present he believed that all chromic ulcers should first be treated by a careful and strict medical regimen, and if that failed and the patients could not live in reasonable comfort, they should then be subjected to an operation.

When Do Gastric and Duodenal Ulcers Require Surgical Treatment?—Dr. Wm. L. Rodman of Philadelphia stated that acute ulcers tended spontaneously to recovery and should be treated medically. Chronic ulcers were usually so from the beginning. At least 50 per cent. remained uncured by medical means, and of the remaining 50 per cent. discharged as cured at least one-half relapsed, and 25 per cent. ended fatally from perforation, hemorrhage, anemia, etc. To relieve inveterate dyspepsia of both acute and chronic ulcers surgical intervention was often necessary. If the ulcer or ulcers were at or near the plyorus, as they were in 80 per cent. of all cases, and the pylorus and duodenum were free from adhesions or could be easily mobilized, pylorectomy or excision of the ulcer-bearing area was the operation of choice. It successfully dealt with multiple ulcers, prevented possible perforation, hemorrhage, cicatrices resulting in disabling adhesions, stricture, hour-glass stomach, and malignant degeneration, leaving the organ in the best condition for future use. Gastrojejunostomy frequently gave relief, but often failed to do so. It could not prevent either pathological or mechanical changes which threatened life either directly or indirectly. Finney's operation or pyloroplasty which made a larger opening, imitated nature, and was not followed by peptic ulcer, was growing in favor and would theoretically seem indicated where there was neither fresh ulceration nor markedly impaired gastric motility.

Surgical Treatment of Gastric and Duodenal Ulcer and Its Results.—Dr. Wm. J. Mayo of Rochester stated that the complications of acute ulcer were always to be treated surgically. He reviewed 600 cases operated on in his hospital, as follows: *Acute perforating ulcer:* Gastric 7, deaths 2; duodenal 9, deaths 3. Operation within 5 hours was usually successful, but after 10 hours the majority of patients died. Treatment by transverse suture was indicated to prevent stenosis and gastrojejunostomy if the patient was in good condition. Suprapubic drainage should be established with or without irrigation, the patient being maintained in a semisitting posture for several days. *Acute hemorrhage:* Eleven cases, 1 death. The stomach should be opened and bleeding area sutured from the inner (mucous) side with catgut on a curved needle; it should be protected on the outside by musculoperitoneal sutures of linen or, if feasible, one should excise the ulcer. Gastrojejunostomy alone was unreliable. *Chronic hemorrhage:* Excision or gastrojejunostomy was efficient. *Chronic ulcer:* Gastrojejunostomy was performed 383 times, 64 per cent. of the whole. It was most useful when there was permanent interference with motility. The posterior "no loop" operation was the best; the incision beginning within three inches of the origin of the jejunum, which should be attached to the bottom of the stomach in such a manner that the distal end of the bowel was to the left; of this there had been 135 operations with 1 death. All "loop" operations with or without enteroanastomosis were obsolete. The anterior operation with Murphy button or McGraw ligature might rarely be indicated by reason of posterior adhesions or anatomical abnormalities. Gastrojejunostomy was not a cure-all. If motility was normal, if the pylorus was open, and if no dilatation existed, muscular action continued to force food out by the natural channel rather than through the artificial opening. *Gastroduodenostomy of Finney:* 72 cases, 4 deaths. There was a growing field of usefulness of this operation. It left an opening in the natural situation and the lines of drainage were downward along the greater curvature. It was most useful in cases of mucous ulcer and loss of motility due to spasm. *Excision of ulcer:* 14 cases, no death. This was indicated for ulcer on the lesser curvature without obstruction or dilatation. It might be combined with the Finney operation when the ulcer was close to the pylorus. *Rodman's operation* (resection of pyloric end of stomach with independent gastrojejunostomy): 7 cases, no death. This was indicated in cases of calloused ulcers. *Resection of stomach,* removing entire diseased area: 12 cases, all recovered. This was indicated in hourglass contractions and calloused ulcers involving the body of the stomach in which there was a suspicion of malignancy. Generally speaking, failure of operation to cure gastric and duodenal ulcers was usually the result of defective technique or bad choice of method.

Dr. J. C. Hemmeter of Baltimore called attention to a method of diagnosis employed by him with great success. The patient was given a large dose of bismuth, and the stomach was then washed out and *x*-rayed. The bismuth adhered to the ulcerated surface and was seen very plainly as a shadow on the plate. Another method of diagnosis was to administer about 8 grains of orthoform in 8 ounces of hot water. This mixture would promptly ease the pain if due to gastric ulcer, but would not affect the pain of gallstones. He believed that in cases of uncomplicated ulcer surgical treatment was not indicated. Only when complications ensued should the patient be referred to the surgeon for operation.

Dr. A. P. Francine of Philadelphia called attention to the fact that many conditions might simulate ulcer very closely, so much so that a mistake in diagnosis might be made. A study of post mortem records had convinced him that tuberculosis did not enter into the causation of ulcer at all. Out of 143 patients dying from advanced tuberculosis there was no case of acute gastric ulcer. He thought that many cases of gastric ulcer produced symptoms so slight that they went unrecognized.

Dr. Stanley Black of Pasadena referred to the occurrence of pentosuria as a diagnostic point of importance. Instead of putting the test for occult blood last, he placed it first.

Dr. Spivak of Denver advised giving the stomach absolute rest and also the intestinal tract so that the peristaltic movements of the intestines produced by rectal feeding would not cause the stomach to move in any way.

Dr. McCaskey urged the individual treatment of each patient instead of trying to make the case fit a routine treatment.

Indications for Surgical Intervention in Infections of the Biliary Tract.—Dr. John B. Deaver of Philadelphia detailed the indications for operation and cited the statistics of 216 cases operated on by him at the German Hospital, dwelling especially on the complications and the results of operation.

Surgical Treatment of Exophthalmic Goiter.—Dr. F. J. Shepherd of Montreal reviewed the various methods of surgical intervention in this affection, and stated that the only method worth considering at present was removal of half or more of the gland. Early operation was imperative, and especially in those cases in which the enlargement of the gland was chiefly on one side and had preceded the advent of the nervous symptoms. In extreme cases of exophthalmic goiter when the disease was very rapid in its course and the right heart was dilated, other than surgical measures had better be adopted. In nearly all cases removal of a portion of the thyroid was beneficial. Eighteen cases were reported, three of the patients dying from thyroidism soon after operation. Eight patients were cured completely. The average age of the patients was twenty-eight years, the oldest being fifty-three and the youngest fourteen years of age.

Treatment of Exophthalmic Goiter by a Specific Serum.—Drs. John Rogers and S. P. Beebe explained the preparation of the serum employed and reported the results of treatment in forty-one cases. (See Medical Record, February 24, 1906, p. 322.) Eight patients were cured, twenty-five improved, six proved failures, and two died. Cases of others: Twenty-eight; three cured, sixteen improved, and nine failures. Personal cases of typical chronic goiter: Two cured, fourteen improved, and three failed. Atypical thyroidism: Three cured, three improved, three died. Acute and chronic toxic thyroidism: Two cured, six improved, two died. Psychopathic and neuropathic exophthalmic goiter: One cured, two improved, one failed.

Indications for Prostatectomy and Its Results.—Dr. A. H. Ferguson described his method of perineal operation which has been described previously on several occasions.

Clinical Significance of Variations of Wrist and Ankle.—Dr. Thomas Dwight of Boston said that these variations were of great importance both clinically and medicolegally. The increased number of bones might be due to persistence of embryonic elements which normally fused or disappeared; thus one bone may be represented by two. Fusion of usually distinct parts might occur at definite points. Through variations of development bones might have different or abnormal relations. The overdevelopment of processes usually small or absent gave many illustrations of such variations. Although the causes were diverse and imperfectly known and although some variations were common and others were rare, it was important that they occurred at certain definite points. Though they were not originally the effect of lesion, yet an extra bone generally was a point of diminished resistance and hence not uncommonly the seat of lesion.

Appendicostomy.—Dr. James P. Tuttle reviewed the origin of this operation by Dr. Weir, described the method of its performance, and cited instances in which it had been employed successfully, especially in ulcers of the bowel and in amebic dysentery.

Cardiac Stimulation for Suspended Animation by Direct Digital Manipulation.—Dr. B. Merrill Ricketts of Cincinnati stated that of eighteen patients in whom inthrathoracic transpericardial massage had been performed, four recovered completely, seven lived from one minute to twenty-four hours, and in seven the pulse never returned. Of the nine patients in whom subdiaphragmatic transperitoneal method had been resorted to, five continued to live, in two heart pulsation was restored for a short time, and in two the heart beat was not restored. The cessation of the heart beat for one minute was sufficient to justify direct digital cardiac massage after the ordinary means had been applied.

IMPROVED CATAPHORIC ELECTRODE FOR HIGH POTENTIAL CURRENTS.

By WILLIAM J. MORTON, M.D.,

NEW YORK.

In the issue of the Medical Record of November 18, 1905, I published a description of a vacuum tube for phoric medication. A deficiency of all such electrodes is that the bulk of the current passes at the periphery of the flat disk. To obviate this I have elongated the entering metallic conductor to the region of the flat surface and have made it a sharp point. (See Fig. 1.)

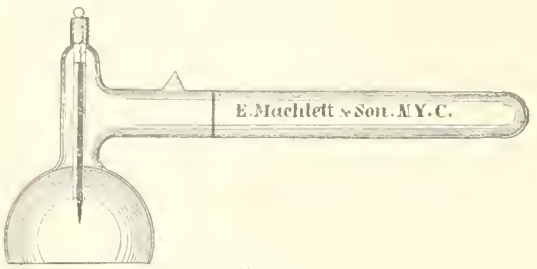

Fig. 1.

Again, if desired, I attach a thin metallic plate of tinfoil or other metal upon the outer side of the glass upon its flat side. The diameter of this plate is considerably less than the diameter of the circular and flat surface of the electrode. (See Fig. 2.)

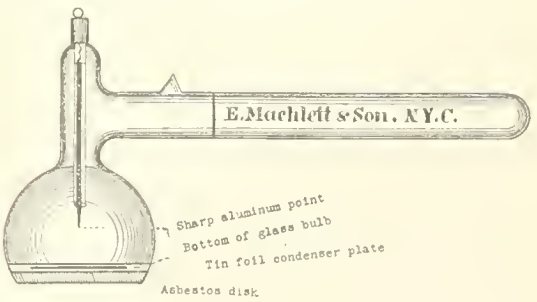

Fig. 2.

As now arranged the current's action is concentrated to this flat surface of the electrode and the cataphoric action is correspondingly enhanced. But the tinfoil adds to the pain of the application and I prefer to use the sharp-pointed electrode without the tinfoil condenser, namely, as illustrated in Fig. 1.

Adrenalin in the Macular Disease of Werlhof.—Augusto Cianni concludes that the use of adrenalin is of great value in Werlhof's disease. In this affection, the tone of the vessels is very much reduced, as is indicated by the abundant hemorrhages from various organs; hence the use of a drug that tones up the vessels is indicated. In a case treated by the author adrenalin carried out this indication in a wonderful manner, and he advises its use as a matter of experiment in cases of this nature. The patient received hypodermic injections of adrenalin 1-1000 for two weeks. Recovery was rapid and complete.—*La Riforma Medica.*

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

The National Confederation of State Medical Examining and Licensing Boards held its sixteenth annual meeting in Boston, on Monday, June 4. The following officers were elected: *President,* Dr. Edward B. Harvey of Boston; *Vice-Presidents,* Drs. A. Walter Suter of Herkimer, N. Y., and George W. Webster of Chicago; *Secretary and Treasurer,* Dr. Murray Gault Motter of Washington, D. C.

California.— The *Southern California Practitioner* makes a suggestion with reference to the State examination that each examiner should give in each subject fifteen questions, with choice of ten. Such a practice would relieve the Board of the charge of giving catch questions and would prevent the sympathy of the public or of the courts being extended to a disappointed applicant. If the public were informed that fifteen questions had been given and that the applicant failed to get the required 75 per cent. on the ten questions of his own choosing, little sympathy would be extended to him.

Maryland.—The Board of Medical Examiners of this State has had printed a complete alphabetical list of all the physicians who are registered in Baltimore City. This will be a material help in the endeavor to keep out irregular and unlicensed practitioners.

South Carolina reciprocates, under certain conditions, with Illinois, Kansas, Maine, Maryland, Michigan, Minnesota, Nevada, New Jersey, Ohio, Texas, Virginia, Wisconsin, and Wyoming.

Wisconsin reciprocates, under certain conditions, with District of Columbia, Georgia, Illinois, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, North Dakota, Ohio, Oklahoma, South Carolina, South Dakota, Virginia, and Wyoming.

Medical Items.

SOME OBSERVATIONS ON PROSTATECTOMY.

By L. BOLTON BANGS, M.D.,

NEW YORK.

CONSULTING SURGEON TO BELLEVUE, THE CITY, ST. LUKE'S, AND ST. VINCENT'S HOSPITALS.

THERE is no question as to the value of prostatectomy. The relief which it affords is incalculable. The management of the patient both before and after the operation and the technique of the operation itself have been so improved that the death rate has been materially reduced and a fair proportion of the patients make an uneventful recovery. But the question may well be raised whether the operation is not being done unnecessarily and without a proper consideration of the cases. The histories of patients obtained in consultation or culled from the literature show that significant symptoms have been unappreciated or overlooked. Small prostates have been removed from patients (somewhat on the principle of "not knowing what else to do for him") whose only symptom was diurnal and nocturnal frequency, with few or no signs of obstruction, leaving them unimproved and in some instances worse than before the operation. In such cases it does not seem to have been appreciated that the capacity of the bladder of the patient had been so reduced by chronic interstitial cystitis that it could not hold over three or four ounces, that, therefore, urination every two hours had become a necessity, and operation could not avail. At least three such post-operative cases left in worse condition than they were before the operation have come under my observation. Again, in reviewing some cases in the literature I find the history of a patient who had been subjected to prostatectomy, in whom there had been frequent and painful urination, some blood in the urine, but, only two drachms of residual urine and a stone in the bladder. Further, there are men, particularly among the higher classes, approaching sixty years of age, with habits of high living or with some form of sexual abnormality, or with both, who come complaining of discomfort in the urinary apparatus, with nocturnal frequency of urination and some residual urine. In these cases besides a small or moderate organic enlargement, there will be found an engorgement or moderate grade of inflammation of the prostate, which, under hygienic living, with regulation of the sexual relations, and exercise, together with some local treatment, will subside, resulting in such a diminution of the symptoms that the necessity for catheter life, still less for radical treatment, may never arise. Each case must be studied by itself, but the number of such who actually never come to operation is not small. It seems to me to be more scientific to have such patients report for observation at longer or shorter intervals, instead of establishing the formula, "The patient has an enlargement of the prostate, therefore he must be operated upon."

In illustration, take the following case of a man who has never had complete retention of urine, but who has unmistakable enlargement of the prostate of a minor grade and who has been advised to have prostatectomy done. (In the following cases, in order to be brief only the essential details will be given.)

A married man, aged 62, temperate as regards alcohol and sexual relations, for several years has had some "discomfort," not pain, in the region of the bladder, together with some diurnal and nocturnal frequency of urination. His urination has varied from once to a maximum of four times at night, and diurnally, from once in two hours to once in six hours. There was also hesitancy in starting the stream. For these symptoms, six years ago he consulted a prominent German surgeon, who examined him, passed into him a metal instrument, hurt him extremely, caused some blood to exude, and advised him to have his prostate removed. With dread of an operation depressing him, he was sent to me by Dr. W. T. Bull. Rectal examination shows the prostate to be twice normal size, regular in outline, soft, very tender, especially at the posterior margin, and pressure along the median line elicits an intense burning sensation. The urethral length is nine inches. The residual urine is two ounces. His urine is perfectly clear and subsequent microscopical examination shows it to be normal. A history of unnatural sexual indulgence is obtained from him. Under local and general treatment the frequency of urination diminished, the hesitancy disappeared and his nocturnal urination was reduced to once. It remains so, and he is able to expel all of a measured quantity of fluid injected into the bladder. He willingly comes for observation once in three or four months.

The degree or form of the organic change and related symptoms, together with the intellectual and social condition of the patient, as well as his immediate environment, ought to be studied before deciding as to the mode of treatment. It may be argued that, independently of the degree of enlargement, the primary retention of urine is sufficient indication for radical treatment; but my observations lead me to think that this is not necessarily the case. Spontaneous urination may be restored, and the patient may go on for several years without another attack of retention, in the meantime maintaining sterile urine. Simple measures may relieve the congestion which produced the retention, and the residual urine may be gradually reduced to an insignificant amount.

To emphasize this proposition take the following case:

A married man, aged 71, with four children, the youngest being 32 years of age. Twenty-four hours before I was summoned to this patient by his family physician, he had had a sudden retention of urine which persisted for hours. He was finally catheterized by the physician's assistant, who was called to him in the night and drew off twenty ounces of urine. I found him twenty-four hours later in great

distress, suffering complete retention and frequent ineffectual tenesmus. He was not able to void even a drop. This condition had recurred within a short time after the first catheterization. Percussion over the hypogastrium showed flatness up to an inch below the umbilicus. Rectal examination showed the prostate to be four times the size of the normal, enlarged in all directions, and exquisitely tender. It was learned that for several years the patient had had nocturnal urination, usually two or three times between retiring and rising. Aided by local anesthesia the catheter was easily and painlessly introduced. The length of the urethra was found to be ten inches. In brief, the overdistention was gradually relieved, the catheter being passed every six hours, and measures were taken to relieve the congestion, which had evidently been superinduced upon a chronic enlargement of the prostate. On the fourth day the patient passed a few drops of urine spontaneously. On the sixth and seventh days he passed four ounces. Catheterization was now reduced to once in eight hours. From this time on there were increased quantities of urine voided spontaneously, and the catheter was used less frequently till, on the eleventh day, spontaneous urination took place every hour and a half, and the residual urine varied from one to three ounces. This patient was seen subsequently at intervals and treated first, twice a month, then once in two months, and finally once in six months. In consequence, whereas before his attack of retention he was obliged to urinate three times in the night, he now urinates but once, holds his urine four hours in the day and has now but half an ounce of residual urine, which remains sterile. He is able to void all but half an ounce of a measured quantity of sterilizing fluid injected into his bladder. He has still an enlarged prostate, a urethra of nine inches; but there has been restored to him a compensatory vigor of the bladder which is sufficient to enable him to overcome the obstructive effects of the prostate. Such patients should not be hurried and urged into operation, because in their misery they will consent to anything, but they should be examined at intervals and careful records kept that the golden moment may not be lost should the bladder begin to fail and thus the indications for operation arise. It is not uncommon to receive a patient who brings a letter from his attending physician containing such a statement as, "The patient has had retention of urine due to an obstructive enlargement of the prostate, and in my opinon ought to be operated upon without delay. I would like your opinion in regard to the matter."

On examining such a patient there was found a urethra of eight and a quarter inches in length; no palpable enlargement of the prostate by rectal exploration, and a steel searcher entered the bladder easily without deflection and without depression of the handle. The patient had a group of symptoms extremely suggestive of the premonitory stage of locomotor ataxia with unusual prominence of the bladder symptoms. In my opinion, before operating upon such a patient he should be kept long enough under observation to determine this, and whether or not any operation can benefit him. Too much stress cannot be laid upon the necessity for a careful preoperative diagnosis. This is so important in our opinion that, before a decision to operate is arrived at in doubtful cases, I and my associates, Drs. Pedersen and Squier, give each case individual consideration, and operation is not advised until there is an agreement of opinion, the patient being kept meanwhile under observation with tentative treatment. For example, in the following case I personally objected to operation. My associates disagreed with me, and the further progress of the case showed that they, and Dr. Squier particularly, under whose personal care the patient had been, were correct:

He is aged 57. For several years he had had attacks of frequent urination, sometimes of a very annoying character, during which, as he described it, he would be obliged to run suddenly to the toilet. At the time that he first came under observation his nocturnal urination was from three to five times, but when he had one of his bad attacks he urinated as often as ten or twelve times in the night; in the day time he could occasionally go six hours without urinating. In addition there was urgency and slowness in starting the stream, and occasionally incontinence. At his first examination it was found that he had a urethra of 7¾ inches and eight ounces of residual urine. The prostate was peculiarly prominent in the rectum, but not markedly enlarged. Cystoscopy revealed a moderate intravesical projection of the prostate in all directions. There was a moderate grade of cystitis present. The rugæ of the bladder were prominent, and the least touch would cause the mucous membrane to bleed. This man's prostatic enlargement seemed to me to be slight, and as there was a very decided neurotic element in the case, I advised at that time against operation, urging that he should take a long rest from business pressure and that his treatment should be tentatively palliative. This was persisted in for about six months, when, his condition being no better, we agreed as to the necessity for operation, and the prostate was removed by the perineal method. He was up at the end of the fifth day, the perineal wound healed in three weeks, and a week later he was sent off for a trip to the country. His improvement after this was progressive. He is now able to hold his urine seven or eight hours. Notwithstanding the delicacy or sensibility of his nervous system, he has retained his arduous occupation, and, although at times under the stress of the latter he secretes a large volume of urine, he is able to void it freely and easily and to empty his bladder absolutely, but occasionally there is a little nocturnal incontinence.

There are patients in whom it would seem that prostatic enlargement of minor degree, coupled with a neurotic temperament, if not with true neurasthenia, excites such a grade of disturbance in the enervation of the bladder and prostate, that the symptoms of obstruction are much more pronounced than would be expected from the degree of obstruction present. The foregoing seems to me to fall into this category. The following recent case also has elements of the same nature and is instructive in other ways:

A married man, aged 59, of refined, even delicate, constitution, was referred to me by Dr. A. A. Smith. In September, 1895, he had an attack of retention of urine following a prolonged postponement of urination, but finally succeeded in emptying his bladder. His second retention took place in London some time afterward, at which time a catheter was first used. He was confined to bed, and evidently had a rise of temperature. He returned home with an infected bladder and placed himself under the care of his family physician. I saw him in consultation and searched for calculus, with negative result. Eventually he recovered from his cystitis and remained well until October, 1899, when, after a period of worry, retention again occurred. The catheter was then used for a few days, and the urine, which was purulent, again cleared up under treatment. He had another attack in 1903 and again in March, 1904, when, after occasional forcible postponement of urination during a period of three or four days, retention again developed. Successive attacks of retention then took

place at increasingly frequent intervals. His physician taught him to use the catheter with careful attention to all antiseptic details. He was intelligent, deft with his hands, and was able to maintain perfect aseptic conditions. A succession of retentions now followed in rapid order, but on each occasion he relieved himself with the catheter, although on two or three occasions he suffered several hours from overdistention before he could conveniently catheterize himself. He is one of those who cannot void his urine in the presence of another, and even when he is alone in the toilet he fails to evacuate his bladder if he knows that someone is waiting. Rectal examination shows a full, round, elastic prostate, slightly tender, and approximately as large as, and of the same contour as, a small orange. His bladder easily tolerates 12 to 16 ounces of urine. The urethra is 8½ inches in length, and there are three ounces of residual urine, which is clear, but with a few flocculi floating in it. There is no projection of the stream of urine, which drops directly down from the mouth of the catheter, and suprapubic pressure is required to obtain the last ounce of the residual urine. Under local treatment the frequency of urination was diminished and the intervals between his attacks of retention lengthened; but the amount of residual urine remained about the same. Any stress upon his nervous system, for example, business pressure or the illness of some member of his family, would increase the difficulty of urination and precipitate an attack of retention, which sometimes would occur suddenly in the middle of the night, but he was always able to relieve himself with the catheter. He now went off to the country, and for three weeks there was no necessity for catheterization. He urinated only once or twice at night, and seemed to be in very good condition, but a change of temperature gave him a chill, which induced an attack of diarrhea, and the necessity for the catheter suddenly arose. He had an onset of pain in the bladder, had to urinate every hour, and the local physician reported to me that he had blood in the urine. This had never occurred before. Under simple treatment the cystitis slightly improved; but he suffered a relapse and the frequent and painful urination persisted. Blood continued in the urine; the least touch of the catheter in the deep urethra and the bladder would induce a flow of bright red blood, and small clots were passed from time to time. Cystoscopy was attempted with local anesthesia. The bleeding was so free that the view obtained was not satisfactory, but stone in the bladder was excluded. As his symptoms persisted and he was progressively running down and losing weight and strength, it was deemed advisable to attempt cystoscopy under general anesthesia and be governed by the condition found. This was undertaken, but the free bleeding interfered, and accordingly the bladder was opened above the pubes. The prostate was found moderately enlarged in all directions and there was a conical cockscomb-like projection of the middle lobe into the bladder. All over the posterior and lateral walls of the bladder were sessile, rounded, nodular masses, smooth to the exploring finger, not hard, but firm. In the right lateral aspect of the lower hemisphere of the bladder was an ulcer with a yellowish base, from which blood exuded. A section of this diffused new tissue was taken for histological examination. The prostate was entirely removed. The very free hemorrhage was perfectly controlled by gauze tampons. The patient soon rallied from the slight shock and continued doing well till the fifth day after the operation, when a state of extreme debility suddenly developed and, with no rise of temperature, with no evidence of sepsis, he died apparently from exhaustion.

The report of the pathologist is not conclusive, but is suggestive of neoplasm.

Although I am confronted in this case with the probability of a neoplasm being present to complicate its study, the history seems to me to bear upon the point, viz., that in a neurotic individual irritation of the peripheral nerves in the prostate, caused by its moderate or even minor enlargement, induces not only an increased functional activity of the bladder, but also of the cut-off muscles of the urethra, and that these two combine to cause not only annoying obstructive symptoms, but also serious secondary inflammatory conditions, with a consequent degree of suffering greater than can be accounted for by the degree or form of enlargement of the prostate. The opinions in this paper are based upon an experience of several hundred cases of prostatic enlargement, over a hundred of whom have been operated upon by my associates and myself, nearly fifty (49) of these being prostatectomies. Of the latter I beg leave to present the following as illustrative of the points which I wish to make:

A married man, aged 61, had his first attack of specific urethritis when he was forty-six years of age. Abortive treatment was tried by the physician under whose care he was, and, to use the patient's words, "very strong injections" were given. During the chronic stage of his malady deep instillations of nitrate of silver were made, and finally a "strong solution" was used. Intense burning followed, and three days later a prostatic abscess developed, which eventually ruptured into the urethra. He has never been well since. A chronic urethral discharge lasted four or five years, and in this period attacks of retention of urine occurred, for the relief of which he was taught to use a catheter. These attacks of retention were very irregular, coming on from once a week to once a month. Gradually the intervals lengthened, and after ten or twelve years they ceased. For the past two or three years (December, 1904) he has remained relatively comfortable. During all these years he had urinated from three to five times at night and in the daytime as often as every two or three hours. The act has been always accompanied by an agonizing sense of obstruction, against which he is forced to strain. Within the last ten years there has been a gradual failing of his sexual powers, and complete impotence has existed for the last two or three years. Palpation by the rectum shows the prostate to be much enlarged in all directions, possibly four times the normal, and the lobes are pulpy and very tender. He has difficulty in expelling urine; the stream is slow in starting, and he makes forcible expulsive efforts to overcome an obstruction of which he complains greatly. The urethral length is 9¼ inches, and the bladder contains two ounces of turbid residual urine. Subsequent examination showed that the residual urine varied from three to seven ounces, according as he was able to overcome the obstruction. Under local treatment he improved somewhat. The urine became less purulent, and his nocturnal urination was reduced from five times to three. The aching at the root of the penis and the burning sensation in the urethra of which he complained disappeared, but the sense of obstruction, although ameliorated, persisted, and, together with the nocturnal frequency, would relapse under slight provocation. There was also restoration of his sexual power to a degree and he again had successful coitus. Treatment failing to sterilize the bladder or to relieve the tendency to nocturnal frequency which disturbed his rest, or to ameliorate further the distress of each act of urination, we advised prostatectomy. The perineal route was chosen. Fol-

lowing the operation there was moderate shock, from which the patient rallied quickly, and made an uneventful recovery. He was out of bed at the end of a week, and left the hospital on the eighteenth day. He now voids his urine without hesitancy and without the agonizing sense of obstruction. He has no residual urine. He retains his erectile power and is in every way contented and happy. It is to be noted in this case that the attacks of retention early in his history were due to an inflammatory condition which gradually subsided sufficiently to enable him to dispense with the catheter, leaving the symptoms of organic enlargement well marked.

The next patient first came under our care in 1897, when he was 57 years of age. His first bladder symptoms appeared in 1892. These were great frequency of urination with violent tenesmus. His physician catheterized him, and by using the catheter once a week he was much improved, so that instead of urinating every fifteen minutes the urinary interval had lengthened to two hours; but he had some burning before the stream started and a great deal of hesitancy. At the time he came under our care he had two ounces and a half of residual urine and a urethra of $9\frac{1}{4}$ inches. The prostate was twice the size of the normal, was succulent and extremely tender. The patient returned two years later. He had done fairly well, excepting for a few days at a time. At this time the urine was purulent; there were four and a half ounces of residual urine, and the prostate was larger than at the previous examination. Business necessities detaining him, we did not see him again for another two years (in 1901), when he again reported with purulent urine. He had had no attacks requiring the frequent use of the catheter, but he used it regularly before going to bed, which saved him from urinary disturbance in the night. His prostate had evidently increased in size, and he now had twelve ounces of residual urine, distinctly purulent. He disappeared from view for about four years, then returned and stated that he was able to void urine spontaneously by allowing over a quart to accumulate in the bladder. If for any reason it was inconvenient to use the catheter he was able to keep himself moderately comfortable by these spontaneous urinations; but he used the catheter night and morning and drew off each time what he called, indefinitely, "a large quantity." In spite of this emptying of the bladder he had attacks of tenesmus which at times were violent. The urine is persistently and highly purulent. He voids, spontaneously and with the catheter, over a hundred ounces in twenty-four hours. Examination of it shows a low specific gravity and evidences of chronic diffuse nephritis. It was evident that serious back-pressure upon the kidneys was present and that the only way to relieve this and to prevent further infection of the urinary tract was to remove the obstruction. Perineal prostatectomy was done after careful and thorough antiseptic preparatory treatment. The patient made an uninterrupted recovery and was out of bed on the eighth day. He now empties his bladder normally and completely. The urine is clear, excepting for a few shreds; but he still excretes a large volume of urine, which obliges him to urinate once at night.

The next case is presented in illustration of a relapse after a Bottini operation and also for some instructive features. He was improved for a year or two after the Bottini, but gradually there developed an increased frequency of urination, the urine became muddy, and at times he had complete retention of urine lasting three or four days. Then spontaneous urination would be resumed, with, however, straining and difficulty. There was also at indefinite times a sudden unaccountable increase in the amount of pus in the urine. He was repeatedly examined very carefully, but the source of the pus could not be found. He suffered two attacks of epididymitis culminating in abscess. It now having become evident that treatment would only modify his local conditions and apprehending deterioration of his general condition we advised the radical removal of the remaining obstructing portion of the prostate. This accordingly was done, the perineal route being chosen. Enucleation was extremely difficult, because of the cicatrices resulting from the Bottini operation. Deep suprapubic pressure and forcible traction from below were required to obtain the fragments of the lobes of the prostate. When the capsule on the right side was incised and the finger introduced to separate the lobe there was a sudden gush of pus, which was estimated to be from half an ounce to an ounce or more in quantity. The source of the excess of pus in the urine from time to time was thus discovered. It should be noted here that during the course of this case there was no rise of temperature such as would lead one to the suspicion of a pus accumulation, excepting during the attacks of epididymitis. The patient was extremely prostrated for several days after the operation. He had a little rise of temperature, to 101°, which disappeared after removing the gauze drains; but he remained weak, with a rapid pulse of poor force, for five or six days, and it was not until the end of two weeks that he was allowed to sit up in bed. At the end of three weeks he was allowed out of bed and left the hospital about four weeks after the operation. He is now, nearly a year and a half since the operation, able to evacuate his bladder without straining; there is no residual urine; the urine has become clearer, but there is still a little pus in it and there is a minute perineal fistula from which a few drops escape at times. This case is instructive, as it shows the failure of the Bottini method to give permanent results in a patient whose prostate is of large proportions, and the difficulties to be met if prostatectomy should subsequently become necessary.

In a study which I made of the Bottini method in 1901 and which I read before the Medical Society of the County of New York, I said as to the permanency of the results, "time only will tell." It is possible and highly probable that if any of the prostatic tissue is left and the causes of prostatic enlargement still acting, some of these patients will have a return of their symptoms. The next case is one of four which bear upon this point, and which I have had the opportunity of examining after prostatectomy.

A married man, aged 59, who in 1901 had a high grade of cystitis, passing blood and pus in the urine and with no spontaneous urination. The catheter was always necessary as often as six times in the twenty-four hours. His prostate was removed by the perineal route by a competent surgeon, and for eighteen months he had great relief, being able to urinate spontaneously, but always retained two ounces of urine. This residual urine gradually increased in amount until some time within the past year it had increased to a pint. In June, 1905, his physician inserted a retained catheter, which was kept *in situ* for about three months. During its presence in the urethra he had bleeding and immeasurable distress; but he persisted until, finally, there being no benefit, its use was given up. Since September, 1905, he has been obliged to use his catheter at least four times a day. When his bladder is full—that is

to say, after an interval of four or five hours—he can void some urine spontaneously. Blood and clots have been detected in the urine at different times during the last year. Such was his history when he came to me in consultation. Examination by rectum shows an enlarged prostate, three, possibly four, times larger than normal, the left lobe being much larger than the right and with thick, indurated areas in it. Bimanual palpation detects a large and thick median lobe. On attempting to introduce a soft catheter, it enters a pocket or pouch posterior to the prostate and enters eleven inches before it is arrested. Fluid injected into this pouch returns by way of the urethra. A metal catheter can be introduced into the bladder by keeping its beak well up against the roof of the urethra so as to avoid the opening into this pouch. At eight inches from the meatus ten ounces of mawkish, purulent residual urine is obtained. He cannot void any of the antiseptic solution which is injected into his bladder. We advised cystoscopy as being necessary to a positive opinion as to the new tissue, and also as to mode of treatment. Apparently there has been a reproduction of the prostatic tissue with a renewal of the obstructive and inflammatory symptoms. It is possible also that a malignant degeneration may be taking place in the remnants of the prostate. In regard to this I have no diagnostic data, but in view of recent knowledge of malignant disease of the prostate this possibility should be borne in mind.

In conclusion let me add, that in deciding whether or not to advise prostatectomy we consider the following factors: the general condition of the patient, his social condition and environment, his temperament and his accessibility to judicious medical advice and assistance; whether or not catheter life is likely to fail, and if it has failed, in what degree; and further, what measure of relief is to be gained, even if after the operation some imperfection should remain, which, compared with his prior condition, is insignificant and minor. The ultimate outcome of the operation cannot be definitely foretold, but the relief and comfort are so great that when the indications are clear, it can be wisely advised.

20 East Forty-sixth Street.

THE FEEDING OF INFANTS DURING THE HOT WEATHER.*

By I. L. POLOZKER, M.D.,

DETROIT.

ASSISTANT TO THE CHAIR OF PRACTICE OF MEDICINE AND DISEASES OF CHILDREN; LECTURER ON POST MORTEMS, DETROIT COLLEGE OF MEDICINE.

The heading of this paper might more properly have been: "The Feeding of Sick Infants During the Hot Weather," for most of my experience has been with babies at the clinic, where an infant never is brought for advice or any other suggestion regarding its feeding unless it is sick. Almost invariably infantile troubles are due to improper feeding, especially such feeding during the summer months. In this connection the splendid humanitarian work done by the Pure Milk fund should be mentioned. I may say that I have the means of knowing that it has been of most incalculable benefit to sick infants during the past summer, and take this occasion to thank the committee of the Pure Milk fund for what they have done for the little sufferers at my clinic.

*Read before the Wayne County Medical Society, April 2, 1906.

Most of these little patients were suffering from some form of acute diarrhea when brought to the clinic. We found just as many cases of acute diarrheal diseases among breast-fed babies as among those fed on the bottle. Indeed, 80 per cent. of our patients treated during July, August, and September were breast-fed babies.

There is an idea prevalent among general practitioners that all the mother has to do with the baby when it is afflicted is to nurse it—a theory which takes no account of the mother's own physical condition. That I may not be misunderstood, let me say that I am a strong advocate of nursing as long as is possible, provided only that the mother's condition is fit. I am always opposed to the baby being deprived of the mother's breast when there is any hope that she can provide the child with the necessary healthful sustenance. I further advise partial feeding at the breast, when no more is possible, such feeding to be continued as long as possible with good results to the patient.

Mother's milk should always be examined by the physician from time to time while she is nursing her infant, according to the simple method recommended by Holt. Holt's objections to the mother's nursing are as follows: (1) No mother who is a subject of tuberculosis in any form should nurse her infant; (2) No nursing should be allowed when serious complications have been connected with the parturition; (3) Nor if the mother is choreic or epileptic; (4) Nor if the mother is suffering from serious chronic disease; (5) Nor when experience on two previous occasions under favorable conditions has proved her inability to nurse her child; (6) when no milk is secreted.

We are considering in the main the babies of the clinic. The reading of these rules will have brought to your minds the fact that it is the indigent, needy mother who is subject to these ailments and who often brings her baby emaciated to the clinic. She has before this time been trying to nurse the babe in spite of her handicaps, unless, as rarely happens, she has been lucky enough to call in some physician who has advised her not to do so. Very often, accordingly, we have to stop this kind of nursing, and there is where our trouble begins.

The rules laid down by Holt, cited above, can be modified. Taking up the second one—if the complications following parturition have not destroyed the milk, and examination of the milk shows it to become satisfactory as the mother improves, the mother may be allowed to nurse the baby. She not only may do so, but should do so. And so with all of the rules cited—they can be modified, and it is for the practitioner to exercise his own knowledge and judgment in each particular case.

I must condemn the improper advice often given by the obstetrician or midwife who attempts also to treat the infant, the advice to the mother not to nurse her child. The child is put on some proprietary food which the accepted authority in this case has been used with good results—some particular brand of condensed milk or malted milk which has produced a fat baby. They take away from the baby a food containing the proper formula of fat, sugar and proteids and replace it with a food containing nothing but sugar, no proteid, or so little that it is invisible. The baby cries because it is hungry. The person advising the mother thereupon takes away from it the food which is at least partially sustaining it, a weak or deficient quantity of mother's milk, and gives no food at all. Fine advice, truly! Our histories of infant feeding will show how very often the physician keeps a baby on a proprietary food, the

composition of which physiologically, is very weak, and hardly capable of sustaining life. I hope the time will come when the obstetrician will attend to his work exclusively, and when there is any question about the feeding, will call in the man who has put in a good deal of time and acquired experience in this special work. I always advise that the child be nursed, and it is surprising in how many instances persistence will prove the wisdom of this advice, despite the mother's original complaint that she has been unable to nurse the child on account of lack of milk in the breasts, or because the child will not take nourishment for some other cause. I meet very often with these cases in which the babe refuses to take the breast at first, but persistence even to the extent of letting the little one go hungry brings success.

When we have to feed the infant artificially, the wet nurse is generally the first recourse, as you well know. For reasons which I will mention, however, it has long been a question in my mind whether I would not rather utilize the laboratory milk properly prescribed. The ideal wet nurse exists only in our imagination in this country. In the old country, with a peasant population, healthy in body and animal-like in mind, wet nurses are found to give satisfactory services. In this country it is rare to find a good wet nurse, free from disease, and when one such is found she has so great an appreciation of her importance to the family that she generally becomes unbearably independent. With all these drawbacks, where no breast feeding is possible, or only partial breast feeding, I favor laboratory percentage feeding. And, as above stated, it is when we put the baby on artificial food that our real trouble begins. The surgeon has been telling us what he has done in the last century. How easily he can open the abdominal cavity and remove the appendix, ovaries, and other organs without any trouble if he is clean. But the task that falls upon the pediatrician is to feed a baby deprived of its natural food, the breast, in the summer months, the child presumably afflicted with a severe form of iliocolitis, with bloody, shreddy, green stools every ten minutes, vomiting, great prostration, a high fever, the child reduced in a few hours to almost nothing, while on top of this there are mother, grandmother, perhaps, and other interested parties to combat his scientific work and formula—all this raises a situation that truly requires the exercise of intelligence, patience, hard work, and diplomacy.

It is to Rotch, who has practically given us the percentage modification of cow's milk, modified and fixed for us in a well-equipped laboratory, that our thanks are due for extricating us from this trouble. In this laboratory the physician can with care modify and write a proper prescription that will suit each individual case, saving the unfortunate infant which nature has crippled by depriving it of its mother's milk. To Rotch, indeed, is due the credit for having saved for their country so many little ones who have grown up to become beautiful men and women, some of them saved, as a matter of fact, for the surgeon, who can later remove their appendix. Seriously, he helps to save the Nation from retrogression. What else would result with our American woman, with her race-suicide tendencies, and our poor immigrant children dying off from improper feeding?

Of the troubles contended with in the case of infants during the summer months, diarrhea is the most common. The classification by Dunn, of Boston, based on the clinical aspect of this trouble, is a very good one. He notes five phases of the affection: (1) Acute nervous diarrhea, loose stools, normal color, and odor, without abnormal constituents; (2) Irritative diarrhea, no fever, curds, and undigested masses; (3) Fermental diarrhea, no fever, green stools, sour odor; (4) Infectious diarrhea, fever and signs of ilioclitis, blood, and mucus; (5) Cholera infantum, or diarrhea due to heat exhaustion.

Dunn says that the second and third of these classifications are the more common. But last summer we had every type mentioned, and found that the third and fourth, fermental and infectious diarrhea, were the most common. The infection is due to the introduction of bacteria from without or to autoinfection from bacteria in the intestines. Dunn's classification is one that I like very much, as it makes diagnosis comparatively easy.

At the clinic last summer two groups of diarrhea were prevalent. There were: Cases characterized by green stools, often with a sour odor, but no fever (classed above as fermental diarrhea); stools green and mucous, or maybe also symptoms of iliocolitis, and always fever. Both of these groups occurred in breast-fed as well as artificially fed babies. Our treatment last summer was the same as that of the summers preceding—first, to stop all feeding and give the patient a good dose of castor oil. Calomel was given in some cases, but oil was preferable, as it seems to have a quicker and more beneficial effect on the gastrointestinal tract after the first unpleasant taste, while calomel often produces a great deal of straining and is slower. Infants under one year old were given two or four teaspoonfuls of oil or calomel and bicarbonate of sodium, one and one-half to two and one-half grains in divided doses, and no food but boiled water was given, and that in small quantities frequently for the first twenty-four hours. The second twenty-four hours the child was put on a little weak whiskey water, a teaspoonful to the pint, or a little barley or rice water, an ounce to the pint, strained. As the temperature would drop to normal and the child would get very hungry, it was gradually placed at the breast, if a breast-fed infant. It will not be necessary to more than mention that the milk of the mother or the wet nurse has to be carefully examined and any defect corrected, as it varies so often.

When the infant was bottle fed we were frequently puzzled as to what course to pursue. My experience with the ordinary milk sold in the city during the past seven years has been very unsatisfactory. I used to stop the giving of milk entirely, for both infants and other children, keeping them during the hot days of the summer months on cereal waters, beef juice, etc., for a while. Since the establishment of the Walker-Gordon laboratory, a great deal of responsibility has been taken off the physician's shoulders. This was especially true last summer, the pure milk supplied to different classes of people making it available for the poorest baby.

As you all know, Walker-Gordon milk means nothing more than a clean milk that we can prescribe as required for our patients' digestion. It is necessary to note, however, that the laboratory milk prepared simply from the book formulas will not do the work. The physician has got to adjust a formula to the digestive capacity of the infant, and very often we have to change it so as to attain the results. We study the principal constituents of the milk—fat-carbohydrates, proteid, separately. We study the trend of symptoms asociated with overfeeding, with the amount of each principal ingredient in the milk, as, for instance, the fat constituent of the milk. We study clinically the effect of too much fat, or too

much sugar or proteids, or of the divided proteids. We also study clinically the symptoms and effect on the child when fed on a deficiency of all three or any one single constituent of the milk.

First, Fat.—The average amount a healthy baby can digest is from 2 to 4 per cent., and it is usually not necessary to increase it above 4 per cent. In the summer months moreover, the child will get along better with 2.5 to 3 per cent. of fat. Now, let us see what an excess of fat will do. It will produce vomiting or regurgitation of food in small quantities about one hour after feeding. Diarrhea, with stools lumpy and colicky, foul smelling, olive green and formation of gas. Jacobi says excess of cow's fat produces acid autointoxication in infancy. I give very little fat, he adds, as a food, say 2 per cent. or less Holt, in (*Archives of Pediatrics*, January, 1905) speaking of disturbances of digestion in infants resulting from the use of too high percentages of fat, reports five interesting cases involving overfeeding with high fat percentages. In these cases there was a rapid increase in weight and apparent development for a while until the infant was about eight months old, then ensued convulsions, followed later by tetanus, laryngismus, stridulus, fatty liver, etc. All five of the cases he reports had convulsions, acute disturbances of digestion, vomiting, constipation, etc. Jacobi, discussing Holt's paper above quoted, asks: What is it that permits little babies to tolerate so much fat that older babies cannot tolerate? But it is not true that little babies can tolerate fat to any such extent. When they can tolerate fat no longer they break down. He says, further, that it is not low fat percentage that causes constipation, but that the constant feeding of low proteids produces insufficiency in the muscle walls which causes constipation. Northrup says, on this point, that too much fat causes vomiting and whitish passages. And in spite of this showing, some physicians increase the fat percentages as soon as the baby is found to be constipated. Now, regarding the effect of too little fat. Fat helps in the production of animal heat. It also adds to the body weight by storing up fat in the body needed for the growth of bone, nerve cells, and fibers. When fat is greatly reduced inorganic salts appear in large quantities in the feces; for fat aids in the absorption from the intestines of the inorganic salts. Thus, too low percentage of fat causes hard, dry stools and a good deal of straining, followed by its consequences, prolapses of the rectum, etc.

Next, as to the proteids, I find that from 1.5 to 2 per cent., or, for a child over a year old from 3 to 5 per cent., is proper. You are all more or less conversant with the ill-effects of feeding with an excess of proteids. Besides this question of excess, we must also take account of the fact that the proteid in cow's milk differs from the proteid found in woman's milk; and in changing from the latter to the former Holt advises four different methods: (1) by reducing the proportion; (2) partially predigesting by peptonizing; (3) separating them by removing the casein by coagulation with rennet; (4) using as a diluent not water, but gruels, cereal waters, etc. All that is involved in these recommendations the laboratory now accomplishes for us. You prescribe proteids, whey, and caseinogen. Now, to consider the question of excess of proteids. The result of this excess is colic, the presence of curds in the stools, and if the excess is great, the result is constipation; if less, diarrhea, vomiting, regurgitation of small quantities of food at times, and if the excess is continued there follow gastroenteric symptoms, convulsions, and other nervous disturbances. And there are these symptoms if the digestion of the proteids is not perfect, even if the quantity for the age of the infant is correct. Accordingly, as much should be given as the baby can digest, regardless of the formula. Begin always with a low percentage of proteids and gradually increase it as the infant's digestion permits. Proteid is, of course, essential to life, as it is the food which repairs the nitrogenous waste of the cells, and without the aid of the other two important constitutents is capable of sustaining life. But the quantities would have to be high. You can see that if very low proteids are prescribed the other elements must be much in excess. Insufficient proteid in the baby's food always causes anemia and depleted vitality, flabby muscles and impaired circulation, and when very low, failure of nutrition, loss of weight, rickets, etc. You can see the folly of keeping the infant on low proteid, especially if the fat is below normal.

Sugar.—It is not necessary, usually, to have the percentage above or below 5 to 7. An excess of sugar produces hyperacidity, eructation of gas from the stomach and regurgitation of small quantities of food, dilatation of the stomach and other gastro-intestinal disturbances, colic, thin green stools, very acid causing eruptions on the buttocks, and various forms of eczema. If very excessive, there is an increase of weight, but not of strength. This is where the patent baby food on the market, being rich in sugar, makes the babies fat. Carbohydrates are the best sources of animal heat. If very low, we have poor circulation and loss of weight. As a rule, it is the easiest to digest. Some authorities advise cane sugar, instead of milk sugar, and often it does better in some cases. As a rule, if sugar is very low, the heat supply lessens and the system draws on the fat and proteid. If the other two are in excess the result might be favorable; but it is necessary to note that if the other two constituents are no more than necessary the whole system suffers.

Summing up, then, proteid is of the first importance as the constituent of food, for it builds up the cells of the body. Sugar stands second in importance, and fat comes third. If it is a matter of heat supply for the body, fat ranks first. To have a proper food all three must be found in their proper proportions. And clinically we have been convinced from our work last summer that excess of fat in our feeding caused us more trouble than any other constituent in the food.

In the case of the clinically treated baby above described, and after the castor oil was given, the baby was fed on boiled water, albumin water for the next twenty-four to forty-eight hours, and if the temperature was normal after that, the child was fed on gruels, and last of all on milk. During past summers up to last summer we have always had a reappearance of the diarrheal trouble as soon as the child was put on cow's milk. But last summer we put those that were not nursed on Walker-Gordon milk. The usual theoretical formula gotten up by the laboratory was as a rule for dispensary use cut in two, that is for a ten months old baby, F. 4.6, S. 3, P. 8 ounces, the regular formula, was reduced to F. 2.3, S. 1½, P. 4 ounces, not only cutting the ingredients but cutting the total amount in two.

This form of prescription I do not advise in private practice. There should be no hard-and-fast rule for infant feeding; every child requires a rule unto itself. In the clinical treatment, the patient was watched, the mother was instructed to come back every day, and especial attention was paid to details such as these: She was instructed just how many bottles of milk she was going to get, what she should

do on receiving them, how she should warm them before feeding, how the nipples must be cared for in a warm saline or alkaline solution, and how often she was to feed the infant during the day and night. And in this lies the secret of our success last summer. It is surprising how ignorant some mothers prove to be regarding those little things one naturally expects them to know. A frequent cause of trouble is that we take too much for granted in feeding infants, depending too much on the mother's supposed knowledge. Ignorance on these points is often manifested by some otherwise very intelligent young mothers. Frequently they will take the perfectly clean milk delivered to them with such care and contaminate it. In some cases we have seen them take the milk out of the bottle in which it was delivered to them, and put it in a dirty nursing bottle to feed it, or put a nipple on that has been kicking around the floor, the plaything of older children. They will take the bottle with them out on the streets on a hot July day, shopping, and have the child in the baby buggy for hours exposed to the sun. The milk bottle will lie in the buggy along with dirty napkins and infection thence arises. One case especially I can trace, that of twins, both in the same buggy, bottle and napkins together, one sick, the other well baby. It was surprising in how many cases when the mother made her second visit to the clinic, the formula would have to be again cut down, the proteids being especially reduced. In some cases the proteid would have to be reduced to less than one-fourth of one per cent. before the patient could digest it. The same applies to fat, but to a lesser extent.

The amount of sugar the little ones could digest when they could not assimilate anything else was surprising. This accounts for so many infants seeming to thrive on a proprietary food. This goes to show that the baby may get along very well for a time on a proprietary food, but the mistake occurs when this feeding is allowed to continue. Then the food, too low in fat and proteids, produces rickets with all the accompaniments.

Reverting again to the clinical treatment, when the formulas still did not agree with the patient we very often advised the mother to add an ounce or two, as the case might be, of sterilized water to each bottle, and in that way we would reduce the quality of the milk one-half to one-quarter. This could be accomplished without having to write a new prescription and without troubling the laboratory.

To carry out this form of treatment a great deal of patience and time was necessary. Our patients had to be seen often and educated. The only way we can win the support and help of the clinical patients is by showing the mother actual results. When it could be pointed out to the mother that the baby was gaining in weight, and it would be so pronounced that the mother would see it, we had no trouble in obtaining the mother's cooperation.

I will here review a dozen cases chosen from a hundred treated in private practice and at the clinic last summer. I do not want to take your time with many cases, but choose for your consideration special cases that have been neglectful in coming regularly, and in spite of the parents being against us we obtained some results, and will give you a general view of the methods and results obtained. I have prepared a chart showing at a glance the age, duration of illness before the child came under observation, the first formula given, the weight when first seen, and the subsequent weight at the end of various periods.

Age in Weeks.	Duration of Illness.	First Modification Percentages of Fat, Sugar, and Proteid; Amount at Each Feeding; Number of Feedings.	Weight in Pounds			Increase in Pounds.
			At Commencement.	At the End of		
45	14	4, 7, 3, ℥ vi, 5	13	36 days,	17	4

13	21	3 5, 6.5, 1, ℥ iii, 6	12	10 "	12	None

Among the hundred cases treated at the clinic and in private practice we had two deaths. There were two other deaths, but responsibility did not lie with us, as I will explain later. Of the two deaths I take account of now, one occurred in private practice. The case was that of the eighteen months old daughter of a physician. She was nursed till one year old, and then fed properly till taken sick. Was always well. Teeth came normally. On July 10, 1905, she was taken sick with diarrhea and vomiting. The doctor ordered one teaspoonful of oil, and as the child was having a great deal of tenesmus and pain, this was followed by large doses of subnitrate of bismuth. I was called forty-eight hours later. The child had a temperature of 100.5°. The bowels moved every half hour with a great deal of tenesmus and pain, but the child apparently was in fair condition. The history obtained was that on the day the child took sick she was at a picnic and partook of a good many good things to eat, popcorn, ice cream and cold meats. The day was hot and the child was in the sun all day. I ordered a tablespoonful of oil and stopped all food, giving only barley water. The mother gave her one-half a tablespoonful, taking it upon herself to make the change. The child cried, and she again gave the baby the bismuth mixture, having it handy. I saw the child the following day, the third day of its sickness, and when I learned what had been done, I explained to the mother that she had done wrong, that we had lost twenty-four hours time and given the germs a chance to do their mischief, and we had to do our work all over again. The child's temperature was 101°, the pulse rapid, 120 to 130, the stools frequent, watery and green, with a great deal of pain. A tablespoonful of oil was given by myself, and an enema of water, followed by an antiseptic peroxide of hydrogen, a weak solution. The temperature dropped to normal the next day, but diarrhea continued, blood appeared in the stools, the gastrointestinal tract was washed out with antiseptic and astringents like tannic acid, etc., were used, but with no effect on the diarrhea. There was continued blood and tenesmus. The following day the blood stopped, but the stools continued frequent and were mucous. The child was rapidly failing and prostration was very marked. In spite of everything done to sustain the rapid loss of fluids by saline infusions and the use of light, predigested foods, on the tenth day the child could not swallow anything. On examination of the mouth and throat nothing could be made out. With the condition that prevailed within the rectum, rectal feeding was impossible. On consultation, antitoxin was suggested and administered, and I also suggested streptococcus serum, and we used both. Ten c.c. of streptococcus serum was injected, followed by 1,500 units antitoxin. Examination next morning showed a characteristic membrane on the tonsils and posterior walls of pharynx. Although no

culture was taken, it did not look like diphtheria. A few drops of beef peptonoid were given with a dropper. She could not swallow. She would keep it in her throat and regurgitate. It was a case of amebic dysentery, and I am only sorry that no bacteriological examination of stools and membrane was made, as it should have been done. No post-mortem examination was allowed, but in my mind I could see a picture of a membrane like that of the throat all through the gastrointestinal tract.

The second death was a dispensary one. The patient was a little girl six months old, never had been nursed at all, was fed on Swiss condensed milk before it took sick. No birth complications. Brought to clinic August, 1905. Diarrhea, green stools, moving every half hour, child wasted weighed only 6½ pounds, which was one pound less than at birth. The mother tried cow's milk, diluted, and it was vomited, as she said. This infant was put on formula, F. 1, S. 4, P.O. 5, 2 ounces every two hours. Baby seemed to retain it, and apparently thrived for a week, but it was impossible to have the mother come to the dispensary. After the first week, she neglected, and had to go out to work. The child's bottles would be left with a neighbor, who would forget to feed the baby, and when she happened to think of it, in order to make up she would give the baby two or three bottles at one feeding. The baby again developed a diarrhea, this time with green stools, with vomiting of everything given. The temperature was 101 to 103° F. The food had to be stopped. The child could not even retain a weak solution of brandy, and it died two weeks after it came to the clinic. A post-mortem examination was not obtainable.

It may be said that we had two deaths in the clinic, of which also we ought not to take any account in this discussion, for if the infants had had a chance for life they would have gotten well. The case I am to speak of was that of two white children three weeks old, twins. Their weight was 6½ and 7 pounds. They had been fed on condensed milk, and had diarrhea and also ophthalmia neonatorum. After putting the twins on castor oil and stopping food for the first twenty-four hours, they were then put on a prescription of F. 0.5, P. 0.25, 1 ounce, eight times a day. As the mother did not bring the children back to the dispensary as required to do, we sent to the home and learned that she had told her physician about it, and he told her laboratory milk was no good, and the mother stopped and the children died a few days later.

So, in feeding infants we must remember that we cannot feed them all alike. In clinical feeding we learned to our satisfaction that all infants, even of the same age and weight, cannot always be fed on the same formula. It is the digestive capacity of the infant that governs. In feeding laboratory milk or cow's milk, the physician must be sure to put the patient on a very low proteid percentage, and as the powers of digestion increase, increase the proteid percentage. In prescribing, it is necessary to take into account the condition of the patient as regards not only age but weight. If there is any trouble with the digestion, lower first the proteid. The proteid gives the most trouble. Second, look to fat, as fat is next. The general rule can be laid down thus: If the child is not gaining, but at the same time shows no symptoms of indigestion, all the ingredients of the milk may be increased in proportion. If colic supervenes, the amount of the proteid should be lessened. If there is vomiting after feeding, the amount of the proteid should be reduced. If there is regurgitation of undigested masses of food, both fat and proteid should be reduced. If there is constipation, increase the fat and proteid percentages.

I revert again to an explanation of what modified milk has done for the infants of Detroit. While in my private practice I commenced to use the modified milk as soon as I was able to obtain it, my experience with it in that practice has not been so extensive as in clinical work, and I prefer to draw my conclusions from the latter. My dispensary practice since the establishment of the free milk fund last summer has given me the advantage of laboratory prescriptions. During the period before that I had not that advantage. I think I can speak with authority from the comparative point of view, having had seven years' experience without the laboratory prescription, and having had the prescription method last summer. I have nothing but praise for the laboratory prescription, if the principle is understood as laid down before. And the comparison thus favorably drawn is emphasized by the fact that the patients to whom the laboratory milk was given were very sick or were just getting over some gastrointestinal disturbances. But, as I have two or three times said, a great deal of the success attained was due to the hard work and careful attention devoted to the work. The patients were seen daily for a while and later were seen three times a week. No milk was prescribed unless the child could be seen at least once a week, and we left orders at the laboratory to have the mother bring a prescription every week. The results were marvelous. We had just as many severe cases last summer as during any summer previous and the mortality was certainly lowered. If it is still asked what accomplished this, the answer can only be, clean milk of proper constituent parts for the poor and needy, for those whose need was most urgent. You can say all you like about being able to get clean milk from some dealers, but the mothers that came to our clinic were satisfied with any milk provided only that they were told that it came always from the same cow. Having this food for her infant, she is satisfied and does less for her baby than she would do for her pet cat. The average woman in moderate circumstances in life who has several children to take care of, or whose time is taken up with her household duties so that she cannot give all her time to her baby, readily accepts the laboratory milk. She has little to do but receive and feed it when the time comes. There is very little chance for contamination if she is only ordinarily clean. Everything is all right but the price. A striking lesson in negligence in infant feeding, due to the ignorance of young mothers nursing their children, came to my notice last summer in the course of my private practice. This was a case of a nursing baby of four months. When first seen there were green stools two or three times a day. The infant was crying day and night, drawing up her limbs and was very sensitive to the touch in the region of the abdomen. Examination of the stools showed green undigested matter. Examination of the child showed otherwise negative, the temperature normal, etc. It was the mother's first baby. The mother looked healthy. The breasts were large and there was plenty of milk. On inquiry, I found that the mother had not been out of doors since the baby was born. She hadn't any clothes good enough to go out in, she said. I told her to get out in the evening, which she did, with almost immediate results. Another case was that of a baby six months old, taken sick in September last. There were green stools and the temperature was 104°. The baby had always been nursed. The mother's condition was good, with plenty of milk, the nursing regular. On questioning

the mother about herself, I found her husband had left her a little while before, and while she had means for self-support, she had not heard from him and began to worry. Just as soon as she began to worry, the child became ill. In this case the child grew worse every time the attempt was made to nurse it, and it finally had to be put on laboratory milk. Then it got along nicely. The third and fourth cases in mind were similar to the preceding. In the fifth case the child was four months old. A neighbor had told the mother that she would never succeed in raising the infant. The milk then seemed to lessen in amount. Examination revealed the fact that it was low in quantity of fat and proteid. The mother continued to worry, and finally the infant had to be put on prescription feeding.

What I have seen and read convinces me of the truth of what Northrup has said: "A prize dairy cow would go dry in a week under the strain which most young mothers endure." And in this connection I may remark, it is lamentable and surprising the amount of discouragement they get from older mothers. In all the cases I have cited above, the mother had to be looked after. Rest, good food, exercise and out-of-door walks would often improve the milk and the child would gain. A cause of trouble in the mother's case which might have been mentioned with the above, has been found to be the use of the scales by which the mother kept close watch on the baby's weight. It is all right if the child is doing well. But for a nervous mother the scales for the young infant and the thermometer for the older child, if the infant is not gaining fast or the child has a little fever—trouble.

Regarding the influence of feeding on infant mortality, W. J. Howarth of London, England, has investigated the question, and reports regarding 8,348 children. Of these, 63.3 per cent. were breast fed, 19.5 were hand fed, 17.3 were breast fed at first and hand fed afterwards. The highest death rate, 107.5 was among hand-fed children. It was nearly three times that recorded among breast-fed children, among whom the death rate was 69.8 and twice that of children partly nursed, 98.7. Among hand-fed children, diarrheal diseases and deaths from defective nutrition prevailed. Next in importance, are chest ailments, and then convulsions due to disorders of digestion. Among children who were first breast fed and then hand fed the death rate is not so high as among purely hand fed, although the aggregate mortality is considerably higher than among breast-fed children, in one or two diseases mortality is lower. Children who have natural food supplemented by artificial food have advantages over those who are fed on artificial food altogether. Children fed on condensed milk show a higher rate of mortality—225 deaths per thousand—the next come children reared on arrow root and farinaceous foods —252 in the 1,000. The death rate of children fed on patent foods is on the average higher than among those fed on diluted cow's milk. And the mother, if she has not enough milk to nurse the child, should not be encouraged to try to feed it.

There is a good lesson to be learned from such an article. How important it is to educate the mothers and to show them that when they feed a child on some of the patent foods they feed it on nothing. It is not only the mothers in indigent circumstances that misunderstand this matter; I find a good many physicians having experience may be of one or two cases or perhaps having had a case in their own family, feed on patent food. Experience has convinced me that the mortality of infants can be reduced especially provided we can do something for the poor—provide pure milk and fresh air, especially in summer. Teach the mother the laws of hygiene and how to care for the baby during an attack of diarrhea, and how to care for the napkins. Distribute literature on the prevention of disease and on the feeding of infants during the summer. Later on it would be a fine thing if we could have district physicians and nurses who would go out and show them how to do it. I can see in such a plan infant mortality much lowered in the near future.

My experiences in the cylinic with laboratory milk have proved to me that the laboratory milk gives the best results. When in the past they were dying rapidly, home modifications of cow's milk made no improvement because of the failure of the mother to carry out our instructions as to modification and cleanliness at home. The last summer, with prescription feeding, and above all by careful attention to details, we had only two deaths to report in the hundred cases. Laboratory milk, properly prescribed by the attending physician, the case watched carefully as to the digestion of the child from day to day, so as to notice the necessity for changing the prescription to a higher or lower percentage of the ingredients as the case may be, is the only proper feeding when artificial feeding is to be resorted to. Some physicians think this artificial feeding is a fad only for sick children, but it provides food for all cases in which the infant cannot get the mother's milk or when the mother's milk is not sufficiently sustaining.

Home Modification.—Unless you have a trained nurse in full charge of the baby, home modification is not the proper method. Where the best results were not obtained from laboratory percentage feeding the physician was to blame, and not the laboratory. If the physician doesn't know the first principles about infant feeding, and doesn't know the constituent parts of cow's milk and mother's milk, if he doesn't know how much the child can digest and what quantity of fat, sugar, and proteid, but relies entirely on a few general formulas given in textbooks or pamphlets, then he will have unsatisfactory results in laboratory feeding and will condemn it. I have seen a case, that of a child five weeks old, having a marasmus vomiting, and diarrhea, taking milk containing 2 or 3 per cent. of proteid and a higher percentage of fat, when it could not digest a formula I prescribed containing one-tenth of one per cent. of proteid, 25-100 of fat, the lowest formula prescribed in a laboratory.

One of the chief causes of failure of laboratory feeding is due to the fact that it is easy for a physician to raise the percentage of the chief ingredient, the fat, sugar, and proteid. And this advantage is abused by a great many, either through ignorance or letting the mother or grandmother run the prescription. An instance: An infant four weeks old, who never had had the mother's nursing, was under my care on a formula of F. 1.5, S. 6, P. 1.25, and was gaining slowly but surely, slept well, was playful and happy. The weight was twelve pounds, but the mother and grandmother were not satisfied, and said I must give the boy more food, it had got to be fatter. I told the mother that it was getting all it could take, and I would rather let go than be run by the grandmother. Finally I told her I could make the baby fatter, but she would have to take the consequences. They agreed. I raised the fat and the child's gain was noticed immediately, so marked in two or three weeks, the mother informed me that even the grandmother was satisfied. She could see a double chin. Baby stood a 4 to 4.5 per cent. fat for a month, and

then the storm came, so bad that it convinced the mother and grandmother that they had better leave me alone. The fat was cut down, the child doing nicely. This illustrates the danger of a prescription in wrong hands. I don't want to try to tell you anything new, because I have no new knowledge to impart; I do wish, however, to emphasize the truths that have been told by our teachers in the past many times, as a last word for the laboratory feeding. I can only quote fully what W. P. Northrup says: "What is the best substitute for mother's milk? When the milk of the mother fully agrees with the child's digestion, which is not disturbed by shocks, sorrow, anemia, overfatigue, and worry, when it is not decreasing in quantity and so losing its balance in quality, there is no substitute worth having."

In comparing nature's formula in fresh cow's milk, putting up in a laboratory nature's prescription and preparing for the infant a feeding as nearly as possible such as the woman's breast furnishes. More than that it is filling in the laboratory prescriptions which may be changed to fit changing conditions and changing needs. It is now possible in a well-appointed laboratory to make artificial breast milk which shall have the right percentage of fat, sugar, and proteid, and alkilinity of the right amount to each feeding, the correct number of feedings in twenty-four hours. Further than that it is possible to rearrange the chief constituents of proteids, so that the whey proteids shall be in excess of the caseinogen and casein. Furthermore, when such a formula is made up, we can know what the infant is taking and ascertain what elements, if any, disagree Otherwise modified milk can be modified to suit, and the milk of the woman or wet-nurse cannot be. The function of the milk laboratory is to furnish the prescription for the physician. No doctor askes the pharmacist to send him medicine suitable for typhoid fever. He directs the druggist to fill him a prescription, that is all. He must look to the druggist for his reliability and exactness. The laboratory should be clean and accurate, but he, the physician, should not write a prescription and then go on a prolonged vacation. Mistakes are made by doctors—they think they can order laboratory milk the same as patent food. The infant during the first year changes rapidly. It is not the same infant more than two weeks at a time.

I want to thank Dr. H. A. Luce for assisting me in the work all summer, and the ladies whose influence is responsible for the pure milk fund. And I have also to thank Dr. C. G. Jennings, chief of clinic, for the aid and advice tendered by him.

In closing, it will be proper to speak of preventative measures in the treatment of summer diarrhea. Procure a laboratory milk, or a good, clean milk. Clean milk, it must be pointed out, is hard to get in this city, as in all large cities. The second thing of importance is to educate the mothers in the care of the child when diarrhea occurs. (a) Give a teaspoonful or two of castor oil, and no food. (b) Give whiskey in water, and rice or barley water. (c) Lastly, milk, and then give only half the quantity the child can take in health.

Teach the mothers the value of fresh air and water excursions. Teach them all about the clothing of an infant. We see this abused in the streets in our city. Teach them the value of bathing infants regularly. Keep them clean and cool; keep flies off; keep the nipples of the bottles clean. A great preventative against diarrheal diseases is the care of the napkins. The napkins should be changed as soon as soiled, put in a closed receptacle, washed and boiled as soon as possible. Don't have them in the same room with the baby.

I have spent much time teaching mothers along this line, and I am satisfied it was time well invested. After changing the napkins, before handling the baby or bottle, I have instructed the mothers to disinfect their hands thoroughly in some antiseptic. Reports from all infant asylums impress me that the danger of infection by the colon bacillus from napkins is greater than from any other source, and sick and well children should not be kept together.

270 Woodward Avenue.

A CONTRIBUTION TO THE STUDY OF THE DIAGNOSIS AND TREATMENT OF ECTOPIC PREGNANCY.*

By HIRAM N. VINEBERG, M.D.,
NEW YORK.
ADJUNCT ATTENDING GYNECOLOGIST, MT. SINAI HOSPITAL; VISITING GYNECOLOGIST, ST. MARK'S HOSPITAL, ETC.

One needs almost to start out with an apology at this time when offering a contribution on the subject of ectopic pregnancy. The subject may seem as trite and overwritten as that of appendicitis, and still the condition is far from being readily recognized and as generally well understood by the profession as is appendicitis. The failure to recognize the disease I find is due *not* so much to any inherent difficulties in the diagnosis (although I grant such do exist in many instances) as to absence of thought of the condition. The medical attendant will often say: "I never thought of ectopic pregnancy." In the hospital, the interne, after a short service in the gynecological ward, learns to spot out the cases of ectopic pregnancy with surprising accuracy. He does this chiefly because his attention has been drawn to the disease and his mind is on the alert for its recognition. It is not so, as a rule, in private practice outside the hospital. The medical attendant seldom makes the correct diagnosis, but usually treats the case first as an early miscarriage, very often does a curetting, and, when things do not go right, as they do not, he diagnoses inflammatory disease of the adnexa. It seems to me, therefore, that it might be of some interest, and perhaps not devoid of instruction, to present a short paper on the subject, based on my own personal experience with 53 cases, the total number operated upon by me from January 1, 1899 to January 1, 1906, a period of seven years.

The ages of my patients varied from 22 to 41 years; twenty-five were under 30 years of age; fifteen had given birth to one child; eleven had given birth to four or more children; one was the mother of eight and another of eleven children; six had never been pregnant before; two more had been pregnant once but had miscarried. Of the six patients who had never been pregnant before, one was married seven months; one, two years; two, three years, one, four years, and one, twelve years. In the latter, that is, the patient who had been married twelve years, the result of her first conception, singularly enough, was a simultaneous uterine and extrauterine pregnancy.†

It will thus be seen from the foregoing that a long period of sterility antedating ectopic pregnancy is not as common as some would lead us to believe. The same, in a measure, applies to the period elaps-

*Read before the Metropolitan Medical Society, February 27, 1906.

†A full report of these cases was published in *New York Medical Journal*, February 24, 1906.

ing between the last normal pregnancy and the faulty one. This period varied in my cases from four months to sixteen years. In three cases it was seven months; in twelve more cases it was two years and less. In sixteen cases, therefore, there was a period varying only from four months to two years between the last normal gestation and the ectopic pregnancy.

Bearing somewhat on the same question of etiological factors, in a clinical sense, the notes of my cases run counter to another common assumption, which is to the effect that inflammatory disease of the adnexa is a frequent forerunner of this condition. In the majority of my cases the history of such an antecedent affection could not be obtained. I will grant, however, that this negative evidence in many of the cases was not very reliable, as the patients were either ignorant or non-observant. But this I can say, that in several of the more intelligent women there was an entire absence of any symptoms referable to the pelvic organs prior to the onset of those caused by the tubal pregnancy. In several of the cases the patients on finding that the expected menses did not recur, had sounds or other instruments introduced into the uterus by midwives or physicians to bring on an abortion. Whether this interference had any causative influence in arresting the ovum in the tube, I am not prepared to affirm. But these attempts with their usual absence of aseptic precautions, leading to the suspicion that the enlarged tube might be due to an inflammatory process, the result of such an infection, did not make the diagnosis in these cases any easier.

The three cardinal symptoms of ectopic pregnancy are: amenorrhea of longer or shorter duration, irregular uterine bleeding, and abdominal pain.

Amenorrhea.—First of all, it cannot be too strongly emphasized that the absence of amenorrhea does not positively exclude tubal pregnancy. That is, the last menstruation may have been regular as to time and quantity, and yet before the time of the next recurring menstruation, symptoms of a ruptured tubal pregnancy or tubal abortion may manifest themselves. In this series five cases presented such a history. The onset of the symptoms varied from nine to twenty-one days after the last menstrual period, which was normal in every respect.

In other cases again the last menstrual period will be normal as to time, but abnormal either as to amount, duration, or continuousness of the flow. In one case, for instance, the flow lasted only one day, while the normal duration was four days. In two it persisted for a longer period than normal; in two more it lasted the usual time but was decidedly less in amount. In three cases the flow was not continuous; it would cease for several hours and then recur.

In the remaining forty cases there was a period of amenorrhea varying from a few days to ten months. The latter period occurred in the only case of abdominal pregnancy in the series.

When I say a period of amenorrhea, I mean by that the time the patient has skipped what should have been her next menstrual flow following the last regular menses. For instance, the patient, we will say, has menstruated normally January 1; she should menstruate again January 28, if it be of the four-weekly type. The period of amenorrhea would be reckoned from January 28. Following this system of reckoning the duration of amenorrhea in one case was six days; in nine cases, seven days; one case, ten days; in nine cases, two weeks; one case, three weeks; two cases, two months. In twenty cases of the series, therefore, the period of amenorrhea varied from six to fourteen days. If we add to this the thirteen cases in which there was no amenorrhea, we have thirty-three cases, or about 62 per cent., in which there was an absence of amenorrhea or in which it was of very short duration.

Irregular Uterine Bleeding.—It is commonly held that the uterine bleeding in ectopic pregnancy is not as profuse as that attending a uterine miscarriage, and that the blood is of a darker color. The latter assertion is entirely unfounded. As far as my experience goes, there is no appreciable difference in the color of the blood from the uterus in the two conditions. It is true that, as a general rule, the uterine bleeding attending a ruptured or aborted tubal pregnancy is less profuse than that attending a uterine miscarriage. Still, there are numerous exceptions. In eight cases of this series the bleeding was just as profuse as any I have seen in the latter condition. Nevertheless, the scantiness and the irregularity of the uterine bleeding in ectopic pregnancy are important differential diagnostic points. The flow ceases, then recurs, and again may be absent for hours or days. Rarely it is continuous as it usually is in uterine miscarriage.

In only five cases of the series do the records state that the patient passed a decidual cast. This, of course, does not signify very much, for many more may have been expelled without the patient's knowledge, and, furthermore, what the patient may have thought was an organized membrane was nothing more than a series of organized blood-clots. It may be safely assumed, therefore, that the statement by the patient of the expulsion or nonexpulsion of a decidual cast is of no aid in the diagnosis.

Abdominal Pain.—Pain in the abdomen is a pretty universal symptom in ruptured or aborted tubal pregnancy. I can recall only one instance in which it was not very marked. Its character varies as well as its degree, and the sensation is descriped differently by different patients. The less intelligent usually compare it with labor pains, a form of pain with which evidently they are more familiar. The more intelligent patients will say it is of a colicky nature, or has a cutting character, or that it resembles the menstrual pain but is much more severe. Others, again, will say that it has a distinctly bearing-down character resembling labor pains. It is usually felt in one or the other side of the lower quadrant of the abdomen, corresponding to the tube affected. Not infrequently it is referred vaguely to the lower half of the abdomen. In one of my cases it was felt in the epigastrium and in the right hypochondrium, and following, as it did, an indiscretion in diet, the natural inference of the medical attendant was that he was dealing with a condition of gallstones.

The attacks are usually paroxysmal, and, as a rule, very severe, so that very frequently the medical attendant is called and he may be compelled to administer morphine hypodermically before relief is obtained. The duration may vary from a few minutes to several hours.

It is interesting to note the relation, as to time, of the pain to uterine bleeding. In some cases the pain may precede the flow by hours or days; in others, again, the flow may last for a considerable time before the onset of an attack of pain. In eight cases of the series the pain and uterine bleeding were synchronous as to time. In fifteen cases the flow preceded the pain for an interval varying from a few hours to several days. In twelve cases the

attack or attacks of pain preceded the uterine bleeding for a period of hours or days.

It is commonly held that fever is absent in ruptured or aborted tubal pregnancy, and that this negative evidence is a valuable point in differential diagnosis between it and inflammatory disease of the adnexa. This opinion is fallacious and misleading. In fourteen cases of this series there was a temperature ranging from 100.2 to 104°. We had a case in Mt. Sinai Hospital ward in which every second day the temperature would go up to 102° or 103° and would be practcally normal in the interval. The blood was examined for plasmodia with negative results. The case was under observation for several days prior to operation. After the operation there was no recurrence of the intermittent fever.

We have found the same unreliability in the leucocyte count as an aid in the differential diagnosis. Many of the cases in the series have had as high a leucocyte count as is ever seen in acute inflammatory affections of the adnexa, even as in those cases in which pus was present. The laboratory men admit now that the leucocyte count may not be of any value in the differential diagnosis, but they lay great store upon the differential count, *i.e.* upon the percentage of the polynuclear neutrophiles, and that when this is above the normal (62 to 70 per cent.) they assert that it is a positive sign of the presence of pus. In some of my cases in which the differential count was made the results did not confirm this assertion. We are continuing the investigation in this direction at Mt. Sinai Hospital, and when a sufficient number of cases has been collected we will furnish a report of the data.

Of other prominent symptoms may be mentioned attacks of syncope corresponding to every fresh effusion of blood into the peritoneal cavity. When they occur they are valuable aids in the diagnosis, but they were not present in more than 25 per cent. of this series. Again, some women with a highly nervous and sensitive temperament may have distinct syncopal attacks from the loss of blood accompanying a uterine miscarriage, or from a much more trivial cause.

I do not propose going into detail regarding the results of a bimanual examination. In some cases the finding may be characteristic, but in the majority of the cases all one can honestly say is that he feels a mass at either side or behind the uterus. Rarely the mass may be in front of the uterus. I know of no way of definitely distinguishing by palpation between a tube distended by blood and blood-clots and surrounded by similar material, and a tube filled with pus and surrounded by inflammatory adhesions and exudation, or a cyst of the ovary bound down by adhesions. There are some men who say they always can, and one might feel envious of the sense of touch possessed by them were it not known that these same individuals have frequently committed errors in this respect.

An intraligamentous cyst with thick walls has often been mistaken for a tubal pregnancy. It is not necessary, after what I have said, to mention all the different conditions that have been confounded with ectopic pregnancy by some of our most skilled and experienced diagnosticians in this branch of medicine.

The clinical analysis of the cases embodied in this paper and the statement I have just made may lead you to think that the diagnosis of ectopic pregnancy is surrounded by insuperable difficulties. I grant that some cases are, but the vast majority of the cases could be detected by the medical attendant if he would merely keep his mind alert on the subject. Every case of so-called early miscarriage in which attacks of severe pain is a marked symptom should be looked upon with suspicion. So should also irregular uterine bleeding during the fruitful period in a woman whose pelvic organs are apparently healthy. In such a condition always rigidly investigate the behavior of the last menstrual flow, as to whether it was delayed a day or longer, whether it was of the usual amount, and whether the flow was continuous and lasted the customary time. It is the early cases that are so frequently overlooked, and, as you have learned, they are by far the most common. The case of amenorrhea of two or three months or longer with a history of a sudden seizure of pain and symptoms of collapse in which profound anemia is a marked feature, is not likely to be overlooked or wrongly interpreted. But to every case presenting such striking features there are at least three in which the symptoms are vague or indefinite and in which the amenorrhea may be totally absent or only of a few days' duration.

I have never carried diagnostic refinement to the extent of attempting to differentiate between tubal rupture and tubal abortion. In several instances distinguished consultants have been associated with me who thought they possessed the requisite diagnostic skill for such differentiation, but the subsequent operation showed their error. The fact is that frequently it is difficult to tell, even during the operation, whether the case belongs to the one form or to the other. Furthermore, the two conditions not infrequently are present in the same tube. The tube may be trying to abort its contents through the fimbriated extremity, while at the same time its walls are being thinned out and eroded by the syncytium of the ovum, so that a solution of continuity occurs which may be attended with profuse bleeding.

A word more regarding differential diagnosis. In many instances it is of no great importance whether the existent mass be an ectopic pregnancy, an ovarian cyst, or an old pus tube. In any of the above conditions there would be an indication for operative intervention. But what is of vast importance is not to confound an ectopic pregnancy with an early miscarriage. In one of the cases in this series the attendant physician thought he was dealing with a retroverted pregnant uterus that was trying to abort its contents. He made several attempts to antevert the uterus with a sound, and evidently in one of these attempts he bored a hole through the posterior wall of the uterus and into the blood tumor. The patient was reduced almost to the last extremity by this treatment. Whenever she stood up there was quite a flow of dark blood from the uterus, which would cease as soon as she would resume the recumbent position. This feature puzzled me at first, but when I heard of the method of treatment I surmised the nature of the traumatism that had been inflicted. At the subsequent operation, which was very difficult, owing to extensive adhesions and to the false passage, my surmise was proved to be correct.

Again, it would be highly important to differentiate an acute gonorrheal infection of the pelvic organs, or acute inflammatory affections of the adnexa of nongonorrheal origin, from ectopic pregnancy. For, in the former two conditions not only would operative intervention not be indicated, but would be injurious to a high degree or might even be fatal.

Acute gonorrheal infection of the pelvic organs presents a fairly typical picture. There is usually marked rigidity of the lower half of the abdomen,

there is considerable distention, and while the abdominal pain is paroxysmal, the paroxysms are more frequent and of shorter duration than they are in tubal abortion or rupture. When the process has lasted for some days the mass or masses found in the pelvis are very hard at first and are usually firmly fixed.

Acute inflammatory disease of the adnexa not of gonorrheal origin may not be so easly differentiated. Here the pain is rather continuous and is not, as a rule, as severe as it is in ectopic pregnancy or as in gonorrheal infection. There will also be more rigidity and tenderness of the lower half of the abdomen than would be found in tubal abortion or rupture. In doubtful cases it is well to defer operation and to keep the patient under close observation until a fairly certain conclusion can be reached.

Treatment.—The consensus of opinion of American gynecologists at the present time is when a diagnosis of ectopic pregnancy is made operative intervention is indicated. This statement requires some modification. In cases of advanced tubal or abdominal pregnancy the question of waiting until the fetus reaches full term is a legitimate one. It is also pretty generally conceded by nearly all operators that the abdominal route is the one of choice in the vast majority of cases. It was the route followed in fifty of the fifty-three cases operated upon by me. In two cases a vaginal incision was made at the outset and the large hematoceles evacuated. In one case, after opening the abdomen, the intestines were found so extensively adherent and matted to the blood-tumor, that an incision was made through the posterior vaginal fornix rather than take the risk of injuring the intestines by the attempt to complete the operation from above. In three cases, including the one of abdominal pregnancy at full term, the uterus had also to be extirpated in order to arrest the hemorrhage. In the remaining cases, with a few exceptions, the tube only that was the seat of the pregnancy was excised, and whenever possible the corresponding ovary was left. In a few cases forming the exception above referred to, the adnexa on the opposite side were so markedly diseased that they had to be removed.

The right tube was the one affected in 26 cases; the left in 17 cases. No mention is made of which tube was the seat of the pregnancy in the remaining 10 cases.

In 16 cases there was a moderate quantity of free blood in the peritoneal cavity; in 14 cases the quantity was very large. The designation of "large quantity" was used only when the abdomen was enormously distended with blood and when the patient was in a condition of most profound anemia. In several of these cases there was no pulse to be felt at the wrist at the time of the operation. It is truly amazing to see, in these cases, how an apparently moribund patient can be brought to life by opening the abdomen, rapidly ligating the bleeding vessel, and injecting a large quantity of saline solution into the veins of the arm.

The cases forming this series were operated upon in various private clinics, in two public hospitals, and many in the homes of the patients. There was but one death in the entire series, and this was in a case operated upon at Mount Sinai Hospital, the patient dying twenty-one days after operation from a double pneumonia, doubtless as a result of ether narcosis. We were then having several cases of pneumonia due to the narcosis. The patient showed evidences of pneumonia soon after the operation. Both lungs became involved early, and at no time were there any manifestations of an embolic process. The processes directly connected with the operation passed off smoothly; at no time was there the slightest peritoneal irritation, and the abdominal wound healed primarily.

There was one other death among the cases of ectopic pregnancy in my practice during the period stated, but that case was, strictly speaking, not operated upon. I mention it as it has an instructive bearing upon treatment. I saw the patient in consultation at 9 P.M., about four hours after she had been brought home in a carriage from her place of business downtown, where she had gone into a severe faint. In spite of urgent appeals on the part of myself and the medical attendant for an immediate operation, consent was obtained only for an operation on the following morning. In the morning, when we came to operate, the patient, who was very fat and flabby, was even more anemic, if that were possible, than she had been the night before. Her pulse was more rapid and was merely perceptible. She was placed on the table and chloroform administered. Before she was fully narcotized she expired. It was difficult to say whether the patient died from the anesthetic or from the intraperitoneal hemorrhage, or from a combination of both. Among the series there were several cases in fully as bad a condition (if not worse) as this patient was when I first saw her, and still they recovered after being operated upon.

This case must form an instructive comment upon the attitude of some operators who hold that in cases of profound shock in ectopic pregnancy from internal bleeding, it is wise to wait for reaction before operating. It was the only case among 15 cases of severe internal bleeding occurring in my practice for the past seven years that was not operated upon, and it was the only one that ended fatally.

It ought to go without saying that the same principle should guide us in dealing with a bleeding vessel within the pelvic cavity as with a bleeding vessel in an external part—to get down to it and ligate it with as much dispatch as possible.

There is considerable discussion going on among German gynecologists whether it is better to remove the blood in profuse intraperitoneal hemorrhage or allow it to remain in great part within the abdomen so that it may be absorbed and thus aid in restoring the vitality of the patient. In the 14 cases of profuse intraperitoneal hemorrhage in this series as much of the blood was removed as was found feasible without unduly prolonging the operation. In some of the earlier cases the abdominal cavity was flushed with hot physiological saline solution, and after the blood was washed away a couple of quarts of the solution were left within the abdomen for the purpose of aiding in the restoration of the patient. In the later cases more prompt results were obtained by intravenous saline infusions, and the abdominal cavity was left as free of fluid as possible.

It does not seem to me to be good practice purposely to leave a large quantity of blood within the peritoneal cavity. While pure blood in the peritoneal cavity may be innocuous, the blood effused in ruptured tubal pregnancy is not always germ free, contaminated as it is with the contents of the tube, which are not always free of germs. Granting even that the tubal contents are always aseptic, operative intervention carried out with the customary aseptic precautions is attended with a more or less degree of germ contamination. And, could there be a better medium for the germs to multiply in than blood? Nowadays, with the ease and safety with which an

intravenous saline infusion can be given by any hospital graduate who has had sufficient experience, there certainly is no need to depend upon the absorption of the blood by the peritoneum to restore the patient.

Another argument used which sounds somewhat more plausible is that the removal of the blood takes time, and that these moribund patients will die on the table if the operation be prolonged. This sounds more plausible than it is in reality. As a matter of fact, as soon as the abdomen is opened the patient's condition shows improvement, evidently from relief of tension, and if one promptly puts a stop to further loss of blood by ligating the bleeding tube, a few minutes more or less in the completion of the toilet of the abdomen will not increase the shock of the patient. I feel confident some of these cases are lost through overhaste on the part of the operator. Time is not taken to investigate whether there be any oozing from the bed where the pregnant tube or extended fetal sac lay, or from the raw surface left by the removal of the semi-organized blood-clots. After the tube is delivered and ligated the abdomen is hurriedly closed and what little vitality the patient has left slips away through the gradual but constant sickering of blood from the oozing surfaces. The patient dies within a few hours or a day or longer after the operation, and the conclusion is reached that she died from "shock," from "lack of action," or, if an autopsy be made, from "secondary hemorrhage," while in reality she died from primary hemorrhage overlooked or neglected, through undue haste, by the operator. The practical inference to be drawn from this is always to take sufficient time, no matter how low the patient may apparently be, to be certain that all bleeding is arrested by suture or by packing with gauze Quick-relief) before closing the abdomen, for it does not take much of the so-called "secondary hemorrhage" to kill these patients.

751 Madison Avenue.

TREATMENT OF PNEUMONIA.

By WILLIAM F. WAUGH, A.M., M.D.,

CHICAGO.

EMERITUS PROFESSOR OF PRACTICE, ILLINOIS MEDICAL COLLEGE.

It is alleged that the treatment of pneumonia so strongly advocated by those who employ the active principles, is based upon a pathology not now in vogue—the humoral or vasomotor theory, which has been supplanted by the bacterial hypothesis. Pneumonia, it is now thought, is due solely to the pneumococcus, and all the symptoms are attributable to the presence of this microorganism in the pulmonary tract, and to the direct effects of the toxin produced by it. It is just that this claim should be considered, and should receive full credit for whatever of truth it possesses. We are the last persons on earth to cling to gone-by theories or beliefs when better ones are presented.

That the pneumococcus is present in some pneumonias, and is the cause of the attacks, is admitted. That this coccus possesses a monopoly of causing this disease is another matter. We believe that the influenza bacillus causes a form of pneumonitis only distinguishable from pneumococcus-pneumonia by the microscope and by a different symptom-picture. Recently the writer attended a case of acute pneumonia that was typical in features and course, except for the absence of fever, and of both pneumococci and influenza bacilli. The only microorganisms found in the sputa were the ordinary diplococci always present in the mouth, and a few other cocci.

The second unproved assumption in the accepted theory is that which attributes all the symptoms of the malady in question to the direct influence of the toxin. This is not a necessary deduction from the pneumococcus-causation theory, and we believe it is not in accord with clinical observation. It has long been recognized that marked gastrointestinal irritation betokens unusual gravity in any case of pneumonia. The malefic influence of unhygienic surroundings over cases of all infectious diseases is one of the best established tenets of modern medical science. The especial danger of contamination of air or water by human excrement is also acknowledged universally. In all febrile conditions the suspension of the digestive secretions, with consequent increased liability of the bowel contents to fermentation and decomposition under the influence of increased heat, the development of virulence in intestinal microorganisms usually harmless, and the increased absorption of intestinal fluids and their dissolved toxins, are all undisputed facts. This renders very strong the position of those who attribute to such toxin-absorption a portion of the symptomatic phenomena presenting in pneumonia, as in all other febrile maladies; and this belief is confirmed by the marked relief following the emptying and disinfection of the alimentary canal.

There must also be a sensible difference in the course of any infectious toxin-generating malady, as occurring in persons whose eliminant apparatus is in good working order, and in others in whom it has been so impaired before the infection developed as to be barely able to cope with its tasks during the period previous to infection.

In fact, granting the causal rôle of the coccus, this organism can only act upon and through the vital functionating elements of the human economy—the cells. We cannot frame any hypothesis that will relieve us of the necessity of considering cellular pathology, for without the cell there is no pathology.

A third objection to the current theory is that it attributes effects to the direct action of the pneumotoxin that are only secondarily due to it. The toxin is one of the causes of fever; and fever is the most important single element exciting the heart to overaction, with consequent early exhaustion. Reduction of the fever conserves the heart strength, even if the toxin remains undisturbed. It is most fortunate, however, that the means employed to reduce fever are also efficacious in promoting elimination.

Nor are the mechanical conditions resulting from the local pulmonary disease to be disregarded. The patient is beset with dangers from interference with the pulmonary circulation and the aeration of the blood. We need not lug in toxemia to account for death when four-fifths of the pulmonary tissues are impervious, and the whole task of blood aeration is thrown upon the small remainder, hyperemic and edematous.

Le Fevre (Medical Record, February 24, 1906) states that the primary action of the pneumotoxin is stimulant. Overstimulation during the primary stages leads to exhaustion of irritability, with prostration later. Granting this, how do we on this basis explain the success of the active-principle treatment?

Aconitine develops pure cardiac inhibition; it slows the pulse, steadies the heart and relaxes vascular tension, in all directly antagonizing the action of the toxin. The development of normal inhibition is not weakening the heart, but conserving its energies, checking the unbridled waste that leads to exhaustion.

Digitalin also develops cardiac inhibition, slowing and strengthening the pulse beats, increasing vascu-

lar tension also and energizing the cardiac muscular fiber. Given judiciously, in doses exactly apportioned to the need, it also is conservative of the cardiac forces, even when administered continuously for prolonged periods. Its vascular toning balances the relaxant action of the aconitine. These two, therefore, fulfil the indication of neutralizing the action of the pneumotoxin upon the circulatory, respiratory, and central nervous systems.

By veratrine a further indication is met. This alkaloid, in the small doses employed, also slows and steadies the heart, directly energizing its muscular fiber and preventing or relieving its fatigue; it relaxes vascular tension and powerfully stimulates all the organs by which toxins are eliminated from the body. It thus energizes aconitine and digitalin in their beneficial actions, and supplements them where they are deficient. We are by no means certain that the old humoral theory is totally inapplicable, and to say that the "antiphlogistic," antiplastic medication was altogether valueless is an unproved and unprovable assumption. There is, therefore, in both the new and the old way of viewing the pathology of pneumonia, ample justification for the high valuation placed on veratrine by clinical observers.

Le Fevre's third indication in pneumonia, to limit the production of the toxin in the lung or elsewhere, may be met by the forementioned remedies—we believe it is; by such applications to the chest, cold or hot, as afford relief to the patient; or by the administration of germicidal remedies eliminated through the lung or brought to it by the blood. For the latter purpose creosote, iodoform, and quinine have each been advocated; and the larger the doses given, the stronger seems the faith they inspire. Le Fevre, who doubts their specificity, admits their favoring influence, but strictly limits their applicability to the early stimulated period. He claims that they are contraindicated by the supervention of cardiac and respiratory exhaustion. This indication would be more directly met by quick saturation with calcium sulphide, which should stop the production of toxin by killing the cocci.

Le Fevre makes an exception of quinine, which may be given late in the course of the malady, in moderate doses, without harm—or much good. He cautions us against accepting the reduction of fever as an evidence of benefit, unless this is accompanied with improvement in the general condition; and this, when the apyrexia is properly induced, is exactly what will occur. At the least it will serve to fill in the time while we await the development of the coming antitoxin.

When the stage of depression has supervened, we still have indications for remedies to sustain cardiac inhibition at the normal standard, but we then face a perilous fall of vascular tension, and an engorgement of the venous system, in which a large proportion of the body's blood supply is collected. The left heart and the arterial system are practically empty. If we now increase the vascular tension we contract the arterioles and capillaries, retaining the blood longer in the arteries and the left heart. Here is the indication for strychnine, to replace the veratrine—not that the latter is no longer needed as an eliminant, but the danger from the other source is more imminent—the patient may bleed to death into his own veins. As the right heart is now still more imperatively called upon to force the blood through the obstructed lungs, we add convallamarin to our digitalin, believing the former a more direct tonic to the right heart. Had we a specific contracter for the veins it would be indicated; but as long as the profession is contented to employ "digitalis" as its one only cardiovascular tonic for all atonic conditions, such an obviously essential differentiation of remedies is not to be expected. We must content ourselves with the knowledge that in the most notable examples of venous paresis, venom-toxemia, strychnine in doses ordinarily lethal will overcome the relaxation and save life. Therefore we now push strychnine to the physiological limit, carefully avoiding such overstimulation as would be followed by exhaustion of irritability, and collapse.

One of the things it seems the profession will never learn is the direct dependence of a considerable proportion of the fever, headache, muscle and backache, delirium, restlessness, anorexia, nausea, debility, etc., upon fecal autotoxemia. We therefore emphasize our initial suggestion as to the imperative necessity of emptying the bowels, disinfecting them, and fulfilling this indication throughout the course of the attack. Nor must we neglect to urge the use of saline colonic flushes, to traverse the blood and be emitted by the kidneys, washing out quantities of toxins with them, and so reducing the toxemia to what the forces of the body may be able to overcome.

It seems to the writer, therefore, that the treatment that has proved so satisfactory to many clinicians may be explained on the modern theories of pneumonia pathology quite as readily as by the older ones. The enthusiasm which is displayed by those who adopt this active principle method in pneumonia is one of the phenomena of the disease, and as such is to be investigated and its causes ascertained, quite as much as any phenomenon observed in the laboratory. Dismissing the subject with the flippant assumption that the clinicians are fools and imbeciles is no more a scientific method of disposing of the one than of the other.

SOME REMARKS CONCERNING THE TUBERCULIDES, WITH A REPORT OF CASES ILLUSTRATING THE PAPULONECROTIC VARIETY.*

By M. B. HARTZELL, M.D.,

PHILADELPHIA.

ASSOCIATE IN DERMATOLOGY IN THE UNIVERSITY OF PENNSYLVANIA; DERMATOLOGIST TO THE PHILADELHHIA HOSPITAL.

With the very remarkable increase in the extent and accuracy of our knowledge of tuberculous affections of the skin which has taken place during the last two decades there has been, to some degree, an abandonment of old, and often meaningless, terms for new ones more in accord with our present ideas of the etiology and pathology of this most important group of diseases. In 1896 Darier proposed the term *tuberculide* for a series of dermatoses, the individual members of which had been described from time to time under a variety of names. This name was at once adopted by the French, and has been slowly taken up by writers in England and Germany, and, to a less extent, in America. Hallopeau has proposed to call all cutaneous tuberculoses tuberculides, dividing them into two classes, viz., *bacillary tuberculides,* or those in which the tubercle bacillus is regularly demonstrable, and *toxitubercul ides,* those in which this organism cannot be demonstrated, the lesions of the skin being due presumably to toxins produced in foci more or less remote from the seat of the eruption, reaching the skin through the blood channels. In the former group are included acute miliary tuberculosis of the skin, lupus vulgaris, anatomical tubercle, tuberculosis verrucosa cutis, and the gummous tuberculide; in the latter, lupus erythematosus, lichen, scrofulosorum, the papulonecrotic

tuberculide, acne cachecticorum, acne scrofulosorum, and the erythema induratum of Bazin. Concerning the members of the first group there is general agreement as to their tuberculous character, the presence of the tubercle bacillus leaving no room for doubt. As to the second group, however, the agreement is by no means so general; and it is quite probable that future investigations may change our views somewhat about some of the members of it. The theory that the eruptions of this second class are due, not to the tubercle bacillus itself, but to the toxins produced by it, while a plausible and attractive one, still needs proof. It is true that a few investigators, like Schweninger and Buzzi, claim to have seen such an eruption as lichen scrofulosorum follow injections of tuberculin, but this lacks the confirmation of other experimenters.

The affection to which Darier first applied the term tuberculide is described in most recent text-books under the name *folliclis*, a name which was given it by Barthélemy to indicate its supposed association with the follicles of the skin; but as it has since been shown that the lesions are not situated in the follicles, the newer term papulonecrotic tuberculide is more appropriate.

It is characterized by an eruption of small, dark-red or bluish nodules most abundant usually upon the backs of the hands, the elbows and knees, the feet and ankles, and the helix of the ear, but not confined exclusively to these situations. The evolution of the lesions, which begin deep down in the skin, is slow, each one lasting from a few weeks to a month or two. When they have reached their acme the summit of each one becomes the seat of a small pustule or vesicopustule which is presently transformed into a black or brown crust covering a small loss of substance in the center of the nodule; with the fall of this crust a deep, pit-like cicatrix is left, not unlike the cicatrix of variola. In long-standing cases with numerous lesions upon the ears these organs may present a cicatricial condition like that so frequently seen in erythematous lupus; and this feature, together with others, led Boeck to describe the disease as disseminate lupus erythematosus. In the majority of cases the subjective symptoms are slight, but exceptionally the lesions may be quite painful, or intense pruritus may accompany them.

In practically every case decided evidence of tuberculous infection is present. Most commonly there is tuberculosis of the lymphatic glands, usually those of the neck—the so-called scrofulous glands; or there are scrofulous gummata upon the legs, or the affection described years ago by Bazin as erythema induratum. Less frequently the eruption is associated with pulmonary tuberculosis, which has usually preceded the cutaneous affection, but may follow it.

The subjects of this eruption almost invariably show a more or less marked cyanosis of the extremities: the hands are dusky-red or bluish as if cold, pressure upon the skin leaving marble-white marks which persist for an unusual length of time owing to the slowness with which the vessels refill; and this same dusky hue is present, usually to a less degree, upon the ears and feet.

The malady is most common in children and adolescents, and according to some recent observations of Nobl, is much more frequent in the former than is usually stated, this author having observed it thirteen times among 430 children sick with various diseases.

Some differences of opinion exist as to its histopathology, but these are most probably to be explained by the fact that the tissue alterations vary considerably with the age of the lesions, not only as to their character but as to their situation. Pollitzer and Fordyce regard the sweat-glands as the primary seat of the disease, while Barthélemy, as already remarked, believes it to be an inflammation of the follicles; but later investigations have shown pretty conclusively that it begins with inflammatory changes in and around the blood-vessels, the sweat-glands and follicles being implicated only secondarily. The morbid process has its origin in the deepest portions of the corium and gradually extends to the surface. The vessels are surrounded by an abundant round-celled infiltration which frequently extends down to the fat tissues beneath the corium, the walls of the arterioles and veins are markedly thickened, their endothelium swollen, and their lumina in consequence much obstructed or even completely obliterated. In lesions somewhat advanced extensive areas of necrosis are present in the central and lower portions of the corium in the midst of which blood-vessels with greatly altered walls may be seen.

If we except the single case reported by MacLeod and Ormsby, which possibly represented another form of disease, the presence of the tubercle bacillus has not been demonstrated. In the paper already referred to, Nobl states his belief that the eruption is directly due to the tubercle bacillus, but that, owing to the low vitality of this organism under the unfavorable conditions presented for its growth in the skin, it dies soon after the appearance of the inflammatory irritation produced by its presence, and in consequence cannot be discovered in the lesions.

The following cases, the first of which was seen some eight years ago, the other two within the past year, will serve to illustrate some of the more prominent clinical features of this variety of so-called tuberculide:

Mary P., a girl seventeen years old, with a marked tuberculous arthritis of the right knee, of six years' duration, came to the Skin Dispensary of the University Hospital for the treatment of an ulcerative affection of the left leg, upon which were three or four quarter-dollar-sized, round and deep ulcers with undermined and livid edges. In addition to these the calf of the leg was the seat of a firm, deep-seated, ill-defined infiltration, over which the skin was dusky-red and adherent. In the immediate neighborhood of the ulcers were a few pea-sized, bluish nodules. The disease had lasted two months and was very painful. In the course of the next two or three months an eruption of shot- to pea-sized, at first dark red, later bluish nodules appeared upon the backs of the hands, more particularly the fingers, the ankles, and the tops of the feet and toes. At the end of a week or ten days small pustules appeared upon the summits of most of these nodules, which soon became black or brown crusts covering small, but rather deep, ulcers; with the falling of these crusts a pitlike scar was revealed. At this time the hands and feet of the patient were habitually dusky-red and at times quite livid, as if cold, the vessels of the skin filling very slowly after they had been emptied by pressure. A small nodule which had not yet developed a pustule upon its summit was excised from the top of the foot for microscopical examination. Sections of this nodule showed practically no morbid change in the epidermis, but the middle and lowest portions of the corium were occupied by a large necrotic area, in the midst of which were a number of arterioles with thickened walls and, in many instances, with obstructed lumina. The walls of the venules showed an even greater thickening. Outside of this area of necrosis was a cellular infiltrate extending down to the fat tissue. A small number of giant cells were present, but no tubercle bacilli were found.

This case possesses a special interest because of the simultaneous occurrence of two distinct tuberculous affections of the skin—the *erythema induratum* of the calf and the papulonecrotic eruption on the hands and feet—associated with a long-standing tuberculous arthritis.

The second case which I shall report was typical of its kind.

Mr. S., twenty years old, was referred to me for advice concerning an eruption from which he had suffered for six or eight months. This eruption consisted of small bluish nodules with pustules or blackish crusts upon their summits, which in the course of some weeks underwent spontaneous involution, leaving small, round, quite deep scars. It was seated chiefly upon the lobes and rims of the ears, around the elbows and knees, and, less abundantly, upon the face and backs of the fingers. The eruption was not attended by spontaneous pain, but was quite tender upon pressure. The lesions began as deep-seated, tender, palpable, but not visible, nodules, which in the course of a week came to the surface, forming bluish, shot-sized elevations which shortly showed pustules upon their summits and, later, blackish eschars. It usually occurred in crops, there being periods of a month or more in which no new lesions appeared. It should be noted that, while the patient presented the appearance of robust health, there was an enlarged gland the size of a pigeon's egg just above the left clavicle. Internal medication seemed to have but little influence over the disease, but an abundance of outdoor exercise was always followed by a diminution in the number of the lesions and an increase in the intervals between the outbreaks. The disease has now lasted about three years, and seems to be slowly disappearing under the influence of outdoor living.

While this form of eruption is seen most frequently in childhood and youth, it may occur at a later period, as is shown by the following case, seen a few months ago:

Miss S., a nurse, thirty-one years old, had suffered for two years from a somewhat scanty eruption of small, acnelike lesions and larger, bluish-red, deep-seated, firm nodules, occupying the forearms, legs, and toes. The larger, intradermic nodules, according to the patient's statement, had appeared some two years ago, being in the beginning so deep-seated as to be invisible, although readily perceptible by touch. As they slowly approached the surface the skin over them became at first bright red, then livid and thin. The lesions upon the forearms and toes were of much more recent origin, having appeared only a few weeks before the patient was sent to me. All were more or less painful. The patient was quite evidently in poor general health, being pale and thin; and there was likewise an enlarged gland in the left axilla which had been present for many months.

These three cases are fair examples of a well-defined and readily recognized type of eruption which, whether we regard it as actually tuberculous or not, is closely related in some way to tuberculosis. Its occurrence in individuals otherwise apparently healthy should lead us to suspect, at least, the possible existence of latent tuberculous foci more or less remote from the seat of the eruption.

Drugs have little or no effect upon the eruption, although Donovan's solution has seemed to me to be of real service in some cases; the most generally useful internal remedy, however, is codliver oil. More beneficial than either of these is an abundance of fresh air and sunlight, and patients the subjects of this malady should be directed to live in the open as much as possible.

Danger in the Ingestion of Tuberculous Bacilli Which Have Been Killed by Heat.—A. Calmette and M. Breton sum up the results of various experiments and give certain conclusions which they have deduced: In guinea pigs infected with tuberculosis, it may be through the digestive system or by intraperitoneal injection, the repeated ingestion of small quantities of tubercle bacilli killed by boiling hastens death to a considerable extent. In healthy guinea pigs the repeated ingestion of tubercle bacilli killed by boiling is not without injurious results, and in certain cases brings about disorders which are absolutely like those that one observes when a non-tuberculous animal is made to consume at intervals of a few days several small successive doses of tuberculin. Certain experiments which are now being carried on in relation to large animals will soon prove whether these facts are true in relation to other species of animals which are susceptible to tuberculous infection. The writers even now, however, believe that the attention of physicians should be called to the fact that the ingestion of tuberculous products, even though sterilized by heat, may prove very dangerous for subjects already infected by tuberculosis and may not be inoffensive to those subjects who are perfectly free from this malady. Milk, then, coming from tuberculous cows, although it be sterilized, should not be used by man. Sterilization by heat is not sufficient to render this milk harmless. Especially must it be remembered that children and individuals already tuberculous should not be fed upon such milk. The public authorities should be impressed with the importance of this subject.—*La Province Médicale.*

Plaster-of-Paris Dressings.—The following hints for the preparation and use of plaster-of-Paris bandages may not be amiss. (1) Bandages should always be freshly made, gauze or crinolin being best for the purpose, into which the best dental plaster should be thoroughly rubbed by hand If bandages have been made up long, bake in an oven until thoroughly dry. (2) Wrap the part to be inclosed in sheet cotton, padding the bony prominences with care. (3) Soak the bandages in warm water; do not add salt to the water, as good plaster sets quite rapidly without. (4) Apply carefully and evenly. Cut every two or three turns, this will secure a much more uniform thickness, and a better appearing cast than by applying the bandage in one length. (5) If a very strong yet light cast is desired, incorporate strips of basket splint material. (6) A permanent cast should be covered with one or two thicknesses of a prepared gluten bandage, which protects the plaster from chipping and cracking, and also adds materially to its length. —*Clinical Review.*

Epithelioma of the Face Developed in the Scar of an Old Lupus.—This patient, a farmer twenty-nine years old and unmarried, was in the service of Dubreuil. The patient was neither an alcoholic nor was he syphilitic. At the age of sixteen the lupus developed on the right nasal ala. The lesion gradually increased, invading the neighboring parts in spite of treatment. At the age of twenty-seven rhinoplasty was performed. In 1902, when the patient was thirty-six years old, he came to the clinic showing the scar of an epithelioma of the lower eyelid and cheek which had been healed by arsenical paste. When the patient was thirty-nine years old examination showed the existence of an epithelioma of slow growth, pale, cornified, and occupying the stump of the nose which was left. No enlarged ganglia could be discovered. This case is an example of the tendency of certain cases of lupus which become complicated by epitheliomata. The latter affection is not a direct effect of the primary lesion. This malignant neoplasm has developed from the multiple scars resulting from the original pus nodules that healed.—*Journal de Médecine de Bordeaux.*

THE NATURE OF THE BLOOD PLATES.

IN a paper on this subject by Kemp, Calhoun, and Harris, appearing in the *Journal of the American Medical Association,* April 7 and 14, 1906, it is stated that while the investigation of the blood plates in disease is a field that promises unusually good results, so far this province of study has been like a rich country undeveloped through lack of railroads. Until recently the methods that have been employed for determining fluctuations in the number of the blood plates have either been open to criticism on the score of inaccuracy or have been too laborious to be readily applicable for clinical work. Two great difficulties that confront the worker are the rapidity with which the plates disintegrate in shed blood under ordinary conditions, and their tendency to adhere to the surface of the appliances used or to stick together in clumps. Numerous diluting fluids have been devised to prevent this, and almost every author who has dealt with the question has elaborated his own technique for performing the enumeration. The tendency appears to be to reject those procedures in which the melangeur of the Thoma-Zeiss or Potain blood-cell counting apparatus is used, in favor of the method of making differential counts of the blood plates as compared with the erythrocytes and then determining the actual value for the latter in the usual way. Pratt (*Journal of the American Medical Association,* December 30, 1905) has adopted this plan, and states that there are four sources of error which have contributed to the production of the great discordancy of results to be noted in the figures given by the different workers in this field: (1) mistaking fragments of erythrocytes, the so-called Arnold's bodies, for blood plates; (2) the use of the graduated pipette; (3) the use of the ordinary counting chamber; (4) the lack of satisfactory preserving fluids. Pratt advises the use of a fluid containing sodium metaphosphate and sodium chloride, and determines the ratio of platelets to erythrocytes in fresh preparations of the blood, using a square diaphragm in the ocular to facilitate counting, then enumerating the red cells in the Thoma-Zeiss apparatus. The method of Kemp and his collaborators consists in the use of a fixative containing formic aldehyde and sodium chloride, for which they claim many advantages, the differential enumeration being then carried out in the ordinary counting chamber. Even in regard to the origin and the nature of the blood platelets many opinions are still held. There are those who look on them as by-products as it were in the manufacture of the red cells, suggesting the possibility of their being the lost tribe of nuclei of the normoblasts; another view is that they are the result of degenerative changes in leucocytes or red cells; and finally, it has been maintained that they are independent morphological elements of the blood. Yet another and a highly interesting suggestion is that recently made by Wright (*Boston Medical and Surgical Journal,* June 7, 1906), who, by means of the polychrome staining fluid to which his name is now universally attached, has been able to stain characteristically the blood plates in sections of fixed tissues and organs so that they may be positively recognized and may be clearly distinguished from other histological elements. After an extensive study of sections of bone marrow and other tissues prepared in this way, he expresses his conviction that the blood plates are detached portions of the cytoplasm or pseudopodia of certain giant cells or megacaryocytes found in the bone marrow and spleen. This view is founded in part on the similarity in morphology between the cytoplasm of the outbuddings of the giant cells and of the blood plates, on the demonstration in specimens of the apparent conversion of fragments of pseudopodia into blood plates, on certain zoological and embryological considerations, and on the relationship between the numbers of the blood plates and giant cells in some diseases of the blood-forming organs, such as pernicious anemia, lymphatic and myelogenous anemia, etc.

While so far but little has been learned in regard to the behavior of the blood plates in disease that is of direct practical benefit, the improvement in technical methods has already been of great service in enabling researches along these lines to be carried out with greater prospects of ultimate fruitfulness, and it is not unlikely that, as our understanding of these curious little structures increases, information that will be of more than theoretical interest may be obtained.

REGARDING FOOD.

THE subject of eating has been discussed from every conceivable standpoint and at somewhat undue length in medical and lay journals in Great Britain of late. The matter has been dealt with, perhaps, almost *ad nauseam,* for although it is one of supreme importance, the value of treating the consumption of food from the sensational point of view will scarcely commend itself to the earnest delver into scientific truths. A daily journal, modeled quite faithfully upon the lines of our own yellow press, has made considerable capital of the fact that the Cambridge University rowing crew, when training for their annual race with the picked oarsmen of the rival university of Oxford, chose eggs as the staple of their diet. Every day the enterprising journal in question published a dissertation on eggs in general, and on their value as food for oarsmen in training in particular. A voluminous correspondence regarding the nutritive value of eggs sprang up, and letters were inserted, some of which were calculated to move to mirth the most stony-faced of mortals and to strengthen further the belief of those who agree with Carlyle that the population of the earth is composed mostly of fools. The Cambridge egg-devouring crew won, so it may be predicted that

more will be heard of eggs as a sustaining and muscle-building diet.

Punch has intruded into the discussion concerning food and has thrown out the suggestion that the next sensational announcement in the medical journals will be that food is injurious to life. Another well-known London journal is of the opinion that this satire is quite legitimate, and intimates that certain modern medical journals deliberately put forward sensational theories in order to be quoted by the lay press.

It is, of course, very difficult to lay down hard-and-fast rules of diet for anyone, and it is manifestly impossible to do so for all. That what is one man's meat is another man's poison, is as true now as on the day when it was first said. So many points must be taken into consideration when selecting a suitable diet. Individuals' constitutions vary, the kind of life led is a very important feature of the situation, and age and climate exert a considerable influence upon the digestive powers. The food that is beneficial in a hot climate might be injurious in a cold one. There are those who pin their faith to meat foods, and who assert that in order to build up a hardy, strong constitution a liberal amount of flesh must be eaten. Opposing this view are the large numbers of vegetarians who hold that meat is valueless if not indeed injurious, and in support of this contention point to the notoriously strong Scotsman whose constitution has been built up on grain and cheese and vegetables in a harsh unkindly climate, while the bravery and dash of Irishmen and the skins and complexions of Irish women have been produced upon a diet of grain, buttermilk, and vegetables. The lessons learned from the Japanese war, so far as food is concerned, tend to show that meat is not indispensable when cold and suffering and hardships of all kinds are to be endured. The chief mainstay of the Japanese soldier in the field was cereals. The Roman gladiators trained and fought on a diet of figs and corn and oil, the Turkish soldiers on dates and meal, the fierce Sikh fighters on corn and pulse.

Dr. Josiah Oldfield, a well-known writer on dietetics in Great Britain, states that "during the first thirteen years of life children should have no flesh foods at all, but should be plentifully supplied with cereals, milk, and dried fruits, with fresh vegetables, and fresh ripe fruits in season. From puberty to adolescence, young people can eat anything and digest almost anything, if only they will take the trouble to masticate properly, but even then observation and experience teach that the best food for developing a well-set constitution, with sound nerves and muscles ready to endure the longest strain, is a dietary rich in the proteids obtained from milk and cheese, and replete with the fat of cream and butter and oil and cocoanut fats, and nuts themselves, with cereals and dried fruits as the basis of diet."

Dr. Oldfield is a decided food faddist and prejudiced against meat, but on the whole, his views so far as they go, are fairly sound. On one point, all authorities are more or less agreed, namely, that the ordinary well-to-do person eats too much. The well-to-do, as a rule, consume a far greater amount of meat than is really required to repair the nitrogenous waste of the body, while the poor eat more cereals and a larger bulk of food in order to get that amount of proteid for which a healthy person has a natural craving. Too much food with the poor usually means a greater proportion than is necessary of carbohydrates, while with the well-to-do, "too much" means an excess of the nitrogenous elements.

ACETONURIA IN PELVIC DISEASES.

There are certain types of acetonuria connected with gastrointestinal disturbances, with diabetes, or with toxemia, which have long been known and thoroughly studied. In addition to these there are other varieties which have been more recently described but regarding the etiology and behavior of which we are still very much in the dark. Here may be included the acetonuria which has been noted during pregnancy, labor, and the puerperium. The appearance of an acetonuria during pregnancy was at first regarded as an evidence of intrauterine death, but when it was shown that the phenomenon might be present during the course of an apparently normal pregnancy, its pathognomonic significance was denied. It was next demonstrated that various complications of pregnancy, including syphilis, hematocele, ectopic gestation, and albuminuria, particularly that associated with eclampsia and hyperemesis, were accompanied by an increased acetonuria. Among those who investigated the cause of this anomaly, the opinion prevailed that this condition was due partly to some disturbance in the metabolism of the fats, partly to an insufficiency of the carbohydrates.

A very extensive investigation with reference to this question has been conducted by Baumgarten and Popper (*Wiener klinische Wochenschrift*, No. 12, 1906), who examined quite carefully for acetonuria the urine of one hundred patients presenting pelvic lesions. In addition to the excretion of acetone itself, they also directed their attention to the closely related bodies, acetoacetic and betaoxybutyric acids. The cases under observation included both normal and complicated pregnancy, inflammatory conditions and tumors of the adnexa, puerperal sepsis, carcinoma uteri, myomata, cysts, and menorrhagia. In all of these the tests for acetoacetic acid were negative and acetone was present in traces in only a few instances. On the other hand a well-marked reaction for both of these bodies was obtained in seven cases of ruptured extrauterine pregnancy. Betaoxybutyric acid was not found in a single instance. The acetonuria invariably subsided in a few days after operation and the writers attributed it to the presence of a free hemorrhage, for when the acetone test was applied to the blood clots derived from these cases, a positive result was obtained. This is in accord with the claims of other investigators who have shown by experiments *in situ* the possibility of acetone formation from albuminoids in the organism.

These observations are extremely interesting, and as the test referred to can readily enough be made, the phenomenon may serve as a factor in the differential diagnosis of obscure cases, where some doubt may exist as to whether we have to deal with an hematocele or an adnexal tumor. The continued presence of a well-marked acetonuria was found in this investigation to be invariably associated with ruptured extrauterine pregnancy, either old or re-

cent, whereas in several instances in which the clinical evidences of an hematocele were prominent, but the test alluded to was negative, the operation disclosed that some other causal condition was present. The more detailed report on this subject, for that referred to here is merely a preliminary communication, will be awaited with interest and will probably stimulate other investigations along this line.

The Dangerous Strawberry.

It is well known that some unfortunate individuals suffer from an idiosyncrasy in regard to the luscious strawberry which bars them from the enjoyment of this earliest and most prized of our small fruits. To such we extend the assurance of our commiseration, and only wish for their sake that someone had elaborated an antitoxin with which they could sprinkle their berries, and so feast upon them during the all too short season without fear of intestinal or dermic retribution. But perhaps our pity is wasted, and it may be that they are fortunate in their abnormality. Such at least is the view taken by no less an authority than Metchnikoff, the Russian savant of the Pasteur Institute. In the second of the Harben lectures delivered by him at King's College, London, the latter part of May, he discoursed upon the hygiene of the alimentary canal, and threw a new light on what we have been wont to regard as the beneficent process of digestion therein. Noting that a marked increase of leucocytes in the blood occurred during the course of an infectious disease, he remarked that a similar phenomenon was observed during the process of digestion, and the analogy between the two cases was so striking that he suggested the disquieting thought that the digestion of food might also be a kind of infection. Indeed, he asserted boldly that after each repast a certain number of microbes passed through the intestinal walls and found their way into the general circulation, the faithful leucocytes then massing in force to repel the invasion. These microbes might effect their entrance into the circulation through lesions in the intestinal walls made by sharp or hard particles of food—an argument against the practice of prescribing bran bread and other irritating foods instead of gently acting laxatives in the treatment of habitual constipation. But the chief offender in this respect, he suggested, might be the helminths which many if not most of us harbor in our innocence. These worms, he said, had been shown to be active agents in the causation of the ever-present appendicitis, Guiard had suggested that they might serve to inoculate the mucous membrane with typhoid bacilli and other pathogenic microbes, and there was reason to believe that entozoa played a rôle in the causation of certain tumors. It was time, therefore, he concluded, to institute an energetic campaign against intestinal worms. It is manifestly impracticable to add vermifuges to the ordinary diet, and man must therefore direct his energies to the exclusion of the ova of those parasites by keeping a careful watch over what he puts into his mouth. And here the lecturer entered the lists against the raw-food faddists, and, indeed, against all of us who occasionally indulge in salads and other comestibles which have not been previously submitted to a temperature of 212°. All food and drink, he contended, should be boiled before being consumed. The tasty salad is, of course, forbidden, for washing with boiled water is not sufficient, and a boiled salad is unthinkable. And here we come to the saddest part. Among fruits this cibiclast, if we may be pardoned the term, said it was principally strawberries which introduced parasites, ova, and infectious germs into the intestinal canal. It was therefore necessary to boil them—boiled strawberries! It is true he said strawberries might be grown under satisfactory hygienic conditions so as to permit of their being consumed raw. But to that end it would be necessary to watch over the soil and manure, and to use only irreproachable fluid for the purpose of watering. The conditions are too hard, and it is evident that the strawberry must go—go to the jam-pot we mean. This is a subject worthy of one of the scare leaders of the *Lancet*, and we leave to our esteemed contemporary its appropriate treatment. If our enlightened readers are willing to defy appendicitis and leucocytosis, and even helminthiasis, during the few remaining days of the strawberry season, we have nothing more to say. Our duty is done in placing the facts before them.

Breast Feeding.

It is claimed by many that the care of infants can no longer be regarded as a purely medical question, but that with the growth of civilization it has also become a social and economic problem. In view of this fact, the question of whether the women of the present day are as capable of nursing their offspring as those of the past, has become one of paramount interest. It is now almost a matter of custom to take a pessimistic view of the situation, and the theory has been advanced that the continued non-use of the mammary glands by several generations of women will gradually result in their atrophy. Such an extreme standpoint is perhaps an exaggeration and it has been repeatedly demonstrated by pediatrists that the situation is not hopeless and that in numerous instances an apparently inactive breast may be made to functionate properly. It therefore remains for the obstetrician to institute such precautions at an early date as will insure to the child his natural supply of food. In the majority, if not in all women, the breasts become physiologically active after parturition, but although this fact is acknowledged we have little reliable statistical information regarding the length of time during which this function persists or to what extent it may become developed. A point which has been clinically demonstrated in connection with this subject is that there are occasionally women who are physically incapable of lactation, although the necessary mammary gland development is apparently present. This question has been investigated by Engel (*Monatsschrift für Geburtshilfe und Gynäkologie*, Vol. XXIII, No. 4), who studied very carefully the breasts of a number of women dying during or after labor, with the idea of determining whether this deficiency was due to a physiological or to an anatomical cause. Among these cases two distinct anatomical types could be distinguished with reference to the glandular and fibrous constitutents. The one was normal, the other represented an incompletely developed organ in which the fibrous elements outweighed the glandular. No reason could be found for the lack of development in the latter class, primiparæ and multiparæ were included in both, heredity was not a factor, neither was nativity or environment. Although no cause was apparent, there is no doubt of the fact, and such breasts cannot become physiologically active to the normal degree, as the necessary elements are present only to a limited extent. But the writer claims that their function should nevertheless be cultivated, and if taken in time they may become sufficiently developed to afford to the child at least the benefits of

mixed feeding. Most diseases in infant life can be traced to improper or defective feeding, and the good start which a baby gets from even a few months of breast nursing furnishes it with an appreciable degree of resistance against future trouble.

The Treatment of Torticollis.

The pathology and therapeutics of this condition have received renewed attention during the past decade, and while we are not entirely clear as to the true pathology, progress of a more satisfactory character has nevertheless been made in its treatment, although the methods proposed by the various writers are by no means in agreement. Traumatism has been accepted as the most frequent cause of the deformity, and many are of the opinion that the changes brought about in the sternomastoid are the result of a myositis following an infection by pathogenic organisms centering in the injured structure. An interesting and very complete discussion of the question has been written by D. G. Zesas (*Zentralblatt für die Grenzgebiete der Medizin und Chirurgie*, Vol. VIII, No. 18), in which he concludes that the treatment of torticollis depends entirely on the length of time during which the affection has been present, on the extent of the change which the muscle has undergone, and on the amount of secondary disturbance. In all acute and uncomplicated cases massage and the various orthopedic measures should be tried. If these are ineffectual, resort must be had to operation. The various subcutaneous methods of tenotomy cannot be accepted as rational, and it seems safer and more satisfactory to do an open operation, in which the contracted muscle as well as all other neighboring constricting bands must be severed. This operation should always be followed by a course of gymnastics and other suitable after-treatment. In all severe cases and when recurrences have taken place, a partial extirpation of the sternomastoid muscle is indicated, great care being taken not to injure the jugular vein or the spinal accessory nerve.

News of the Week.

Orators of the American Medical Association.—The following have been elected to deliver the annual orations before the American Medical Association at the meeting in Atlantic City in 1907: *Oration on Surgery*, Dr. William H. Wathen of Louisville, Ky.; *Oration on Medicine*, Dr. James B. Herrick of Chicago, Ill.; *Oration on State Medicine*, Dr. Samuel G. Dixon of Philadelphia, Pa.

Lane Medical Lectures.—The course of Lane Medical Lectures of the Cooper Medical College of San Francisco commencing August 20, 1906, and continuing two lectures daily during the five days of the week, will be given by John C. McVail, M.D., D.P.H., of Glasgow, Scotland. The subjects of the lectures will be "Practical Hygiene, Epidemics, and Preventive Medicine."

A New Michigan State Medical Society.—At a meeting of physicians and surgeons of Grand Rapids, on June 11, a committee was appointed to formulate a plan of action looking toward the organization of a new and independent State Medical society. The new organization will be independent of the American Medical Association. The committee is composed of Drs. Perry Schurtz, J. B. Griswold, J. Kirkland, Charles E. Hooker, and Henry Hulst.

Outings for Children and Convalescents.—The Society of St. Vincent de Paul will begin its season of fresh-air work among the poor children of the tenements next Monday by sending out a party of 250 to its fresh-air farm at Spring Valley, in the Ramapo Hills, Rockland County. Other parties will follow every fortnight until the middle of September. Last summer the society gave about 1,500 children a two weeks' free outing on the farm. This year it is hoped that the number will be increased to upward of 2,000. The society also maintains at Spring Valley a free convalescent home for women, which was opened last September. It makes no distinction of race, creed, or color, and is kept open all the year round.

Fresh Air for Sick Babies.—In order to demonstrate the value of fresh air for the sick children of the poor the Association for Improving the Condition of the Poor has constructed an out-of-door camp for sick babies on the bluff at Sixty-fourth and Sixty-fifth streets facing the East River. There are seven double-roofed, windowless tents 16 x 30 feet, each with a 12-foot porch. Each tent has cots for twelve babies. Three tents will be reserved for sick babies staying day and night and the others for babies to be cared for by their mothers during the day. It is hoped in this way to convince the city authorities of the desirability of setting aside parts of the reservation piers as babies' clinics.

The "Edinburgh Medical Journal."—Since this venerable publication first appeared in 1805 it has undergone many changes, both in its ownership and among the incumbents of its editorial chair. A transition that will no doubt prove especially gratifying to its readers is the recent purchase of the journal by a representative body connected with the Edinburgh Medical School.

Yale Medical School.—Dr. George Blumer has been appointed to the Chair of the Theory and Practice of Medicine in Yale University to succeed the late Dr. John S. Ely. Dr. Blumer was formerly a director of the Bender laboratory at Albany, and Professor of Pathology at the Albany Medical College, and was, until recently, connected with the Medical Department of the University of California.

A Pathological Study of the Beef Question.—At a special meeting of the Council of the Chicago Medical Society, recently held, President C. S. Bacon was instructed to appoint a committee of three pathologists to cooperate with the committees appointed by the Chicago Commercial Association and the Illinois Manufacturers' Association in the proposed investigation of the stockyards. In response to the request contained in a recent letter written by Health Commissioner Whalen the specific object of the committee will be to determine whether carcasses affected with localized tuberculosis are fit for food after the diseased parts are cut out.

Hospital vs. Fish Market.—Owing to the stench from a fish market in the rear of the Beth Israel Hospital at Cherry and Jefferson streets it became necessary to remove all the patients from the children's ward. On complaint to the Health Department an inspection of the market was made, and it was found to be in a thoroughly insanitary condition, the venders throwing all sorts of refuse on the floor and exercising no attempts at cleanliness. An order was served on the owner compelling him to make improvements.

Hospital for Infants in Worcester, Mass.—Green Hill Park and its buildings, the large estate in Worcester of the late Andrew H. Green of New York, will be opened next month as a hospital for infants with the title of "Green Hill Summer Hospi-

tal for Infants." The officers of the executive committee are: *Chairman,* Dr. Wallace T. Clark; *Secretary and Treasurer,* Dr. Eldridge Mix. The scheme for the infant hospital, like the Boston Floating Hospital, originated with Dr. Clark when he was city physician of Worcester.

A New Children's Hospital in Rhode Island.—A hospital for crippled children is to be established on the north end of Prudence Island, in Narragansett Bay, through the generosity of James A. Garland of New York. Accommodations are to be provided for from twenty to twenty-five patients.

A Measure of the Suffering Saved by Hospitals.—Sir Frederick Treves, Sergeant-Surgeon to the King, in delivering an appeal for contributions to the London hospitals from the pulpit of the celebrated Union Chapel at Islington "on Hospital Sunday," said that the amount of pain relieved could be roughly gauged by the quantity of morphine consumed at the hospitals. One-sixth of a grain would relieve pain for an hour. By this test 87,000 hours of pain—that is practically ten years—were avoided in one London hospital alone in 1905.

Illinois Northern Hospital for the Insane.—The superintendent of this institution, Dr. Frank S. Whitman, recently sent in his resignation, to take effect July 1. Dr. V. H. Podstata, superintendent of the Dunning institutions, has been offered the succession to Mr. Whitman, and it is understood that he will accept; but the date of his retirement from his present position has not been decided.

To Study the Drug Trust.—United States District Attorney Keating has been deputed by Attorney-General Moody to investigate the conditions in the drug trust, suits against which were filed in Indianapolis some weeks ago. He is expected to study the character of the druggists' associations in Philadelphia, New York, and other cities in order to be able to direct the trial of the cases in Indianapolis.

No Yellow Fever at Panama. — According to despatches from the Isthmus there are no cases of yellow fever at Colon, and the general health conditions are excellent. During May the death rate among employees was the lowest recorded in twelve months. The diagnosis of the three alleged cases of yellow fever reported from Ship Island is discredited by the Panama authorities.

Quarantine Against Havana.—Owing to the recent occurrence of a case of yellow fever in Havana and in Matanzas passengers arriving on incoming steamers from Cuba will be obliged to produce immune certificates at quarantine. All persons without these certificates will be transferred to Hoffman Island for observation until the period of five days has expired from the time of leaving Havana. No case of yellow fever has been reported from Havana since June 5, and there are said to be no suspected cases.

A Severe Typhoid Epidemic is reported from Greens Cut, Ga., a village of about 200 inhabitants, fifty of whom are down with the disease.

New York Sausage Factories Closed.—Two sausage factories in this city have been closed by the Health Department, owing to the filthy and insanitary conditions found to exist in them.

Enlargement of Chicago Baptist Hospital.—The directors of this hospital contemplate the erection of administration offices, and an addition to the present building, at a cost of about $10,000.

American Gastro-Enterological Association. — At the ninth annual meeting of this association, held at Boston, Mass., June 4 and 5, 1906, the following officers were elected for the ensuing year: *President,* Dr. H. W. Bettmann of Cincinnati; *First Vice-President,* Dr. Julius Friedenwald of Baltimore; *Second Vice-President,* Dr. F. H. Murdoch of Pittsburg; *Secretary and Treasurer,* Dr. Charles D. Aaron of Detroit.

American Urological Association.—At the fifth annual meeting of this association, held in Boston on June 4 and 5, under the presidency of Dr. Ferd. C. Valentine of New York City, the following officers were elected: *President,* Dr. Bransford Lewis of St. Louis; *Secretary,* Dr. Hugh Cabot of Boston; *Treasurer,* Dr. F. R. Hagner of Washington, D. C.

South Dakota Medical Association.—At the meeting of this association held in Watertown on May 25 Sioux Falls was chosen as the place for the meeting in 1907, and the following officers were elected for the ensuing year: *President,* Dr. E. T. Ramsey, Clark; *Vice-President,* Dr. J. G. Collar, Brookings; *Secretary,* Dr. Alway, Aberdeen.

North Carolina State Medical Society.—At the meeting of this society, held in Charlotte on May 30, the following officers were elected for the ensuing year: *President,* Dr. S. D. Booth of Oxford; *First Vice-President,* Dr. C. L. Strong of Charlotte; *Second Vice-President,* Dr. J. E. McLaughlin of Statesville; *Third Vice-President,* Dr. W. F. Hargrove of Kinston; *Secretary,* Dr. D. A. Stanton of High Point; *Treasurer,* Dr. H. McKee Tucker of Raleigh. Morehead City was chosen as the place for the next annual meeting, and the movement to have the time changed from spring to fall was defeated.

The Æsculapian Society of the Wabash Valley held its fifty-ninth semi-annual meeting at Robinson, Ill., May 31, 1906. Dr. H. N. Rafferty of Robinson, Ill., was elected secretary and treasurer, to fill the vacancy occasioned by the death of Dr. H. McKennan of Paris, Ill., which occurred in March last.

Vermont Homeopathic Medical Society. — At the sixty-fifth annual meeting of this society recently held in Montpelier the following officers were elected: *President,* Dr. F. H. Davis, Lyndonville; *Vice-President,* Dr. F. H. Everett, Castleton; *Secretary,* Dr. George I. Forbes, Burlington; *Treasurer,* Dr. J. F. Shattuck, Wells River.

Maine State Homeopathic Medical Society.—At the fortieth annual session of this society, held in Bangor, on June 12, the election of officers resulted as follows: *President,* Dr. R. J. Wasgatt of Rockland; *Vice-Presidents,* Dr. R. S. Graves of Saco, and Dr. John T. Parmer of Portland; *Secretaries,* Dr. Carrie E. Newton of Brewer, and Dr. L. A. Brown of Portland; *Treasurer,* Dr. W. S. Thompson of Augusta.

Obituary Notes.—Dr. Charles H. Alden, Brigadier-General U. S. A., retired, died at Pasadena, Cal., on June 7. He was born in Philadelphia in 1836 and was graduated from Brown University in 1856, with the degree of A.B. He received his medical degree in 1858 from the University of Pennsylvania, and a year later he entered the medical service of the United States Army. He served in several Indian campaigns in the West, and also in the Civil War. He occupied many positions of prominence in the army medical corps, and in 1894 was the first president of the Army Medical School. In 1894 he was made president of the Army Medical Examining Board at Washington, D. C. In 1899 he was elected president of the Association of Military Surgeons, and in 1900 he was retired from active service on account of age. In 1904 he was

promoted brigadier-general on the retired list by act of Congress. He is survived by a daughter and two sons, one of whom is Dr. Elliot Alden of Cleveland, Ohio.

Dr. GILBERT L. GIFFORD, the oldest practising physician in Hamilton, Madison County, N. Y., died suddenly on June 11 while attending a meeting of church trustees.

Dr. EDWIN T. JONES, chief of the staff of the Jamaica Hospital, died of apoplexy in Utica on June 11. Dr. Jones was on his way to Saranac Lake and stopped at Utica over night to visit a friend.

Dr. ANDREW D. BLANCHARD of Melrose, Mass., died on June 11 at the age of eighty-three years. He was graduated at Harvard in 1842 and received his medical degree from Harvard Medical School four years later. He was said to be the oldest surviving surgeon of the Civil War.

Dr. JOHN R. MAXWELL of Keokuk, Iowa, died on June 3, at the age of thirty-four years. He was the son of Dr. T. J. Maxwell and received his medical education at the Keokuk Medical College.

Dr. HENRY A. CARRINGTON of Bristol, Conn., died on June 9, at the age of eighty years. He was a graduate of Harvard College, and also received his medical degree from that university. For many years he practised medicine in New Haven. About fifteen years ago he retired from active work and went to Bristol.

Dr. SAMUEL H. LOWREY of Huntsville, Ala., died on June 7, at the age of fifty-seven years. He was formerly health officer of Huntsville, and had served as vice-president of the Alabama State Medical Society.

Dr. JOHN A. WAKEMAN of Minneapolis, Minn., died on June 8, at the age of ninety-one years. Dr. Wakeman was one of the oldest homeopathic physicians in the United States, having practised for more than sixty-five years in Ohio and Illinois.

Correspondence.

TRYPSIN AND AMYLOPSIN IN CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The published report (MEDICAL RECORD, May 19, 1906, p. 809) of a discussion before the Medical Society of the County of New York tempts the writer to offer the following remarks as a preliminary note, based upon the result of his scientific study of eclampsia. The medical profession in America can easily test the truth of the writer's contention, by using diastase in any case of pregnancy where there is the slightest threatening of eclampsia.

The "trypsin" treatment of cancer had not long been in use, when in January last some French and Italian physicians informed me of certain bad symptoms of vomiting, nausea, pain in the back, "sleeping in any position," mental and physical torpor, etc., following injections. In answer to their requests for scientific advice, I urged them to treat it as they would the vomiting of pregnancy, and for myself I began to study eclampsia. For the treatment is based upon the introduction of an artificial "critical period" (*vide* J. Beard, "Certain Problems of Vertebrate Embryology," 1896, and "The Span of Gestation," 1897, Jena, Gustav Fischer), and its course would naturally be the same as the events from the seventh week of a normal gestation. It was soon seen that no rational treatment of eclampsia existed. There was an extensive experimental study of it in the *Archiv für Gynäkologie* (Vol. 76, 1905, pp. 507 to 585) by Professor Zweifel, as well as a lecture by him in the *Münchener medizinische Wochenschrift* for February 13, 1906. His article bears the title "Zur Aufklärung der Eklampsie." It would take up much space to describe his results. Briefly, he sets it down to the formation of sarcolactic acid in the fetal blood and placenta. In my opinion his conclusions rest upon very thin ice, and there may well have been other substances. However that may be, I have gone behind it all, to the true source of the mischief.

As Professor Zweifel himself found, the diastatic ferment is absent in fetal blood. The reason of this is not far to seek. In the days of long ago, and as now happens in most marsupials, birth took place at the critical period, and the milk-nutrition was initiated. In this the diastatic ferment is of no use.

When, as she did, Nature prolonged the gestation, in order to bring the young into the world in more perfect form, she deferred in so doing more and more the start of mammary nutrition. In prolonging the gestation she forgot to introduce diastase at an earlier period, and the "memory" remained that it was not needed until the milk-period had passed. Consequently there is an absence of the diastatic ferment during all fetal life. Usually the difficulties caused by this can be got over, if the maternal pancreas form sufficient diastase. But if there be any failure in this respect, the consequences may well be disastrous. In a way the difficulties may be said to have been usually overcome, but pregnancy, from the seventh week onward, owing to this absence of the diastatic ferment, is a sorry business. Probably in all cases the oral or hypodermic administration of diastase during the last months of pregnancy would be of great benefit to the mother. In certain forms of cancer, more especially uterine cases, it cannot with safety be dispensed with. When the patient becomes drowsy, it is called for. In some cases, not in all, symptoms of eclampsia, varying in degree, arise in the "trypsin" treatment of cancer. The comparison between this and the phenomena of gestation proves to the embryologist that it is and can only be the absence or the insufficiency of diastase which causes it. In a gestation without eclampsia there must be something being formed either by mother or fetus which prevents its arising. If eclampsia ensue, the want of diastase alone can be at its basis. Therefore, in the treatment of cancer by pancreatic ferments injected into the blood it is most desirable that a pure trypsin alone without much diastase should not be employed, and if bad symptoms arise, these should be met by the giving of sterile hypodermic injections of 5 per cent. diastase solution up to 40 minims daily. The like treatment is called for in cases of eclampsia, or where it is threatened.

It is becoming more and more evident that, in the treatment of cancer by the pancreatic ferments, after some few weeks of the trypsin injections, say four, if not earlier, this injection should be replaced in the treatment, until the remains of the degenerating tumor be removed, by injections of the diastatic ferment, up to 40 minims daily. There is not a particle of doubt in my mind that such injections would also remove the symptoms of eclampsia in pregnancy.

JOHN BEARD, M.D.
University Lecturer in Comparative Embryology.
EDINBURGH, SCOTLAND, June 4, 1906.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL COUNCIL—OPERATIONS FOR NON-MALIGNANT DISEASES OF THE STOMACH—THROMBOSIS OF ABDOMINAL AORTA—PULMONARY EMBOLISM—ACUTE ATONY OF THE STOMACH AND INTESTINES.

LONDON, June 1, 1906.

THE further discussions at the Medical Council are not likely to be of much interest to our readers, although some of them are of importance to us here. Charges against four dentists trading as the "American Dental Institute" and registered under the companies' acts for promoting advanced American dental surgery were made and proved by the Council. Their names were ordered to be removed from the register as guilty of conduct infamous in a professional respect.

The same fate overtook two English dentists who had formed a "two-man company," and with the aid of unqualified assistants carried on practices in several places.

The little scheme of the ruling clique of the British Medical Association to monopolize the representation of direct members to the Council was brought up, and evidently was disapproved, although a number of members abstained from voting. The president stated, in reply to a question that persons elected under the conditions proposed, could not, with propriety, take part in discussions brought before the Council by the association. This should, perhaps, be a sufficient hint of the general opinion which has been evoked by the interference of the association. It is a return to some of the bad old ways which optimists hoped had been discarded; and this is not the only instance of such return.

Sir V. Horsley proposed that the Privy Council should be approached with a view of getting some form of ballot substituted for the signed voting papers now used. It seems strange that for such an election a demand for a secret ballot should be made. If indirect representation had been the method, as was actively advocated at the time, this and other matters would not have been a source of differences. The British Medical Association has something to regret for its action there—and will probably have still further proofs of its mistake.

For the first time in ten years the Council is possessed

of a surplus. This is largely due to the greater expedition with which business has been transacted—a fact to be commended to the notice of the president and his colleagues.

The Pharmacopœia Committee has collected material and obtained reports for future use, but there is no prospect of a new edition for some time.

A meeting was held last week in promotion of the aims of the British Red Cross Society, which, as explained by Lord Rothschild, presiding, is the outcome of a fusion of two existing bodies, viz., the National Society for aid to the sick and wounded, and the Central Red Cross Council. A message was read from the Prince of Wales, wishing success and saying he was "impressed with the necessity of making preparations for war in times of peace." H. R. H. also said the Queen had the welfare of the society much at heart, and he hoped in time a branch would be found in every part of the Empire. Lord Rothschild said the National Society, from its foundation in 1870, had expended nearly half a million sterling in assisting the sick and wounded in war. Lord Tweedmouth said that the overlapping of hospital work in the field was not desirable, consequently it had been realized generally that there should be some central organization, active in times of peace, which would interest the public in the provision of material for the sick and wounded in war times. General Lord Methuen said he hoped the society would study sanitation, in which we were much behind the Japanese Army.

Mr. Moynihan gave, as the Royal Medico-Churigical Society, an account of 282 cases of operation for non-malignant diseases of the stomach, being his complete series of such cases to the end of 1905. These he arranged in four groups: Perforating ulcer of stomach and duodenum, 24 cases with 9 deaths; persistent hemorrhage, 27 cases with 3 deaths; chronic ulceration and dilatation, 209 cases with 2 deaths; hour-glass stomach, 22 cases with 3 deaths. Mr. Moynihan believes that the mortality from hemorrhage in chronic gastric or duodenal ulcer is greater than usually supposed. It is the constant recurrence of hemorrhage that renders a resort to operation necessary in these cases. No single hemorrhage, however large, would justify operation, but only frequent recurrences at lesser intervals and in larger quantities. In no case should an operation be performed during the hemorrhage.

Mr. Paterson remarked on the diminishing mortality of gastrojejunostomy, in those cases, fallen to a little over 1 per cent. After-history is often difficult to ascertain, but he had collected 116 cases of operation for perforation. In 92 per cent. there was definite history of perforation, and in only a small proportion a history of hemorrhage.

Perforation on the posterior wall occurred in 12 per cent. The mortality of operations for perforated ulcer would probably be reduced by gastrojejunostomy after suture of the ulcer done at the same time.

Dr. Hale observed that in two of the twenty-seven cases of hematemesis no ulcer was found at the operation or after death. In twenty-seven cases which he had collected the same fact appeared. In records of 10,000 post mortems there were only two deaths from hematemesis without any ulcer being found. Thus merely oozing might give rise to the bleeding when operation would not be required. Mortality from simple hematemesis was shown to be very low. It was probably better for no operation to be done while the bleeding was going on, but after it had ceased a gastrojejunostomy, if it had been severe.

Mr. Eve laid stress on diagnosis, asking on what symptoms chronic ulceration of the stomach could be certainly diagnosed, and, further, by what signs we might recognize the presence of the ulcer when the abdomen was opened. Palpation of the exterior was not sufficient, as a rule, and an opening on the posterior wall was needed for exploration. Many seemingly typical cases showed no ulcer at the operation.

Dr. Hawkins commented on the rarity of death from hematemesis even when most severe.

At the Clinical Society, on the 25th ult., Dr. F. Hawkins gave an account of a case of thrombosis of the abdominal aorta in a woman of fifty-six. She had complained of giddiness, reeling, and pains in the head in 1900. In January, 1904, cramp in right leg, and afterward in left, seized her. In May of same year numbness in the legs and sensitiveness to touch, with great pain on pressure, came on. On June 4 sudden coldness and numbness of legs, cold hands, blue lips, and feeble pulse at wrist. No femoral pulsation perceptible; an hour later vomiting, abdominal pain, and later great distention and death. At post mortem mitral stenosis was found. The femoral and iliac arteries were occluded and a clot found in the aorta, extending above the superior mesenteric artery. A calcareous plate was on the posterior wall at the bifurcation. An old infarct was in the right kidney, and several recent ones in both kidneys.

Dr. Fawcett showed three specimens of thrombosis of the aorta. Mr. Harvard spoke of the rarity of thrombosis in comparison with atheroma of the aorta. Mr. Baker related a case in which a woman woke up with great pain in her legs. Pulsation was absent in both femorals, but returned in right forty-eight hours afterward, when gangrene set in on the left foot. Amputation was done, but the vessels found normal. The suddenness and gangrene led to the supposition that embolism had occurred. Dr. A. E. Garrod said he recollected a similar case in which the patient was admitted with numbness, but no abdominal pain. But after death a clot was found extending one inch above the bifurcation.

Pulmonary embolism was the next subject brought before the society. Dr. C. R. Box communicated six cases, in each of which he believed that a thrombus had first formed in the pulmonary artery, and that later the clot became displaced and the symptoms of embolism set in. He insisted on the importance of recognizing the premonitory signs, viz., development of a murmur at the base of the heart, acceleration of the pulse, moderate cyanosis, and dyspnea. Death may be instantaneous with pallor, or there may be some delay, with cyanosis and asphyxia. Infarction of the lung is exceptional. In reference to treatment it was mentioned that artificial respiration would be dangerous, as it might dislodge further clot.

Mr. Spencer said he did not consider it proved that the clot had been formed in the pulmonary artery from its absence in the peripheral vessels.

Dr. Tooth mentioned some cases in which a coiled clot was found and one in which the clot looked like a cast of the inferior cava.

Mr. Clutton and Mr. Makins related cases in which clots had formed in the veins, and Dr. Box replied to a question raised that a cast of the pulmonary valves on the clot proved where it was formed. Surgeon-General Longhurst suggested that ammonia might be of service.

Dr. Parkes Weber gave a short account of a case of acute dilatation or atony of stomach and intestines, which might, perhaps, be termed rather "gastrointestinal tympanites." He spoke of the analogy with "ballooning of rectum," "paralysis of the non-gravid uterus," and of "acute atony of the bladder during operations," all of which conditions were temporary states of atony in hollow viscera. His case was in a woman of twenty-one, who, six weeks after an illness, was admitted about the third day of an attack of pleuropneumonia. She took food, but could not bring up the flatus which rapidly formed. Great distention ensued. There was some relief by lavage of the stomach, but intestinal meteorism seemed to remain. A pericardial friction was heard for some time, but ultimately the patient did well. It was remarked that out of forty-four cases of acute gastric dilatation collected by Campbell Thomson three were connected with pleurisy and pneumonia.

A member suggested the term paralytic as better than atonic, and another thought obstruction in the duodenum might give rise to acute dilatation.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE NEW OPIUM ACT—PLAGUE—INFECTED RATS IN BINONDO—PERSONAL.

MANILA, P. I., April 28, 1906.

THE new opium law, Act No. 1,461, recently passed by the Philippine Commission, became effective April 1, 1906. The law is the outcome of the agitation against the opium vice, which is so common among the Chinese, and is designed primarily with a view of preventing the Filipinos from becoming its victims. The Act of Congress passed March 5, 1905, in Section 80, Subsection (b) provides that after March 1, 1908, it shall be unlawful to import opium into the Philippines in whatever form, except by the Government, and for medicinal purposes only, and that at no time shall it be lawful to sell opium to any native of the Philippine Islands, except for medicinal purposes. In order to regulate the traffic in opium until 1908, when its importation is to be strictly forbidden except as provided above, the Philippine Commission passed an opium law, of which the following is a brief résumé:

Only Chinese persons are permitted to use opium in any of its forms, unless prescribed by a physician, and they are required to make a formal application to the effect that they are confirmed users of the drug, whereupon a certificate will be issued to them upon the payment of $2.50, and even then opium may not be used except in the residence of the user. It shall be unlawful to sell, transfer, give, or deliver opium in any of its forms to any person, unless such person is a duly licensed physician, pharmacist, or duly licensed wholesale or retail dealer in opium, or a registered user of

opium. Exception is made in the case of scientific bureaus of the Government, and hospitals.

Duly licensed physicians may prescribe and administer opium as a medicine, but any physician who habitually prescribes opium for his patients, when the physical condition of such patient does not require its use, shall have his license to practise medicine revoked by the Board of Medical Examiners for the Philippine Islands, and, in addition, shall be punished by a court of competent jurisdiction, by a fine of not less than $125 nor more than $500, or by imprisonment for not less than six months nor more than one year.

Any person other than a licensed pharmacist, who imports, cooks, or prepares opium or any narcotic extract from opium, in quantities of one kilo or more, shall be deemed a wholesale dealer, and must have a corresponding license. Every other person, other than a licensed pharmacist or wholesale dealer in opium, who sells, deals, or traffics in opium in any of its forms, shall be deemed a retail dealer in opium, and must have a corresponding license, provided however, that persons engaged in selling, or offering for sale, giving away, or bartering opium in such manner and in such quantity as to bring them within the definition of either wholesale or retail dealer shall be subject to both the wholesale and retail license tax.

It shall be unlawful for any other persons than those mentioned above to have in their possession opium in any of its forms, except on the permit from the Collector of Internal Revenue, or as a medicine prescribed by a duly licensed and practising physician. Any dealer in opium must display a sign above his place of business, with the words "Licensed Dealer in Opium."

Ten days after the Act went into effect, all dealers were required to submit an accurate statement showing the amount of opium on hand. Opium may be stored only in places approved by the Collector of Internal Revenue. A book must also be kept, either in English or Spanish, which shows the full quantity of opium at time of last report, the amount and date upon which additional amounts were received, the firm or person from whom received, and the kind. In addition, the book must also show the date and hour and price of each sale made from stock.

If at any time an inspector of the Bureau of Internal Revenue finds a discrepancy between the actual amount on hand and that shown by the records, the penalty shall be double the value of the deficiency or excess that exists. With every sale of opium, the dealer must furnish the purchaser a certificate of sale which shows the name and address of the purchaser, the kind, quantity, and price, and such other information as the Collector of Internal Revenue may desire.

Every wholesale dealer in opium must pay a tax of $500 per year, and give a bond to the amount of $5,000 for the carrying out faithfully the provisions of the Act. Retail dealers shall pay $100 per year. For all opium on hand, or that will be purchased hereafter in the Islands, must be paid an internal revenue tax of $1.25 per kilo. All opium imported must pay the regular customs duty of $4 per kilo for crude opium and $5 per kilo for prepared or manufactured opium. In addition, before opium can be released from the Custom House, there shall be paid an internal revenue tax of $1.25 per kilo on crude opium, and $3.75 on prepared opium.

The license and internal revenue tax required to be paid by the Act shall be covered into the Insular Treasury and shall constitute a special fund to be devoted solely to the following purposes: (1) The printing and dissemination among the people of information as to the evils resulting from the use of opium; (2) the payment of the reasonable expenses, in some reputable hospital, of those desiring to cure themselves of the opium habit; (3) the payment of the expenses of such Filipino students as may be sent by the Insular Government to the United States for education; (4) payment of salaries of Filipinos who have been appointed Insular teachers; (5) the construction of schoolhouses and school buildings in the various municipalities of the Islands: Provided, that 25 per cent. of all fines imposed by reason of violations of this Act shall be paid to the person who furnished the original evidence and substantiated it, which led to the detection of the offense and the imposition of the fine. The name of the informer shall be specified in the judgment of the court, when conviction is had in the court.

From the foregoing it will be seen that the law is most drastic in character, and if rigidly enforced, it would seem that the sale of many patent medicines will be stopped.

Plague-infected rats still continue to be found in the district of Binondo. Several have also been found in the adjacent district of Tondo. The Bureau of Health has had rats caught in every section of the city, and had them bacteriologically examined, but so far the results have been negative with the exceptions noted above. The rat-infected area does not extend over more than a few blocks. Active disinfection and rat catching are still being carried out.

The last case of human plague occurred April 14, and was the sixth that had been recorded since January 1, 1906. A Japanese woman, having symptoms resembling those of plague, arrived here from Kobe, Japan, April 22, and is now under observation at the San Lazaro Plague Hospital.

Dr. Dudley of the St. Paul Hospital, who was formerly connected with the Bureau of Health, and who has recently recovered from a severe illness, departs for the United States to-morrow, for several months' vacation.

Lieut.-Col. D. M. Appel, Asst. Surg.-Gen., U. S. Army, has completed his tour of duty in the Islands, and will return to the United States on the transport that leaves April 30. He has been in charge of the medical supply depot in Manila, during the past year, and now has been ordered to similar duty in San Francisco.

FIFTEENTH INTERNATIONAL MEDICAL CONGRESS.

(From Our Special Correspondent.)

PROSTATIC HYPERTROPHY AND PROSTATECTOMY—URINARY CALCULI—THE TREATMENT OF NEURALGIA—TUBERCULOSIS IN LAUNDRESSES—CORTICAL LESIONS OF TOXIC ORIGIN—DIAGNOSTIC METHODS IN RENAL SURGERY.

LISBON, April 29, 1906.

TUFFIER of Paris presented a paper on the treatment of hypertrophy of the prostate. He divided this into three groups, preventive treatment, palliative treatment, and curative treatment. The first he said was the classical method of Guyon and embraced all procedures which tended to relieve congestion in the gland. Palliative treatment involved the use of the catheter. Catheterism should be employed only if it was easy and was well borne, and should always be desired from if threatening manifestations developed in the upper urinary passages, if the bladder could not be totally emptied, or if persistent hematuria or chronic cystitis appeared. In spite of all these contraindications catheterism remained the method of choice in the majority of cases. Curative treatment necessitated operative intervention. Freudenberg's operation had the same mortality as prostatectomy, and did not preclude the possibility of relapses. Partial extirpation of the gland was to be recommended only in those cases in which the organ was only partially hypertrophied. Rydigier's operation of resection and excochleation of parts of the lateral lobes did not obviate relapses, and the total removal of the gland was the only method of choice. Neither old age nor gravity of the patient's general condition contraindicated operative treatment, but diabetes and albuminuria were to be regarded as rendering operation inadvisable. The perineal operation was rather more difficult than the suprapubic one, was likely to be followed by impairment of the sexual function, and often gave rise to sinuses. The transvesical method was more rapid but was attended by higher mortality. In general it should be stated that operative treatment should be the exception and not the rule.

Albarran of Paris in discussing prostatectomy said that he always preferred the perineal route. If the operation were carefully planned and carried out injuries to the bladder and rectum could be avoided; it was true that in some rare instances sinuses persisted, but this was only in very stout patients and in cases in which the urine was highly infectious and the prostate was the seat of a chronic inflammation. It was just in these cases, however, that the suprapubic method was least indicated. The largest statistics were those of Freyr for the suprapubic route with a mortality of 8 per cent., and of Albarran for the perineal operation with a mortality of 2.4 per cent. Averaging the results of all surgeons, the suprapubic operation gave a mortality of 17 per cent., and the perineal operation one of 9 per cent. The speaker himself did the transvesical operation only on young, strong patients who were anxious to retain their potency.

Kallionsis of Athens in a long dissertation considered the etiology and the pathology of urinary calculus. Regarding climate, he said that its influence could not altogether be denied, particularly when frequent changes altered the solubility of the salts of the body. Drinking water undoubtedly had a double effect, as it could induce both frequency and rarity of stones; the latter not through any solvent action, however, but through their rare formation. The character of the food was said to be of effect, and heredity also appeared to have some influence. Age and

social condition as well as racial differences did not play a rôle of any importance. It could not be said, however, that any of these points were to be regarded as affording a satisfactory explanation of the formation of stones, and apparently a general disposition in this direction had to be assumed.

Bardenheuer of Cologne spoke on the treatment of neuralgia, which he considered was often due to a condition of venous congestion depending on various causes. Some of these were, alterations in the character of the blood, as in intoxications for example, changes in the vessel walls themselves, such as occurred in arteriosclerosis, or finally disturbances in the surrounding tissues, like the ascending congestion following an injury or inflammation, such as is observed for the trigeminal nerve in the case of affections of the teeth. Bardenheuer stated in confirmation of this view that in his operations he had always observed swelling and congestion of the blood-vessels of the nerve bundles, and that he had been able to secure immediate and permanent relief in sixteen cases of sciatica by exposing the nerve and freeing it from constriction by its sheath. The advantages of his method of operation consisted in the fact that if a relapse should occur, which was very rare, however, one could always resort to one of the more radical procedures.

Bernheim and Bienpart of Paris discussed the subject of tuberculosis in laundresses, and stated that the handling of dirty linen involved considerable danger for laundry employees. The authors had observed that a very considerable proportion of their tuberculous patients belonged to this class, and they urged the necessity for disinfection of the linen before it was turned over to the laundries. If it was considered advisable to disinfect dwellings and furniture, it was a great deal more so to free dirty linen from disease germs.

Battet and Laignet-Sarassine of Paris, in considering the cortical lesions of toxic origin, stated that as the result of their observations they had come to the following conclusions: It was possible by Nissl's method to recognize a diseased condition, but the procedure did not permit of conclusions regarding the nature of the underlying malady. While it was undoubtedly true that there was a definite theoretical relationship between certain intoxications and cellular lesions, it was practically still impossible to draw far-reaching conclusions owing to the imperfections of present technical methods. They had found that similar cellular lesions existed in the psychoses of toxic origin. Cortical cell lesions and disturbances of mentality were both manifestations of the same toxic affection, although their parallelism was not always very evident.

Kapsammer of Vienna read a paper on renal surgery, in which he said that the science owed its present stage of development to the invention of cystoscopic catheterism of the ureter through Brenner in 1887. Casper and Albarran had improved the technique to such a degree that it was now possible to attain the ideal of directly collecting the urine of each kidney. The endovesical separation of the two urines was a much less effective method, since the urine under the latter conditions came in contact with the mucous membrane of the bladder before being drawn off. Urine obtained in this way should be subjected to every possible means of investigation, since the physical and chemical examinations might simulate severe renal lesions without any such state being present, and the reverse was also possible. It had been found unsatisfactory to place reliance on urea determinations, and in order to make these of value it would be necessary to carry out an exact metabolism experiment on the patient, which was too troublesome and difficult for routine use. For practical purposes cryoscopy of the urine did not afford more reliable information than the specific gravity, and might even lead to serious errors, since, owing to the reflex polyuria induced by the ureteral catheterization, even normal kidneys might produce urine having a freezing point low enough to simulate a severe renal lesion. Kümmell was an ardent advocate of cryoscopy of the blood, although such observers as Israel, Tuffier, Barth, Kapsammer, Stoekmann, and Rovsing had not found it a reliable method. With the exception of Kümmell all surgeons had discarded cryoscopy in renal diagnosis. The methylene blue test under some conditions made it possible to appreciate marked differences, but it could not be recommended for ordinary use, as we were ignorant of the mechanism of excretion of this substance and its derivatives. A preferable procedure was the indigo carmine test, though this had not yet been sufficiently developed. The determination of the length of time that elapsed before the appearance of sugar in the urine after phloridzin injections had been found the most valuable means of diagnosis. Normally the sugar appeared ten to fifteen minutes after the subcutaneous injection of 0.01 of phloridzin, but the greater the anatomical and functional damage to the kidney the later was the appearance of the sugar in the urine. If no sugar were present in the mixed urine forty-five minutes after the injection, both kidneys were so severely damaged as to contraindicate nephrectomy.

Kümmell of Hamburg stated that cryoscopy of the urine and the determination of urea was of value if the two results were always compared and cryoscopy of the blood were also carried out. The use of these methods in over 1,000 cases during the past six years had never proved misleading. The discrepancies in the results of other observers were to be ascribed to the differences in technique. The author believed that if the blood freezing point reached 0.6 every operative procedure on the kidney was contraindicated, assuming that the cryoscopy had been properly performed. In five cases in which nephrectomy had been performed in defiance of this rule death followed immediately.

Progress of Medical Science.

New York Medical Journal, June 9, 1906.

Adominal Hysterectomy for Uterine Fibroid Complicated with Pregnancy and Prolonged Retention of a Fetus and Placenta.—The patient of H. T. Williams was a woman of thirty-one years in whom a diagnosis of pregnancy and fibroid was made. Menstruation was absent for the first three months of the period, but flowing came on regularly thereafter and was quite profuse. She finally consented to an operation, which was done about one year from the date to which the supposed pregnancy had been referred. The Dudley method of uterine removal was followed, one-half inch of the cervix being left, the operator uniting the stump flaps in an anteroposterior direction, closing the peritoneum over it, and uniting the cut ends of the broad ligaments in the same anteroposterior direction by end-to-end approximation, thus making the ligatures and sutures all extraperitoneal. She made an uneventful recovery, the incision healing by first intention, and left the hospital for her home three weeks after the operation. Upon opening the uterus after its removal, a fetus and placenta, evidently of three months' development, was found in the left side of the uterine cavity; they were in a good state of preservation and there was no odor; the uterine cavity below them had been shut off by the encroachment of the fibroid, and the same pressure had probably caused the death of the fetus.

Exfoliative Dermatitis in the Newborn.—A case of this rare affection (Ritter's disease) is reported by B. M. Baker. As far as he can learn, only seven similar cases have been reported in this country. He gives a general description of the malady based on the literature of the subject, noting that it comes on generally between the second and fifth week of life, and that there has been a mortality of about 50 per cent. Ideas are vague as to etiology and pathology. Ritter himself suggested a pyemic infection, while later writers have referred it to a parasite as yet undiscovered. Baker's own case was a male child, weighing at birth eleven pounds and well developed. There was a fungoid base left where the umbilical stump came away, but this healed up without incident. On the nineteenth day of life the child became fretful, face swelled and was reddened; later the erythema involved the body; temperature was normal and the face began to crack, wrinkle, and exfoliate. On the extremities were a few large irregular bullæ containing seropus, which dried up and exfoliated. The erythema referred to finally affected the entire skin, which in turn exfoliated. In about a week the skin had cleaned off. Treatment consisted in the free use of bland soap and local use of a weak carbonized sweet oil. Forced feeding and a little alcoholic stimulation were needed for a little time. Gonococcus infection was excluded, but no further bacteriological examination was made, nor was there a search for the mycelia—supposed by some to be the cause of the affection.

Abuse of Ether in Abdominal Surgery.—J. W. Kennedy describes the methods followed in administering ether in the hospital of Joseph Price of Philadelphia. Nurses and attendants are forbidden to discuss the subject with the patient. The etherizer gives a few reassuring suggestions as he begins his work. A gauze towel one yard square, folded to make a pad nine inches square, is used for the ether, which is fed, as it were, to the patient by the drop method Care is taken not to crowd it before the special senses are benumbed. It is the rule to place the gauze (tent-shape) over the patient's face, the thumb and index finger controlling the gauze, the remainder of the hand splinting the lower jaw to the upper. Allow your patient to take a few breaths before any ether is put on the gauze. Kennedy believes this a better plan than to start with ether on gauze, held some distance from the face. These are small but important factors in a peaceful etherization. Do not, he says, interpose gauze between the

patient's chin and the hand that is supporting the jaw. The gauze may become saturated and give the patient an ugly burn. Begin the anesthetic by putting one drop on gauze and give the ether continuously, increasing progressively. The patient can take more ether the second minute than he can the first, so why not feed it to him as he breathes? In the last two thousand administrations in the hospital named, the average amount of ether used has been about four and a half ounces; time for inducing surgical anesthesia has varied from four to six minutes. The preceding use of the lighter anesthetics is condemned, as is also the change of anesthetizer during a given operation. The Trendelenburg position is never employed. In an operation of ordinary length, from two-thirds to three-fourths of the amount of ether given will be taken before the patient reaches the surgical anesthetic, very little being required after this stage. If at the outset the patient seems unable to take a deep breath, one or two breaths of fresh air are given.

Journal of the American Medical Association, June 16, 1906.

The Assault on Tropical Diseases.—L. F. Barker notes the increasing interest in tropical medicine at the present time, as shown by the establishment of institutions for the special study of diseases peculiar to the tropics and of expeditions and commissions for the study of special disorders. In England there are two institutions for this purpose, and similar establishments exist in Germany and France. This country has thus far established but one laboratory for this study, that at Manila. Nevertheless American physicians have contributed very important additions to the knowledge of the subject. Among the special diseases mentioned as subjects of study at the present time are bubonic plague, dengue, yellow fever, Malta fever, malaria, beriberi, uncinariasis, and sleeping sickness. The records of the last few years show that in this country we are alive to the importance of this line of research, but still more is called for.

Bennett's Fracture.—R. Russ calls attention to this fracture, which he believes to be the most common as well as the most important one of the metacarpal bones. It consists, as Bennett has pointed out, in an oblique fracture of the base of the first metacarpal bone in which the palmar half or more of the surface articulating with the trapezium is detached and the shaft of the bone slips upward and backward past this detached fragment simulating a backward dislocation of the thumb. Russ reports eight cases, all observed during the past year, and mostly in the surgical dispensary of the University of California. With this increase of these cases there has been a marked decrease of the diagnoses of thumb sprains and metacarpo-trapezial subluxations. The diagnosis is sometimes very difficult, hence the general impression that this fracture is rare. The first attention may be called to it by a radiogram. Russ discusses the mechanism and reports his cases in detail. In all cases the fracture resulted from a considerable force, usually applied on the distal end of the metacarpal bone, though in one case it was due to injury inflicted on the palmar surface. The diagnosis between this fracture and backward subluxation is important, and Bennett has claimed that a permanent partial displacement is impossible. Russ shows, however, by a case here reported, which illustrates the differential diagnosis, that it does occur. In obscure cases the *x*-ray must be resorted to, but he thinks that, ordinarily, the diagnosis can be made if care and pains are taken.

Vitreous Opacities in Young Girls.—C. J. Kipp quotes Hirschberg's reference in regard to certain enigmatical white tissue formations in the lower anterior portion of the vitreous body in girls and young women. Two cases are reported in which only one eye was affected, and Kipp remarks that such cases are probably not uncommon and have doubtless been observed by most ophthalmologists. He reports a third case, however, in which the condition, coming on during good health, was extensive in both eyes, causing practical blindness for a time. The opacities, however, gradually disappeared and vision was restored, though latterly cataractous symptoms have intervened in from 20 to 25 years after the first condition was observed. Kipp thinks that there were probably hemorrhagic effusions in the vitreous from the ciliary body antedating the opacities. The condition in this case so closely resembled retinal detachment as to deceive an experienced specialist. The participation of the choroid in the morbid process was shown by the appearance of an atrophic spot.

Pretuberculous Conditions.—R. R. Shurly believes that the pretuberculous stage of phthisis, as we now classify it, is in the vast majority of cases only a latent unrecognized tuberculosis and that the development of the *Bacillus tuberculosis* is in many a problem of cell nutrition, the biochemical phenomena of which are not understood. Sharp lines of demarkation between the pretuberculous and incipient stages cannot be drawn. Among the leading symptoms of the former he lays stress on a progressive loss of weight accompanied with general malaise and sometimes also acceleration of pulse. When these symptoms are present, without other definite signs, and acute and chronic diseases can be excluded, a true latent tuberculosis exists. Chest measurements and vital capacity should then be carefully tested and the conditions of lymphatism and digestive disturbances which may exist, be looked for. He specially calls attention to the relation of the chloroanemias to the development of phthisis. The constant association of anemic blood change with imperfect chest development and progressive loss of weight is very noticeable, the hemoglobin is diminished out of all proportion to the loss of red cells. A recognition of this sign as frequently only the initial evidence of a slumbering tuberculosis would prompt the recourse to the hygienic and medicinal measures that would produce a complete recovery. Shurly recommends in these cases the hypodermic administration of iron and arsenic, the former in the form of the green ammoniated citrate in doses of from .05 to 1 gram and of arsenate of sodium, .001 to .002 gram. The good effects are quickly manifested and an increase of 5 to 10 per cent. hemoglobin a week can be expected. He likewise calls attention to two prominent characteristics of the pulse in the pretuberculous stage; the slight variation on change of position noted by Wells and Loomis, and the relative feebleness of arterial pressure.

The Lancet, June 2, 1906.

Primary Malignant Disease of the Vermiform Appendix.—H. D. Rolleston and L. Jones have been able to collect records of sixty-two supposed examples of this localization, including one hitherto unpublished, and their paper, which closes with a complete bibliography, is an analysis of these records. For various reasons they exclude twenty cases as not conclusive. Of the remaining forty-two, thirty-seven were diagnosticated as carcinoma, three as endothelioma, and two as sarcoma. The age limits were twelve and eighty-one years. In only five of the forty-two were secondary growths recorded. In thirty-three, in which exact situation is given, nearly one-half were localized in the distal third of the appendix. The authors find it impossible to build up a clinical syndrome, and, in fact, as far as they can learn, a correct diagnosis has never been made before operating. Symptoms were variously referred to the female pelvic viscera, fistula following iliac abscess and acute appendical attacks. Of the latter (twenty-seven) symptoms of the first acute attack accounted for ten cases; chronic symptoms with an acute attack, three cases; recurrent attacks, nine cases, and chronic appendicitis, five cases. The growth, it appears, may be either the cause or the effect of the changes producing the symptoms, and may give rise to the symptoms of appendicitis; it is probably the cause in those cases with an apparently acute onset, or in which the symptoms, having been chronic, the growth is the main feature of the appendix. It is probably the outcome of chronic irritation in those cases of obliterating appendicitis in which the growth is recognized by the microscope only. The extent of the operation called for rarely exceeded the simple removal of the appendix. The results of operation were surprisingly good. There were four deaths within two weeks of operation. Of twenty-nine patients who recovered, one died four months later after operation to relieve obstruction caused by a band in the right iliac fossa, but there was no recurrence of malignancy. None of the others presented any suggestion of recurrence.

The X-Ray Diagnosis of Kidney Stones.—C. T. Holland refers to his previous paper on this topic published some two and a half years ago, and makes some observations suggested by his experience since that time. His present views are summarized in the following propositions: (1) When a stone or stones are present in such size as to produce symptoms suggesting the desirability of operation, if a careful and thorough examination is made such stone or stones can nearly always be shown by *x*-rays. And this would also apply to the presence of stone even if the symptoms alone were not sufficient to demand operation. (2) In most cases where shadows are shown the size, shape, and position can be relied upon in diagnosing them as from kidney or ureteral stones. In other cases when doubt may arise as to the cause of the shadows, the experience of the examiner will often settle the matter, and in some cases stereoscopic radiography, the use of ureteral bougies, etc., can be used as a help. (3) The negative diagnosis can be relied upon only when the whole region on both sides is carefully examined and when the plates are taken under the essential condition for successful examination and when they are of the necessary quality in showing sufficient differentiation of the soft structures in the kidney and ureteral regions. (4) There can be no

justification for operation or prolonged medical treatment without an efficient *x*-ray examination being made.

British Medical Journal, June 2, 1906.

The Pathology of the Thyroid Gland.—Kocher makes the following classifications: (1) Vascular goiter. (2) Colloid changes. (3) Typical Graves' disease. He declares that the latter means a thyrotoxic affection in opposition to cachexia thyreopriva. He considers the question whether the functional disorder consists in a perverse activity of the gland in the sense of dysthyrosis or in a simple exaggeration of the normal function—hyperthyrosis—as still open to discussion. From examination of specimens of true Graves' thyroid and the colloidal form, Kocher inclines to the view that the histological changes noted in the former justify us in thinking of an increased or altered activity of its parenchyma and secreting cells. A second evidence in favor of the increased activity of the gland is the constant swelling of the lymphatic glands in the neighborhood of the thyroid in severe Graves' casse, and the changes which may be traced in the composition of its blood. Lymphocytes increase up to even 60 per cent. of the white cells, though as a rule the proportion is from 30 to 40 per cent. Among the lymphocytes are found many atypical forms with large nuclei and greater quantity of protoplasm. Moreover, there is a lessened iodine content in the Graves' thyroid. Hence arise the good results from ligation of the arteries going to the thyroid whereby its activity is diminished. There is a parallelism between the degree of diminution of marked symptoms and the amount of thyroid tissue deprived of its blood supply and removed, and this parallelism seems to prove that the abnormally increased activity of the gland throws some poisonous substance into the circulation; but the question still remains open whether it is exclusively the excess of the normal secretion which exerts that poisonous influence on the nervous, and especially the sympathetic, system, or whether it is that some abnormality of the secretion plays a certain part. In favor of the theory of pure hyperthyrosis it may be added that the administration of extracts of the normal gland gives rise to the same symptoms as Basedowian goiter. In regard to the value of operation, we are conditioned by the fact that undoubtedly the first change is in the nervous system in many cases; in others the disease dates from an acute infection. Prolonged or sudden nervous exhaustion is frequently the cause of the appearance of the first symptoms, and it is probable that a suddenly increased metabolism in the nervous tissue brings toxic substances through the circulation to the thyroid gland, and gives rise to irritation and reaction, causing increased activity of the parenchyma. This influence must never be forgotten, and has its share in affording indications for treatment. We must in these particular cases do everything to diminish influences tending to exhaust the nervous system, and, above all, keep the patient perfectly quiet in every way for a long time. At the same time we may try to compensate the loss of phosphates accompanying nervous disorders by the administration of phosphates, one of the best treatments for Basedow's disease. In addition, a well-chosen diet and good food are necessary. On the other hand, it is important not to delay the operation so long that it becomes a danger to life. Kocher has lost only three patients out of his last 1,000 operated on for ordinary goiter (excluding malignancy), but has lost nine out of 175 operated on for Graves' disease. It is important not to wait until organic changes have been set up in the cardiac muscle.

The Dystrophy of Tabes and the Problem of Trophic Nerves.—W. R. Gowers declares that progressive research has afforded no direct evidence of the existence of special trophic nerves and centers. The theory still lingers, but is not supported by conclusive evidence. He describes the changes occurring in the typical knee, ankle, and tarsal affections of tabes. If we scrutinize the conditions under which these local dystrophies occur, we shall find, says the author, that there is always some impairment of the nerves of ordinary function, the nerves of motion and sensation. In muscular athropy the motor nerves have suffered. In tabes we usually have clear evidence of an affection of the sensory nerves on the defective perception of pain in the skin; the slightness of pain in the affected joints shows always that the deeper nerves have also suffered. Similar lessons are taught by the corneal changes. Thus the only certain element in tabes which we can associate with its dystrophy is the altered state of nutrition of the sensory nerves. The only mechanism for the perverted nutrition we can conceive which harmonizes with other known facts is that this determines an alteration in the processes of nutrition, disturbing that which is primarily due to the vitality of the tissues themselves. It induces a derangement which, once set up, continues and increases. In all cases of tabes there is reason to believe there are such changes in the deeper nerves, and it is very rare to meet with a case of pronounced arthropathy in which they are not evident in the cutaneous nerves. The results of these sensory disturbances may seem to us to be very surprising. So also the effect of slight traumatic influences, in affording the opportunity for derangement of nutrition, may also be variable, and the peculiar distribution of the arthropathy is strong evidence of the frequency of such an excitant, even when unnoted. A local cause is suggested by the fact that usually only one joint is affected, and seldom more than two. It is also possible that rarely a true rheumatic affection may be the excitant. An inflammatory process, however excited, may be, as it were, misguided by the influence of the impaired nutrition of the nerves. Once excited and thus perverted, it progresses, in morbid form, growing more and more until the results seem surprisingly great. One reason why these cases progress to the extent we find is the fact that the absence of pain does not call attention to the lesion. Gowers believes that tabetic arthropathy would often be arrested if wisely dealt with in its early stages. He believes that most cases begin as a slight acute process whether due to a traumatic influence or not, and much may be done to promote its subsidence by rest and the measures suited to any acute arthritis; but these measures are scarcely ever adopted or thought of. The malady is painless, and scarcely attracts even the patient's notice until enlargement becomes obtrusive. Then, too often tissue changes are established which have a tendency not only to persist but to spread. If considerable effusion is the chief element, it may need aspiration followed by elastic compression, which, even alone, has often a great influence on such cases. The conditions which would not prevent the recovery of a joint with normal nerves may be persistently harmful to one that is inflamed, however slightly, in a subject of tabes. The absence of pain permits the perpetuation of harm, and is to us a grave misfortune. With pain to emphasize our advice we can often secure rest when it is needed; without it, we too often fail. It is seldom recognized how good a friend pain may be to those who suffer it.

Berliner klinische Wochenschrift, May 28, 1906.

Pyuria Through Leucocytosis.—Talma says that it is possible for pyemia to exist as a true infection of the blood without any demonstrable portal of entry of the invading organisms, in other words, as what is commonly called a cryptogenetic pyemia. He states that there is nothing remarkable about the conception of such cryptogenetic infections, for pneumococci, for example, may be found transported by the blood stream to almost any part of the body without the development of pneumonia, and streptococci may give rise to septicemia without localized suppuration. He describes two cases of pyuria in which he considers that the kidneys served as excretory organs for the pus present in the blood without themselves being the seat of an actual suppurative inflammation. Examination of the urine in these cases showed that not only pus cells but also pus serum had passed through the kidneys. In the one case examination of the blood showed 43,000 leucocytes with 94.4 per cent. of polynuclears, and in the other there were 17,000 leucocytes with 79 per cent. of polynuclears.

The Demonstration of the Precipitin of Cow's Milk in the Blood of Marantic Children.—Bauer states that ordinarily the precipitins of milk are destroyed through the activity of the gastric and intestinal ferments, and that in this way the transmission of unchanged foreign albumin into the circulation and organs is prevented. Only if the foreign albumin is administered in excess can it be demonstrated in the body of the overfed animal, the fermentative powers evidently not being quantitatively adequate for the task. It therefore seems possible that in gastrointestinal diseases the impairment of the digestive powers might permit albumin to pass into the blood, and this condition might be conceived as being present in cases of infantile marasmus. Attempts to demonstrate the precipitin of cow's milk in the blood of infants are unsatisfactory owing to the technical difficulties involved, and the author resorted to Moreschi's method of deviation of the complement in order to carry out the reaction. In this way he was able in a child dying of marasmus to show the presence of cow's milk precipitin in the blood, and he suggests that the clinical manifestations of the condition may depend on the toxic effect of this foreign albumin circulating in the blood.

Münchener medizinische Wochenschrift, May 29, 1906.

The Cultivation of the Typhoid Bacilli from the Blood.—Fernet recommends the following procedure, by means of which he says that typhoid bacilli may be detected in small quantities of blood early in the disease and at a time when cultures from the stools and the Widal reaction are still negative. The procedure is based on the

enriching properties of bile as a culture medium, and it is carried out as follows: Ox bile, which may be readily obtained in any slaughter house, is placed in test tubes of which each receives about 5 c.c. of the fluid. The tubes are plugged with cotton and are sterilized for one half hour in the steam sterilizer or in boiling water. The tubes are then kept cool and used as required. The blood clot resulting from the coagulation of specimens submitted for the Widal reaction is added to one of the bile tubes and is allowed to stand overnight in the incubator. In making the plates care is taken to secure the upper layers of the fluid in the tube which are removed with a loop, about 0.5 c.c. in all being used, and the material is spread on the surface of a large Drigalski-Conradi plate by means of a glass spatula in the usual way. While this method is not intended to replace the other procedures, it is of use when it is impossible to collect the blood directly in the bile tubes, or when only very small quantities of blood are available, as 0.25 c.c. can be used with satisfactory results.

A Case of Cesarean Section for Intestinal Obstruction.—Martin describes this case, which was that of a woman of thirty-four years who had had a laparotomy done five years previously for the removal of a large fibroid tumor of the uterus. She had suffered from persistent constipation, vomiting, and abdominal colic during two subsequent pregnancies, which had terminated in the seventh and eighth months respectively. When she was seen by the author she was about at full term, and presented symptoms pointing toward intestinal obstruction from adhesions and peritonitis. On opening the abdomen a considerable amount of yellow fluid was evacuated and it was seen that the small intestine was adherent to the posterior surface of the uterus over a considerable area, the loop of gut being also twisted about its axis, 180 degrees, and its mesentery being tightly stretched so as to serve as an additional constricting band. On liberating the sharply angulated loop of intestine the uterine wound thus made bled freely so that on this account, as well as owing to the fact that the patient's poor condition made a prompt termination of the pregnancy seem desirable, cesarean section was performed in the usual way. The abdomen was closed without drainage, and mother and child made a good recovery. The author ascribes the symptoms noted during the former pregnancies to the same cause.

The History of Spinal Anesthesia.—Bier considers Corning's claims to priority in the matter of spinal anesthesia and endeavors to show that although the American author had described the injection of cocaine solution into the spinal canal years before Bier himself had issued his first publication on the subject, Corning should not be regarded as the originator of the method since he himself had not realized the significance or the possibilities of the procedure and did not induce surgeons to take it up as a practical method. Bier accordingly criticises those American and Continental authors who acknowledge Corning as the originator of spinal anesthesia, and quotes a number of European authorities who give Bier the credit for having placed the procedure on a practical basis.

Deutsche medizinische Wochenschrift, May 31, 1906.

The Value of Sahli's Desmoid Reaction.—Alexander and Schlesinger describe the results obtained in making a study of the value of Sahli's desmoid reaction. This consists in giving the patient small rubber bags tied up with catgut and containing methylene blue, iodoform, or some other substance whose absorption can be readily demonstrated in the excretions. According to Sahli raw catgut can be digested only in the stomach and only in the presence of free hydrochloric acid. The authors describe the results of forty-eight observations which lead them to the conclusion that the Sahli method is thoroughly unreliable and cannot, as Sahli claimed for it, be regarded as a satisfactory substitute for the use of the stomach tube in cases in which the introduction of the instrument is for some reason contraindicated. Not only were great irregularities and inconsistencies shown in the appearance of the test reagents, both in normal and abnormal stomachs, but experiments on patients with gastric fistulæ showed that contrary to Sahli's statement catgut was digested in the stomach in the absence of free hydrochloric acid, so that the underlying principle of the method appears to be fallacious.

A Case of Extrauterine Pregnancy Operated on at Full Term.—Seelgmann says that although cases of extrauterine pregnancy that have gone on to quite or nearly the full term of gestation present what are perhaps the greatest operative difficulties on gynecological surgery, so that many authors recommend an expectant plan of treatment in the hope that the fetus may become transformed into a lithopedion, he considers that operation as soon as the diagnosis is made is the preferable course of procedure. The statistics collected by Schauta show that out of 241 cases of this sort lithopedion formation without symptoms took place only nine times. It is the management of the placental site and the hemorrhage from it that causes the difficulties in such cases, and these may tax the resources of the surgeon to the utmost. In the case that he operated on himself the placenta was situated on the lower surface of the liver, gall-bladder, and parietal peritoneum of the right hypocrondrium. On attempting to remove it the hemorrhage was so severe as to necessitate immediate packing of the entire amniotic cavity. The placenta was removed in portions at several subsequent operations, the large wound cavity being drained in the meanwhile. Six weeks after the operation the patient was discharged cured.

Is the Injection Treatment of Acute Gonorrhea Rational?—Canon of Berlin has come to the conclusion that the injection treatment of gonorrhea as ordinarily practised frequently causes damage, is not well advised, and can be dispensed with. The passage of gonococci from the urethra into the blood stream is facilitated by the application of caustic or irritating substances to the urethra, while antiseptics have but little power over organisms concealed in the lower epithelial layers. The author considers that under proper management the general powers of resistance are adequate to combat the infection without the use of local applications during the acute stage. The administration of suitable remedies intended to be excreted through the kidneys is advisable, as is also the often neglected admonition to the patient to take large quantities of fluid in order that the urethra may be flushed as thoroughly as possible.

French and Italian Journals.

Origin of Mucus Found in the Feces in the Course of Enteritis.—Jean-Ch. Roux and A. Riva have recently investigated this question. Many authorities have thought that the mucus found in the feces originates almost exclusively in the large intestine. The mucus from the small intestine rapidly separates, appearing in the feces only if the evacuation from the intestine is extremely rapid. In such a case it will appear under the form of very small fragments of hyaline mucus, colored by bile. Roux and Riva, in order to clear up this question, undertook a series of experiments. They provoked an enteritis in the small intestine of the dog, and then established a jejunal fistula. They injected a solution of silver nitrate, which was left in contact with the mucosa for several minutes. The silver nitrate was then precipitated by a weak solution of sodium chloride. On the day following they always observed in the feces, which were loose, many small fragments of hyaline mucus which was in the form of flakes. This mucus was not colored by bile. At the end of forty-eight hours the feces, having become normal, contained no trace of mucus. These experiments prove that in the course of enteritis there may exist in the feces hyaline mucus which comes from the small intestine and which does not differ from the mucus in the colon.—*Le Bulletin Médical*, April 21, 1906.

The Advantages of Mixed Narcosis.—O. Dauwe declares that either ether or chloroform in producing anesthesia gives rise to a disturbance of the general condition, a veritable poisoning of the organism. Statistics testify to a certain number of deaths due to the action of both of these anesthetics. Careful experiment, as well as clinical experience, teaches that the mixture of these two anesthetics is more advantageous than either one by itself. The small drop-bottle should be used for administering this mixture, which seems to be best made by adding one part of chloroform to nine parts of ether. By the use of the mixture of these anesthetics the period of excitation is reduced, the frequency of syncope is diminished, and postoperative malaise is decreased.—*Gazette des Hôpitaux Civils et Militaires*, April 26, 1906.

Epidural Injections.—Buzi Emilio recommends the use of the epidural injections of Cathelin in various painful affections, especially in sciatica. He has treated eight cases in all, most of them affected by sciatica, and all these cases have had an undoubted cure, even in well-established conditions. The injection is made into the epidural space, between the dura mater of the cauda equina and the periostium. This space reaches above to the occipital foramen, and at its deepest portion is in contact with the sacral canal, and is filled with cellular tissue. The liquid does not penetrate the subdural and subarachnoid spaces, and hence any poisonous effects from the drugs used is avoided. The author used as injection fluid of 1 per cent. solution of cocaine, or normal salt solution. He does not believe that the cure results from the anesthetic effect of the cocaine, because pain did not cease immediately, but after several days. He used it with some success in incontinence of urine, where he ascribes the effect to shock from the mechanical effect on the cauda equina.—*Il Policlinico*, April, 1906.

Book Reviews.

Uric Acid. The Chemistry, Physiology, and Pathology of Uric Acid and the Physiologically Important Purin Bodies. With a Discussion of Metabolism in Gout. By Francis H. McCrudden. Boston: The Fort Hill Press.

The increasing complexity revealed by each advance in the domain of the chemistry of metabolism has made it highly desirable that some plain-spoken iconoclast should clarify our conceptions of certain problems by setting forth clearly just how much we really do know and how much is pure theory. The author of this monograph has performed this task in masterly fashion for the question of uric acid, and his clear exposition of the facts as already ascertained should make his work of value to subsequent investigators by enabling them to take a fresh point of departure and proceed with their studies unhampered by the mass of useless lumber which has accumulated in the literature of the subject. The practitioner will doubtless be dismayed by the destructive character of the book, and it will be painful to him to find many cherished notions such as the existence of a quadriurate in gouty blood, Haig's plausible theories, the value of alkaline therapy in gout, the view that uric acid is a precursor of urea in the breaking down of proteid, etc., thrown bodily out of doors. It is also disappointing to find that in spite of the enormous amount of labor that has been expended on the study of gout, the author's own researches as well as his sifting of the voluminous literature lead only to the admission that, although we know that in gout there is uric acid in solution in the blood and that there are urate concretions in the joints, we do not know which of these conditions is cause and which is effect, and we are not even sure that they are related in this way at all. The available data are still inadequate to explain either the cause of gout, the etiology of the acute attack, or the formation of the concretions. To disprove old errors is perhaps even more valuable than to present new facts, and a perusal of this important work cannot be too warmly urged on all interested in the subject.

On Professional Education, with Special Reference to Medicine. An Address Delivered at King's College, London, on October 3, 1905. By T. Clifford Allbutt, M.A., M.D., F.R.S., Hon. D.Sc. Oxon., etc., etc.; Regius Professor of Physics in the University of Cambridge. London and New York: The Macmillan Company, 1906.

Anything from the pen of Professor Allbutt is sure to be not only worth reading, but also entertaining reading. The present address is no exception, and it should be carefully studied by all interested in the subject of medical education. Among the more important of the topics discussed are: Education and instruction, specialization, maintenance of standards, university education, the medical curriculum, graduate work, examinations, research, clinical instruction, the outlook of modern science, and education and ethics. The Regius Professor at Cambridge has his own views on many of the questions of the day; and he has the following to say on a subject that was quite lately exploited by the now Regius Professor at Oxford from the opposite viewpoint: "I opine that no teacher reaches his best till middle life. Not till then does he gather the fruits of experience, or attain to a rich and vital sense of our ignorance; not till then does he wholly escape from formula and routine; not till then does he learn what to leave unsaid; then it is that erudition and experience mellow into wisdom." The above eminently sane and seasonable statement will give our readers a fair idea of the style of this interesting book.

Gynæcological Diagnosis; a Manual for Students and Practitioners. By Arthur E. Giles, M.D., B.Sc., Lond.; F.R.C.S., Ed.; M.R.C.P., Lond.; Gynæcologist to the Tottenham Hospital; Surgeon to the Outpatients, Chelsea Hospital for Women. With Thirty-five Original Illustrations. New York: William Wood and Company, 1906.

The plan of the present work is to start from the various symptoms as they are given by the patient, and to pass on systematically from these symptoms through physical signs to a diagnosis. In the first part are discussed general considerations, such as case-taking, methods of examination, the use of instruments for examination, the significance of symptoms, and the interpretation of physical signs. The second part takes up in turn each of the symptoms, and shows by methods of grouping and of exclusion how a diagnosis may be reached. The author recognizes the fact that a positive diagnosis is often difficult and sometimes impossible, and also that it is only the young and inexperienced who can invariably make a positive and dogmatic diagnosis. There is a separate chapter on each of the following symptoms: Amenorrhea, pain, hemorrhage, discharge, pruritus, dyspareunia, sterility, repeated abortions, bearing down, bowel and bladder disturbances, swelling of the abdomen or of the vulva. At the end of each chapter is a tabular summary of its contents. The book is written by a master of his subject, hence it is authoritative; at the same time it is practical and useful. The general practitioner will find this little volume a capital investment; from a monetary standpoint alone each chapter will be worth more than the price of the book, and the educational value far exceeds that of many larger and more pretentious volumes.

Case Teaching in Medicine. A Series of Graduated Exercises in the Differential Diagnosis, Prognosis, and Treatment of Actual Cases of Disease. By Richard C. Cabot, A.B., M.D., Instructor in Medicine in the Harvard Medical School, and Physician to the Outpatients at the Massachusetts General Hospital. Boston: D. C. Heath & Co., 1906.

In this volume the author presents a very ingenious and serviceable suggestion for facilitating instruction in medicine, together with the means for carrying it into effect. The book consists of a series of seventy-eight case histories, with a concise account of the physical signs present, in a very extensive variety of diseases. Appended to each of these are a few paragraphs which are suggestive rather than didactic, and are intended to point out the manner in which the teacher may profitably use the case in question as a text for discussion. Finally, the diagnosis, treatment, and ultimate outcome of the case are given. The method suggested for the use of the book is to have the instructor read the case history to his class, each member of which must then write on a slip of paper his diagnosis. The case is then discussed, possibilities and probabilities are suggested by the teacher, and finally the correct diagnosis is announced. The plan is one that has a great deal to commend it, and instruction along some such method should be very valuable in impressing on students that the ability correctly to elicit a few physical signs is not diagnosis, but that the latter is a process of pure reasoning, a lesson that is usually not learned until late in the undergraduate course. The cases described here are all interesting paradigms, some of them of rare diseases, but for the most part representing conditions that are constantly being encountered in actual work. Both the book and the pedagogic method on which it is based may be most warmly commended to all instructors in medicine, while even the practitioner may find it stimulating to see how many of these clinical problems he can solve without looking at the "answer."

Diseases of the Eye. A Handbook of Ophthalmic Practice. By G. E. de Schweinitz, M.D., Professor of Ophthalmology in the University of Pennsylvania. Fifth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders Company, 1906.

The fifth edition of de Schweinitz's work is presented in a volume of 894 pages. The style is similar to that of the previous editions. In this edition paragraphs on the following subjects appear for the first time: "Solid Edema of the Eyelids," "Noma of the Eyelids," Blastomychosis of the Eyelids," "Herpes Facialis of the Eyelids," "X-Ray Treatment of Epithelioma," "Xeroderma Pigmentosum," "Influenza Bacillus Conjunctivitis," Catarrhal Epidemic Conjunctivitis," "Purulent Conjunctivitis in Young Girls," "Non-specific Purulent Conjunctivitis," "Jequiritol and Jequirirol Serum," "X-Ray Treatment of Trachoma," "Conjunctivitis Nodosa," "Serum Treatment of Infected Corneal Ulcers," "Infected Marginal Ulcer (Zur Nedden)," "Keratitis Marginalis Superficialis (Fuchs)," "Keratitis Punctata Syphilitica (Mauthner)," Peripheral Annular Infiltration of the Cornea," "Annular Scleritis," "Uveitis and Its Varieties," "Circumscribed Plastic Choroiditis," "Fatigue Contractions of the Visual Field," "Eye-ground Lesions of Hereditary Syphilis," "Macular Atrophy of the Retina," "Congenital Color-blindness," "Congenital Word-blindness," "Methyl-alcohol Blindness," "Training of the Fusion-sense with Worth's Amblyoscope," "Stovain, Alypin," "Motais's Operation for Ptosis," "Kuhnt-Müller's Operation for Ectropion." The volume is fully illustrated, 33 cuts in the text having been added in this edition. De Schweinitz's "Diseases of the Eye" is so well and so favorably known that little need be said regarding it. It is a standard work, valuable alike to student, general practitioner, and ophthalmologist. The admirable index enables one to find just what is wanted without loss of time, and the information supplied is reliable and up to date.

The International Medical Annual for 1906; a Year Book of Treatment and Practitioner's Index. By Various Contributors. Twenty-fourth year. New York: E. B. Treat & Co., 1906.

This annual makes an attractive volume of handy size. Among the features that have most appealed to us are, the general dictionary arrangement, the complete index, and the references to the literature of the topics under discussion; all of which add to the value of a book of this sort. The subject matter is well and concisely presented, and the illustrations and general make-up of the book are good.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Annual Meeting Held in Washington, May 15 and 16, 1906.

(Special Report to the MEDICAL RECORD.)

DR. FRANK BILLINGS OF CHICAGO IN THE CHAIR.

(*Continued from page 899.*)

Some Dangers of Thoracentesis with Special Reference to Pneumothorax.—Dr. GEORGE G. SEARS of Boston considered the danger of sudden death to reside in two causes, viz., exploratory puncture and pneumothorax, and related some cases in support of this.

Dr. HENRY KOPLIK of New York said that in children air was not well absorbed and in cases of pneumothorax he advocated opening the chest as soon as possible and evacuating the contents.

Dr. E. G. JANEWAY of New York said that this danger of pneumothorax following paracentesis was more common than generally supposed.

Dr. T. B. FUTCHER of Baltimore said that pneumothorax should be recognized as one of the dangers attending aspiration of the chest. He said that Emerson had reported 49 cases in Osler's wards and in 11 this condition was due to paracentesis for exploration of chest.

Dr. SHATTUCK of Boston reported a case of pneumothorax caused by the aspirating pump working the wrong way.

Dr. S. J. MELTZER said that in those cases of sudden death one had to deal in many cases with an air embolus. He said that air was always easily absorbed from the pleural cavity.

Therapeutic Principles Based upon Pathological Physiology.—Dr. RICHARD C. CABOT of Boston said that pathological physiology was the effort of nature to react against the cause of disease, such as leucocytosis, fever, hyperemia. The treatment based upon pathological physiology had three aims, as follows: *a.* Examples of treatment aiming to imitate or supplement pathological physiology—(1) Antitoxic or antibacterial sera, (2) removal of gangrenous appendix, (3) removal of hidden sorrow (Freund's psychoanalysis), (4) bed (only asthenic conditions), (5) diet in fevers, (6) washing products of stasis out of stomach, (7) purgation in acute fermentative diarrhea, (8) setting of a broken bone, (9) passive hyperemia (Bier's method), (10) active and passive exercise. *b.* Exology—(1) Forced feeding in Graves' disease and in phthisis, (2) restraining a dangerous delirious patient, (3) the use of enemata and laxatives, (4) massage and passive motion for adhesions and contractions, (5) counterirritation, (6) massage after a sprain, (7) exercise and diet in obesity, (8) alkalis in diabetes, (9) dilatation of strictures of any kind, (10) climatic treatment of Raynaud's disease. *c.* Examples of treatment intended to modify, divert, or limit pathological physiology—(1) Sitting up with a "jumping" toothache, (2) diverting thought from self by occupation in psychosthenia, (3) opium towards the end of a dyspeptic diarrhea, (4) bathing in typhoid fever, (5) diet in diabetes, (6) reeducation in tabes dorsalis, (7) education on neurasthenia, (8) *x*-ray treatment in leukemia. Treatment based on pathological physiology was not the best type of therapeutics yet worked out; neither was it the worst. It occupied a position intermediate in value and efficacy between etiological treatment (which removed the cause of disease) and symptomatic treatment (which simply smothers the symptoms). It was based on the theories of the nature and trend of the body's reactions against the *materies morbi*, theories which, like all hypotheses, might lead to disaster unless constantly and empirically verified. Empiricism therefore was an essential element in every type of treatment, not a separate type coördinate with the other three types mentioned. Theory was nevertheless invaluable because it furnished the motive power of scientific progress; empirical verification guided, but did not initiate this progress. Treatment which aimed to remove the nonhuman causes of disease should neglect very largely the individual or human factors in the case; but treatment based on pathological psysiology could be effective only by ascertaining the physical and psychical peculiarities of each individual, and the unequal relations in which he stands to his family, his work, his education, his place of residence, and many other aspects of his environment. Etiological or symptomatic treatment must ask: Where is the disease? At what spot in the organism does it reside? To what spot does it direct remedial energies? Treatment based on the individual's manner of reacting to disease, he said, studied no single organ or region, but attempted to estimate functions and to estimate the whole individual so far as it could discover him.

The Pathological Physiology of Chronic Arterial Hypertension and Its Treatment.—Dr. THEODORE C. JANEWAY of New York considered hypertension as a striking departure from the physiological norm of the circulation, and, though only a symptom, yet a cause of such important secondary lesions in the heart and vessels, that it deserved independent consideration. It was common in nephritis, especially of the chronic interstitial type, and occurred occasionally in arteriosclerosis. It constituted the chief feature of a clinical group of cases which presented the same cardiovascular lesions as chronic Bright's disease, but no evidence of renal involvement. In an analysis of 130 cases showing a systolic pressure of over 200 mm., 13 per cent. belonged in this category. He discussed the probable physiological mechanism of the production of hypertension in arteriosclerosis, in nephritis, and in cases of unknown origin, and said that, whatever might be the exact mechanism of its production, we could not avoid the conclusion that hypertension expressed an attempt of the organism to maintain an adequate speed of capillary flow through the kidney, or other important organ, which would be impossible without it. While it was a symptom of disease, it was still more truly a proof of the body's defensive reaction against the disease. This conception was the foundation of rational treatment. Persistent high blood pressure was necessarily followed by important changes both in structure and function of the circulatory organs. Besides hypertrophy of the left ventricle and the arterial changes there was a diminishing distensibility of the arteries as the pressure within them arose, causing an increasing systolic elevation of pressure, and suddenness of the pulse wave, which predisposed to rupture at any weakened point. The danger most to be anticipated was insufficiency of the left ventricle, with resulting pulmonary and general venous stasis and their symptoms on the one hand, and inadequate capillary circulation, which intensified the primary trouble, on the other. The therapeutic indications were: (1) Prevention. This was directed toward limiting or ameliorating the primary disease, as the general hygienic management of chronic nephritis. Massage and the iodides belonged in this category. All hypertensive influences must be excluded. (2) Adjuvant Treatment. As a rule, a fall in blood pressure without other evidence of improvement marked the onset of cardiac insufficiency and called for digitalis. The indications for the drug were the same with hypertension as without, and no blood pressure reading should make us hesitate to administer it. Increasing blood pressure would sometimes be the evidence of a winning fight. (3) Emergent Treatment. This included all the means used to forestall or cut short those dramatic moments when life suddenly hangs in the balance. Here the vasodilators find their rational use. Nitroglycerin and other nitrites in attacks of angina and cardiac asthma, venesection and light chloroform narcosis in uremia. The induction of rapid vasodilatation would sometimes stop dangerous nasal hemorrhage. Attacks of edema of the lungs did not admit of simple explanation or routine treatment. The simultaneous use of rapid heart-muscle stimulants and of vasodilators to reduce the demands on the ventricle seemed rational. The hypertensive effect of severe pain made morphine at times a necessary agent.

The Therapeutics of Insufficient Kidney, Based upon Pathological Physiology.—Dr. Robert B. Preble of Chicago said a few words regarding the amount of urine passed in cardiac failure and said that the same care should be utilized regarding the intake of water and saline as in the ordinary cases of nephritis. With a low secretion of urine in infectious diseases there was nothing more important than the free administration of fluids. With regard to the treatment of renal insufficiency one should keep in mind the fact that, so far as clinical manifestations were concerned that were due to toxic bodies, we knew but little about them. There were two objects, first to limit the forming of toxic materials, and, secondly, to favor their excretion. The toxins came either from without or from within and both were under control. One external source was from the gastrointestinal canal; food underwent fermentation and that fermentation supplied toxic bodies. He considered sweating, purgation, and venesection; the latter procedure should be first thought of by the clinician and not delayed too long; it should be the measure first resorted to in these cases.

Therapeutics Based upon the Physiological Principles of Environment in Hospital and Private Practice.—Dr. Walter B. James of New York discussed the place of environment in therapeutics with special reference to the application of fresh air, or of out-door treatment, to other diseases than pulmonary tuberculosis, together with a plea for the more careful consideration of environment in hospital practice. Environment had two sides, the psychical and the physical. What constituted good and bad air, he said, had been under dispute for a long time. The temperature, stillness of the atmosphere, and ventilation had been based upon respiratory needs of the individuals who were expected to inhabit the rooms. No well man would be well off in an even temperature; then why should one expect the sick one to be? During the past year, he said, he had had the ventilating system cut off from one of his large wards and he opened windows and allowed the room temperature to be the same as the outside temperature, and he had seen nothing but good results follow. He asked why it would not be better to take a typhoid patient and subject him to the cold open air all the time than to shock him at intervals by the tub bath. Apply it slowly, but at all times. He referred to Dr. William P. Northrup's experience in treatment of cases in the open air at the Presbyterian Hospital.

The Physiological Principles of Feeding in Typhoid and in Other Fevers.—Dr. Francis P. Kinnicutt of New York offered a digest of metabolism experiments in some of the specific fevers, with a view to determining the value of different kinds of feeding. He also made a study of hospital statistics of typhoid fever, with a view to determining the influence of different diets upon the development of some of the complications. In 733 cases of typhoid fever fed upon a liberal diet there were 48 relapses, or 11.38 per cent.; hemorrhages occurred in 35, or 4.77 per cent.; perforation in 10, or 1.36 per cent.; mortality, 60, or 9.47 per cent. There were 4,277 cases fed upon a fluid diet, with 500 relapses, or 11.69 per cent.; 382 cases had hemorrhage, or 8.93 per cent.; perforation occurred in 104, or 2.43 per cent.; mortality, 457; or 10.68 per cent. It was rather interesting to note the wide range in the death rates from typhoid fever at the Presbyterian Hospital, New York, for the various years, as follows: 1894-1895, 87 cases, 10 deaths, mortality, 11.49 per cent.; 1895-1896, 67 cases, 11 deaths, mortality, 16.41 per cent.; 1896-1897, 67 cases, 4 deaths, mortality, 5.97 per cent.; 1897-1898, 127 cases, 9 deaths, mortality, 7.08 per cent.; 1898-1899, 101 cases, 16 deaths, mortality, 15.84 per cent.; 1899-1900, 150 cases, 23 deaths, mortality, 15.33 per cent.; 1900-1901, 152 cases, 14 deaths, mortality, 9.21 per cent; 1901-1902, 123 cases, 17 deaths, mortality, 13.90 per cent.; 1902-1903, 127 cases, 18 deaths, mortality, 14.17 per cent.; 1903-1904, 138 cases, 16 deaths, mortality, 11.59 per cent.; 1904-1905, 135 cases, 15 deaths, mortality, 11.85 per cent.

The Physiological Limitation of Rectal Feeding.—Dr. D. L. Edsall of Philadelphia gave a review of the experiments relating to rectal feeding, indicating that the most favorable effects to be expected by present methods were far below the nutritional requirements, except in regard to the introduction of water and salts. He discussed the explanation of the rare instances in which rectal feeding appeared to provide sufficient nutrition and also some of the possibilities of improving the methods of rectal feeding. From 150 to 300 calories were probably absorbed in this way, and probably more might be absorbed and the nutritional equilibrium maintained by nutritive enemata. The marked increase in weight following these enemata in disease was probably due to the absorption of the water. Again the ileocecal valve might allow some of the food to pass, and absorption then could take place, but this of course was only under very unusual circumstances. He did not expect or anticipate any great clinical value to be attained from rectal feeding. It could not be made to equal the natural methods of feeding. Present methods might be improved by providing artificially certain substances which the bowel could absorb. At present he found the best absorbed food to be dextrinized carbohydrates. Considerable amounts of dextrose, if acid free, can be absorbed by the large intestines. Some means might be devised by which the ileocecal valve could be made to allow the enemata to pass by.

Dr. W. S. Thayer said that it was important to treat the patient and not the disease, and that the mortality was higher, as a rule, upon a milk than upon a fluid diet. He believed the country doctor showed more wisdom in the treatment of these cases because he was more thrown upon his own resources.

Dr. William H. Thompson of New York regretted that more had not been said regarding the study of the changes occurring in the veins analogous to those occurring in the arteries. This, he believed, would throw more light upon the study than a mere study of the arterial changes. He briefly referred to work he had done in this line.

Dr. Thomas McCrae of Baltimore said that most cases of typhoid would get over their attack regardless of what one gave them; at least 75 or 80 per cent. of them would. But, not knowing who those 75 or 80 per cent. were, one took a certain risk in disregarding the diet.

Dr. H. A. Hare of Philadelphia said that he fed his typhoid fever patients as liberally as possible. During the first ten days they received a milk diet, but so soon as they became adjusted to their environment they were placed on a liberal diet, such as carbohydrates aided by some diastase, etc. He said that when a dog was sick, for several days he hid and ate nothing; he thought the same amount of starvation might very often benefit the typhoid patient. In reference to Dr. Janeway's paper he said there were two sets of cases, those with spasm and those with fibrosis. In the latter the nitrites would do no good whatever; the only drugs which would then be of value were the iodides. In such cases the nitrites gave no headache. He reported one patient with fibrosis who got 1-50 grain of nitroglycerin every hour without the production of any headache.

Dr. S. J. Meltzer of New York said that the instillation of 1-500,000 grain of adrenalin would cause dilatation of the pupil of a frog. He emphasized the employment of kindness in the treatment of patients. A more liberal diet in typhoid fever he believed should be given.

Dr. Shattuck of Boston said he had been using a liberal diet in typhoid fever for over thirteen years, feeding the patients according to their digestive powers.

Dr. Henry Koplik of New York said that he had treated 169 children with typhoid fever during the past five years and the proportion of relapses he found to be above that which occurred in adults. The diet was strictly a fluid one; if the children craved food they got minced food. There were four cases of perforation, and they occurred at a period when they were not on a fluid diet.

The Effects of Aperients on the Peristalsis of the Stomach and Intestines.—Drs. F. Pfaff and L. Nelson

of Boston presented this communication, giving a description of normal peristalsis as observed in the exposed intestines of animals in a salt bath, and a comparison of the results with those obtained from a series of observations of peristalsis in animals made by the *x*-ray. They also gave the effects of certain aperients on peristalsis in the stomach and intestines. Croton oil and aloes contracted the stomach, while podophyllin had very little effect on the stomach waves. Scammony had no effect on stomach, small or large intestines. The effects of rhubarb, cascara, senna, gamboge, jalap, and others were briefly considered. Only three had any effect on the stomach peristalsis, viz., croton oil, aloes, and podophyllin.

Dr. S. J. Meltzer of New York said that with the *x*-ray one was able to see the action only of the bismuth in the canal and not the action of the stomach or intestines. He then referred to some studies he was then engaged in making on the behavior of the cecum in rabbits, the results of which were to be published later.

Dr. H. A. Hare of Philadelphia spoke of the dangers of applying the results of animal experimentation to the human subject. He spoke of the selective action the intestines appeared to have in holding back certain substances and allowing others to pass on.

The Therapeutic Advantages of a Refined and Concentrated Diphtheria Antitoxin.—Dr. William H. Park of New York said that the comparative results in over 1,000 cases of diphtheria in which this refined and concentrated antitoxin was used indicated that the rashes and other deleterious effects occurred much less often and were on the average much less severe. They now saw children with a roseola or urticaria lasting but a few days and then disappearing. What was now being done by the Health Department was the first step in procuring a pure antitoxin.

(To be continued.)

THE AMERICAN THERAPEUTIC SOCIETY

Seventh Annual Meeting Held in New York, May 3, 4, and 5, 1906.

(Special Report to the Medical Record)

Carl Beck, M.D., President, in the Chair.

(*Continued from page 902.*)

SECOND DAY—FRIDAY, MAY 4.

Why the Medical Profession Should Sustain the Pharmacopœia.—Dr. F. E. Stewart of East Orange, N. J., read this paper. The first part of it was devoted to a historical sketch of pharmacy and of the Pharmacopœia. The speaker then went on to say that history shows that pharmacy is naturally a part of medical science and practice, and that the medical profession is responsible for pharmacy both from a scientific and practical standpoint. By relegating the practice of pharmacy to the apothecaries the medical profession had not escaped that responsibility. The medical profession was a privileged class of the community, responsible to the State for the advancement of medical practice, including pharmacy and the maintenance of a pharmacopœia. Thus far, with the exception of a devoted few, the profession had taken very little interest either in pharmacy or the Pharmacopœia. It was time for a change of policy in this matter. Without a pharmacopœia progress in drug-therapeutics was impossible. Common standards for determining the identity, purity, and strength of medicines were necessary to maintain uniformity in them, for in no other way could pharmacy be redeemed from those who were attempting to convert the practice of pharmacy into a commercial business; in no other way could pharmacy be restored to medicine as a branch of medical science and practice. It was not a question of the retail druggist *versus* the manufacturer, as some would have us believe, but a question of pharmacy and the Pharmacopœia *versus* a commercial business carried on under the name of pharmacy by those retail druggists and manufacturing houses alike who conducted their vocation in opposition to scientific and professional requirements.

Dr. Robert Reyburn of Washington, D. C., said that the thanks of the profession were due Dr. Stewart for the arduous work which he had done in behalf of pharmacology and legitimate pharmacy. The medical profession ought to stick to the Pharmacopœia. It was greatly to be regretted that our young graduates did not have a more adequate knowledge of pharmacology and the use of drugs. When they began practice they very easily got into the way of prescribing proprietary medicines. He thought that we should use our influence to have students better instructed and that we ourselves should strictly adhere to official preparations.

The Dietetic Treatment of the Vomiting of Pregnancy.—Dr. L. Kolikinski of Washington, D. C., read this paper. For precision of diagnosis and propriety of treatment he thought that the vomiting should be considered pernicious whenever the loss of strength was sufficient to prevent the patient from leaving her bed. A careful study of the phenomena presented in the condition had led him to discard the treatments hitherto in vogue, and to attempt the plan of a diet comprised of substances limited in number and of such physical structure that, by reason of their density and heaviness, their ejection from the stomach was well nigh impossible. Of proper foods, pork (ham or bacon) was first. A woman who had vomited incessantly for several weeks, who was too feeble to leave her bed, who had received varied and unsuccessful treatment, whose whole appearance was one of alarm, would find to her intense astonishment that the emesis did not occur after a breakfast of fried ham or bacon. She would then find that partaking of other solids improved her condition, and within a few days sleep and strength would have returned. In considering the factors producing this state of quiet, Dr. Kolipinski said, it was apparent that the chief one was the stable tone given to the distressed stomach, much like ballast to a vessel in troubled waters. The cooperation of the patient, due to new confidence and the assurance that her malady could be cured, was also very helpful. The daily breakfast should consist of pork in some form, with corn bread and cocoa or chocolate. At other meals might be taken beefsteak, roast or corned beef, and such vegetables as rice, potatoes, spinach, cauliflower, and turnips. Fish, game, fowl, and cheese were also good articles of diet. Foods which induced vomiting were water, if taken freely, milk, tea, coffee, soups, and fluids in general. The most unstable combination of a diet was toast, eggs, and sweetened tea.

The Medical Treatment of Cancer.—Dr. Robert Reyburn of Washington, D. C., read this paper. Believing that cancer was simply an error of cell development depending upon the retention of waste matter in the system, he would divide the treatment into preventive and curative. Prophylaxis was all-important, and he thought the treatment of cancer might be epitomized by saying that it should be the effort of physicians to endeavor to bring their patients into the highest possible condition of personal health and excellence of hygiene. To him it was lamentable to see the apparent helplessness of most medical men when confronted with a case of cancer. Generally no attempt was made to treat the case by medication or to improve the patient's hygiene, and the sole resource seemed to be the knife, the *x*-ray, or some form of electricity. Valuable as these agents were, it was his firm conviction that our success would be far greater if we would conjoin them with appropriate medical treatment.

Drs. F. H. Gerrish, R. T. Morris, Samuel Lloyd, and others urged immediate operation in all operable cases of cancer, unless the disease had progressed to such an extent as to be quite hopeless.

Dr. T. E. Satterthwaite said that methods other than surgical were applicable to cancer. It often yielded to light-therapy and occasionally to local applications, while spontaneous cures were possible. Besides, inoperable can-

cers were apt to fall to the care of the medical practitioner. But, notwithstanding, he would unhesitatingly take his stand on the side of surgery, to the extent of saying that in the vast majority of instances the treatment of cancer involved the use of the knife, sooner or later. Some years ago, in conjunction with Dr. W. H. Porter, he had made a study of one hundred cases of cancer in which all varieties of the disease were included, examining the tissues microscopically and following out their subsequent histories for some years. As a result he became convinced that the larger success which had been secured was due primarily to early and thorough operations.

Removal of the Prostate for the Care of Prostatic Dysuria.—Dr. L. S. Pilcher of Brooklyn read this paper. He said that in previous papers, the last of which was read before the Medical Association of the Greater City of New York in June, 1905, he had discussed quite fully the methods and results of prostatectomy for the relief of prostatic dysuria. Having given a summary of the conclusions reached in them, he stated that these conclusions had in no wise been shaken by the experience of another year. Of the 30 patients who formed the basis of his personal report in his last communication, 5 died as the result of the operation. Of the remaining 25, he had seen or heard of most since his last report; 2 of these had since died as the result of progressive renal disease, and 1 other had died about a year after operation, from pneumonia. In the very nature of the case, a considerable mortality from ordinary causes must rapidly diminish the number of survivors, but up to the present time there still remained so large a proportion of men who had been restored to comfort and usefulness, which they continued to enjoy even in their great age, that the series of operations unquestionably was properly the source of profound satisfaction from a surgical standpoint. Thus, after the expiration of periods varying from four years to one year after operation, twenty out of the thirty patients remained in good health, free from urinary obstruction. Only two of them had still to use a catheter. In all the cases which formed the basis of his previous papers, with a single exception, the method of approach to the prostate was through the perineum. During the year which had elapsed since the close of the period included within his previous statistical report he had had occasion to remove the prostate for dysuria in six additional instances, the patients being aged respectively 51, 63, 66, 73, 77, and 86 years. In only one of these cases had he adopted the perineal route; in the remaining five the suprapubic transvesical route was employed. In the perineal case the patient, 77 years old, died from progressive general asthenia, aggravated by a term of excessively hot weather on the twelfth day after the operation, which was difficult and prolonged. Of the five cases submitted to the suprapubic method, one, a man of 73 and hemiplegic, developed, on the fourth day, a hypostatic pneumonia which terminated fatally one week after the operation. In the other cases the aftercourse was without incident, and the treatment had resulted in a satisfactory relief of the urinary disability. In these suprapubic cases he had been well pleased with the control over the region of operation secured by the introduction of the gloved finger into the rectum, making counter-pressure against the prostate. Although his experience with it was limited, it had been sufficient to demonstrate to him that a very considerable advantage in the way of obtaining an intelligent direction of the work of enucleation could be secured by this method of conjoined rectal and intravesical manipulation, and he was now inclined to give a larger field for the suprapubic route than he had done in his earlier studies. In the majority of cases, however, he thought it probable that some method of attack from the perineum would continue to be the method of choice. He was inclined to think that for the best fulfillment of all the operative indications, when the perineal route was adopted, it was desirable that a free exposure of the gland by a suitable perineal incision and retraction of overlying parts should be made. The gland, after it had been exposed, was to be brought down as much as possible into the superficial operative field by the use of suitable tractors, and the removal of the obstructing masses was to be carefully and systematically affected, under the guidance of the eye as much as possible. This was simply an application of that tenet of general surgery which demanded the adequate exposure of an affected part as the first step of an attack upon it. Dr. Pilcher illustrated the technique of his operation with a series of drawings and a number of large photographs taken at several stages during the actual performance of an operation.

The Etiology and Treatment of Uremia.—Dr. Howard Van Rensselaer of Albany read this paper. He reviewed the prevailing opinions as to the etiology and pathology of uremic states and then went on to say that he thought we were justified in assuming the following conditions to be present: Probably by the action of bacteria in the intestine or liver there was circulating in the blood a poisonous proteid, which was the actual exciting cause of uremia. This proteid, by its irritant and destructive action on the kidney tissue, prevented not only itself from being changed or excreted, but prevented the elimination also of other excrementitious matters, such as urea, extractives, and salts, and permitted their accumulation in the blood. These excrementitious matters were capable of producing part of the symptoms, as vomiting, diarrhea, prostration, increased heart-action, contraction of the pupils, and perhaps muscular tremors. The hyperosmosis produced by the increased amount of the crystalloid substances might perhaps modify the composition of the cellular structure in different parts of the body, sufficiently to interfere with their functions and give rise to symptoms. If these premises were correct, he thought the treatment of uremia ought to be conducted along four general lines: (1) Removal of the exciting causes; (2) prevention of the reappearance of the exciting causes; (3) physiological rest to be diseased tissues; (4) the treatment of individual symptoms as they arise. For removal of the exciting causes he would give venesection first place. While the most important cause of uremia was probably the poisonous proteids referred to, unfortunately we knew of nothing that would change the composition of this body from a dangerous into an innocuous substance, nor of anything which would surely and rapidly cause its excretion through the ordinary emunctories. There was but one quick and certain method at our disposal for its elimination, and that was by a direct removal of a part of the poison from the body by venesection. This was to be employed as early as possible during the uremic seizure. For an average-sized adult a pint of blood, or even a little more, might be withdrawn. This method was also the quickest means of reducing the tension in the blood-vessels. Next, he would lessen the toxicity of the blood by dilution. This might be done in three ways: by the intravenous injection of saline solution, by hypodermoclysis, or by copious draughts of pure water. The last-named was the slowest, but also the simplest and safest, and was that preferred by the speaker. In the third place, removal of urea and extractives was to be aided by dialysis. This was to be accomplished by stimulating the emunctories in four ways: by the drinking of water, by catharsis, by diaphoresis, and by diuresis. In regard to the prevention of the reappearance of the exciting causes he said that if a poisonous proteid were produced by bacteria, it was obvious that we should keep the intestinal canal as clean as possible by catharsis, possibly aided by antiseptics, and be exceedingly cautious in the administration of food containing proteid. In order to give physiological rest to the diseased tissues food, in the case of adults, should be withheld for at least twenty-four hours, and then small quantities of peptonized milk or well-diluted gruels might be used. Milk had worked best in the hands of most observers. Next to it, he favored those prepared infant and invalid foods which contained but a very small proportion of proteid content. Cathartic and diaphoretic treatment, by

taking up the excreting function usually performed by the kidneys, helped also to give these organs physiological rest. As to the treatment of individual symptoms as they arose, the obvious symptoms of convulsions might sometimes be controlled temporarily by chloroform or ether anesthesia, or by morphine hypodermically. While a marked difference of opinion existed in regard to the advisability of the use of the latter drug, he thought an indication as to whether it should be given or not might perhaps be found in the condition of the pupil. In those individuals in whom the pupil was dilated, the morphine seemed to act beneficially, but in those in whom it was contracted the reverse was true. On the theory that the symptoms of convulsion and coma are due to increase of intracranial pressure, successful results had recently been reported from the employment of spinal puncture, an amount of cerebrospinal fluid being withdrawn sufficient to bring the intracranial pressure down to normal.

Significance of Jaundice.—Dr. Samuel Lloyd of New York read this paper. Within the last four years, he said, jaundice had taken on a new significance, and without doubt the great bulk of our present knowledge regarding its causation was the result of surgical investigation. He referred to the various classifications of jaundice, and presented Mayo Robinson's tabulation of the extrahepatic variety. He then mentioned one condition, not included in the latter, which he believed to be the direct result of chronic catarrh of the gall-ducts. This was an inspissation of the bile filling the common duct and sometimes the gall-bladder, and even the hepatic ducts for a considerable distance into the liver itself, with a thick, pasty dark mass. This was about the consistency of soft putty, and offered a complete obstruction to the natural escape of the bile. Medical treatment could be of little avail in removing this, while the results of operative treatment were so prompt, and offered so little danger, that it should be undertaken early. Two conditions had to be considered most carefully in the surgical treatment of jaundice: the changes in the blood and the changes in the kidneys. As regards the former, the change of most serious character was the marked decrease in coagulability (in fact, a pseudohemophilia), and it constituted one of the most dreaded conditions that surgery had to contend with in operations on the liver and bile-ducts. The hemorrhages resulting from it did not as a rule occur immediately after the operation, but began from one to four days later. In all cases of prolonged jaundice marked and increasing anemia had also a be contended with; therefore it was important that the percentages of hemoglobin should be determined at the same time that the coagulability of the blood was investigated. Operations of any kind undertaken with a percentage below 30 were exceedingly serious. Changes in the kidney were important, both in determining the anesthetic to be employed and in influencing the prognosis. It was not the surgeon's fault that the percentage of deaths in these cases was so high, but rather that of the medical practitioner, who delayed calling in the surgeon until a grave condition had developed as the result of the combined toxemias of jaundice and nephritis. Cases of jaundice which came to the operating table early, before they were suffering from general toxemia, did well and usually recovered promptly. It was also well to remember that in all probability the chronic irritation of gallstones might be the potent cause for the development of cancer. Many of the conditions referable to the stomach and treated as chronic gastric affections were also due to a spasm of the gall-bladder and ducts, either with or without a chronic empyema. Exploratory incision would undoubtedly reveal the cause of many of these gastric troubles. Taking up the intrahepatic conditions, Dr. Lloyd said that, leaving out the malignancies (which were nearly always metastatic when they appeared in the liver itself, and in which operative interference was out of the question), gumma of the liver and benign tumors generally might be operated upon successfully. Abscesses of the liver, including those of amebic origin, should be operated upon and drained, and in cases of hepatitis or of jaundice either to inflammatory changes in the acini, where the condition was not promptly relieved by medical treatment, the suggestion made by Dr. W. E. B. Davis, of doing a hepatotomy, was practicable and comparatively safe. In hepatic cirrhosis the Talma-Morris-Drummond operation was well worth a trial in cases in which the ascites was great and the patient losing ground.

Recent Advances in Special Therapeutics.—A symposium on recent advances in special therapeutics concluded the scientific sessions. The subjects and writers were as follows: "Pediatrics," Dr. J. Madison Taylor of Philadelphia; "Ophthalmology," Dr. W. B. Marple of New York; "Gynecology," Dr. H. C. Coe of New York; "Surgery," Dr. J. B. Deaver of Philadelphia; "Obstetrics," Dr. E. H. Grandin of New York; "Neurology," Dr. E. D. Fisher of New York; "Laryngology," Dr. C. H. Knight of New York; "Electrotherapeutics," Dr. W. J. Morton of New York; "Otology," Dr. W. C. Phillips of New York.

THIRD DAY—SATURDAY, MAY 5.

Election of Officers.—The following officers were elected for the ensuing year: *President,* Dr. Robert Reyburn of Washington, D. C.; *First Vice-President,* Dr. J. E. Janvrin of New York; *Second Vice-President,* Dr. F. H. Gerrish of Portland, Me.; *Third Vice-President,* Dr. Howard Van Rensselaer of Albany; *Secretary* Dr. N. P. Barnes of Washington, D. C.; *Treasurer,* Dr. J. S. McLain of Washington, D. C.; *Members of the Council,* to fill vacancies, Drs. Abel and Osborne; for the term ending in 1911, Drs. Barnes, Fisher, and McLain; *Censors,* Drs. Satterthwaite, Osborne, and Leech.

It was voted that the next meeting of the Society should be held at Washington, D. C., in May, 1907.

AMERICAN MEDICAL ASSOCIATION.

Fifty-seventh Annual Meeting, Held in Boston, June 5, 6, 7, and 8, 1906.

(Special Report to the Medical Record.)

(*Continued from page 995.*)

SECTION ON MEDICINE.

Third Day—Thursday, June 7.

Recent Advances in the Physiology of the Circulation.—Dr. Joseph Erlanger of Baltimore gave a critical review of recent work on the physiology of the blood pressure, with special reference to the principles employed in the estimation of the blood pressures in man, and to the interpretation of the results obtained. The recent work on the relation of periodic respiration to blood pressure variations was also considered. Of the many recent contributions to the physiology of the heart, those relating to only two topics were reviewed, namely (*a*) the survival of the mammalian heart after the death of the organism, and (*b*) conduction from auricles to ventricles in the mammalian heart.

A Study of the Heart in Chorea.—Dr. W. S. Thayer of Baltimore reported some studies of the heart and blood vessels of old choreic patients treated at Johns Hopkins Hospital, and made comparisons of the conditions at present and during the time they were under treatment. A brief summary of the work was as follows: There were altogether 808 cases, 698 of whom were treated in the dispensary and 110 in the hospital wards. Three per cent. of them were colored, showing a relative infrequency of the colored. Over 71 per cent. were females. The cases were divided into three classes, first, those giving a history of one attack, 62.5 per cent.; secondly, those who had had two attacks, 20 per cent.; and thirdly, those who had had three or more attacks, 17 per cent. Of particular importance was the frequency of cardiac complications, or history of them, preceding, succeeding, or complicating the symptoms. There

were 789 cases in which a definite history was obtained as to whether such manifestations were present or not. In 22 per cent. there was a history of rheumatism; in 78 per cent. there was no such history. Cardiac murmurs were observed in 41 per cent.; in the hospital cases, where more careful observations were taken, cardiac murmurs were observed in 85 per cent. In somewhat under one-half of the cases in both dispensary and hospital the signs were heard which were indicative of functional and not organic lesions. In a little over one-quarter of all the cases conditions were found which justified the diagnosis of organic heart disease. These lesions were mitral in 157 cases, aortic in 12, and acute endocarditis was present in 6; there were 20 cases in which definite organic lesions were present, and also an acute endocarditis at the time of observation. There were three cases of pericarditis. In two cases which came back with relapses the diagnosis of adherent pericardium was made at the time of relapses. In 83 per cent. there was no history of rheumatism, while in 17 per cent. there was. Cases without cardiac complications, 66 per cent. had one attack, 19 per cent. had two attacks, 15 per cent. had three or more attacks. Cases with cardiac complications showed 50 per cent. had one attack, 25 per cent. had two attacks, 25 per cent. had three or more attacks. These figures showed that relapses or recurrent attacks brought greater danger of cardiac complications. Of the 110 cases treated in the hospital, there was only one instance in which the patient had no fever whatever; there were four cases in which the temperature occasionally rose above 99° F. Among 51 cases without cardiac involvement, 39.5 per cent. had a temperature between 99° and 100°, 50 per cent. between 100° and 101°. Among the cases with cardiac involvement, 15.5 per cent. had temperatures between 99° and 100°; 32.2 per cent. had a temperature between 100° and 101°. He said that definite febrile manifestations without rheumatism, occurring during an attack of chorea, especially when in association with an unduly rapid pulse, might be regarded at least as strongly suggestive of evidences of a complicating acute endocarditis. In conclusion, he said that out of the 698 cases of chorea observed during one or more attacks, over one-half showed evidences of cardiac involvement; that the heart was involved with somewhat greater frequency in those cases in which there was a history of acute polyarthritis; that the dangers of cardiac involvement appeared to increase with the recurrent attacks or relapses; that in 110 cases treated in the hospital wards, fever of moderate extent was present in almost every instance; that in the majority of the cases in which fever was above 100° F. there were evidences of cardiac involvement; that there was good reason to believe that the presence of persistent fever in an otherwise uncomplicated chorea in the large percentage of the cases gave evidence of a complicating endocarditis.

Effects of Pericarditis upon the Heart.—Dr. N. S. Davis of Chicago read this paper. He said that pericarditis was not necessarily a fatal lesion; it was variously estimated that from 50 to 75 per cent. of all cases recover. Rheumatic pericarditis was, as compared to that caused by other infections, benign. Hemorrhagic and purulent pericarditis was almost uniformly fatal, always so unless recognized and successfully treated. About one-third of the cases of pericarditis were serofibrinous; about one-sixth were hemorrhagic or purulent; one-twelfth tuberculous; in approximately the same number there was total synechia, but in one-third there were adhesions between part of the pericardial surfaces. A rapidly developing effusion was dangerous, but recovery could be effected, or life prolonged, even in the majority of the cases by aspiration and treatment. A large, slowly developed effusion was not as threatening or immediately dangerous, and a small effusion was of no greater gravity than fibrinous inflammation. The prognosis must be influenced by the condition of the muscle of the heart at the time of the pericarditis. Chronic alcoholism and the cachexia of cancer, Bright's disease, and tuberculosis made slight the possibility of prolonging life. Pericarditis in these cachexias was usually due to a terminal infection, and was often the immediate cause of death. It was also a much more serious complication of pneumonia than of pulmonary tuberculosis, and a very grave complication of sepsis. As might be expected, it was most dangerous in the earliest and latest years of life.

Relation of the Heart in Chronic Nephritis.—Dr. Nathaniel B. Potter of New York reviewed the theories of mutual relationship between heart and kidneys, giving experimental, pharmacological, and clinical evidences. He also considered the dynamic and chemical problems. He gave an analysis of autopsies on chronic nephritis cases at New York City Hospital during the past three years.

Angina Pectoris—True and False.—Dr. James M. Anders of Philadelphia read this paper. He said that the mechanism involved in the pathogenesis of true angina pectoris was still imperfectly understood. It was definitely known, however, that structural changes involving the cardiovascular system, more especially coronary sclerosis with myocardial degenerations, were present in the vast majority of the cases. Some of the hypotheses, which had been advanced, merely attempted to explain the cause and seat of the pain, forgetting that this symptom was but one of a group of characteristic features. Dr. Anders then briefly reviewed the multiple theories regarding the cause or causes of the precordial paroxysms. He expressed the view that an impaired nervous vitality was to be looked upon as a marked predisposing element. The fact that angina pectoris was a neurosis of the heart was too constantly overlooked. While not desiring to underrate the etiological importance of angiosclerosis, he thought that many instances of angina pectoris were clearly the traceable result of a nervous or mental mechanism that had been overworked, with insufficient rest. This condition might be looked upon as a form of neurasthenia, but Dr. Anders suggested the possibility of some peculiar nutritional or degenerative change in the nervous system, brought about by the high-pressure changes that served as the predisposing elements in angina pectoris. No theory, however, of the genesis of this syndrome was complete that did not account for the angina sine dolore. An interesting case was reported by Dr. Anders, in which the starting point of the pains was the precordial region for a time, but later it shifted to the epigastrium. Great cardiac oppression was associated, and constituted the dominating feature; it invariably originated, like the pain, in the epigastrium, then traveled wavelike upward over the thorax. The case terminated fatally, preceded by the usual manifestations of angina sine dolore. This clinical form was found to be engrafted upon a variety of structural cardiac diseases, such as mitral regurgitation, mitral stenosis, dilatation of the heart, and aneurysm of the first portion of the arch and adherent pericardium. The absence of intense pains in these cases was probably due to oncoming dilatation, which relieved endocardial pressure. The cases in which the pain originated below the diaphragm were not less threatening to life than the more usual, typical instances. Dr. Anders called attention to a form of angina pectoris dependent on a diet containing an excess of proteids. These cases sometimes manifested, as an associated condition, chronic intestinal toxemia. The term "pseudo-angina" should be retained until additional light shall have been thrown upon the whole subject under discussion. Most cases originated in vasomotor instability or irritability, and the vast proportion occurred among females of the hysterical type and about the period of the menopause. The pseudo-angina of Nothnagel, due to suddenly induced vasoconstriction, was characterized by a special set of symptoms. The instances of angina directly traceable to autointoxication from errors of diet should be placed in the same category, provided that no sub-basis in the nature of an organic lesion of the cardiovascular system was discernible. True angina and pseudoangina, therefore, had causative factors and symptoms, as pains and vasomotor disturbances, in

common, but spurious angina differed from the true form in three leading particulars: (1) Gross lesions were absent; (2) it differed symptomatically, and (3) it usually yielded to appropriate treatment. Dr. Anders expressed the view that apparently typical cases of pseudoangina might develop gross cardiac lesions, followed by the symptoms and course of the true form. Cases of this sort had been reported by a number of writers. From personal observations, the writer felt himself privileged to speak confidently regarding certain cases, which so far as could be determined by known methods of examination, at least, were noncoronary, although they might be fraught with lurking dangers. The cases of pseudoangina were divisible into three groups: (*a*) The neurotic; (*b*) toxic (two groups suggested by Osler), and (*c*) reflex pseudoangina. The last named clinical or etiological type was usually classified as a subvariety of the neurotic type, but in his opinion it was of sufficient importance to demand separate grouping. Dr. Anders stated that true angina pectoris could be differentiated from the false form in a decisive way by the *angor animi*, and the strong sense of imminent dissolution. Attention was called to the mild and doubtful cases and the importance of carrying out an exhaustive survey in the individual case before pronouncing in favor of false angina, was strongly urged. There was evidence, chiefly clinical, to establish a certain relationship of the two forms of angina, although it was commonly held that the false variety was solely of neurotic origin, a sort of unsteadiness, which had been designated by S. S. Cohen as vasomotor ataxia Finally, the balance of the cases belonging to pseudoangina differed widely and fundamentally from true angina pectoris.

Dr. Woods Hutchinson of Redlands, Cal., Dr. Frank Jones of Memphis, Tenn., Dr. W. S. Thayer of Baltimore, Dr. James Tyson of Philadelphia, Dr. Clayton of Washington, Dr. C. M. Cooper of San Francisco, Cal., Dr. Norris of Philadelphia, Dr. Bertram W. Sippy of Chicago, Dr. De Lancey Rochester of Buffalo, and Dr. Black of Pasadena discussed the papers.

Quackery.— Dr. A. Jacobi of New York read this paper. He said that the distrust of medicine and its powers was as old as the world, for not many ever knew or cared to appreciate what medical science or art was capable or not of accomplishing, or should be held responsible for. The more uncultured or uncontrolled the human intellect, the greater was the predominance of mysticism. The public was not always edified by the doctors. Hippocrates complained bitterly of the contests of physicians among each other, and more than 2,000 years later Peter Frank thought and advised seriously that the only way to procure an orderly consultation was to call in the police. The masses were at last driven into the arms of sectarians and the quacks. The era of scientific medicine, beginning a little more than half a century ago, was built up on anatomy and physiology. One would have supposed that the darkness of quackery would disappear before the new light; on the contrary, it had grown in geometrical proportions, until the accumulated ignorance of quacks and fakirs had become a power in every land. The Germans, who liked to style themselves the nation of thinkers, had more quacks than any other people. Saxony and Bavaria had one quack to every two physicians; Berlin had two to nine. Physicians were responsible for much of the self-dosing with patent medicines. For babies they prescribed artificial foods, the composition of which they knew not. They prescribed nostrums and took journals that printed "reading notices" of proprietary medicines, that printed advertisements of drugs in the shape of "original articles," that alternated their medical with advertising pages. Dr. Jacobi said that a friend of his examined 50,000 prescriptions compounded in a number of drugstores, and between 1850 and 1873 he met with no nostrums; in 1874, 1 in 1,500; and from that time the number increased, until in 1902 and 1903 it was from 20 to 25 per cent. In one of the large drugstores he had been assured that 70 per cent. of the prescriptions sent in by reputable physicians contained either nostrums pure and simple, or as a part of the compound. One of the reasons for this demoralization should be generally known and appreciated, and that was that there were very few medical schools a graduate would leave, diploma in hand, with the knowledge and practice of writing a prescription. Our medical colleges neglected their duties by thus omitting to teach the art of medicine in combination with what was obviously and pompously called science. He asked the medical schools to remember what all the general practitioners could tell them, that medicine meant both science and art.

The afternoon session was devoted to a symposium on diseases of the joints.

A Review of the Bacteriology of Acute Articular Rheumatism.— Dr. Lewis A. Conner of New York read this paper, and said in conclusion that one was justified in believing (1) that acute rheumatism was a specific, infectious disease, and was not merely an attenuated pyemia resulting from the common pyogenic organisms; (2) that the bacillus of Achalme had no etiological relation to acute rheumatism; (3) that while there was considerable evidence in favor of the view that the disease was caused by a specific diplo- or streptococcus, there were still lacking positive proofs of the specificity and identity of this organism and of its causal relation to rheumatism.

Gonorrheal Arthritis.—Dr. John A. Witherspoon of Nashville, Tenn., read this paper. After considering the etiology, pathology, and symptomatology, he took up the differential diagnosis from acute inflammatory rheumatism. In gonorrheal arthritis the presence of the primary disease, while not pathognomonic, was important; the fever was not so irregular; the lactic acid sweats were absent; the joints were brighter red, more painful, tended more to suppuration, etc. There was not the sudden subsidence of trouble in one joint, and the sudden involvement in another; the endocardium was rarely involved; the case was much more prolonged, and did not yield to the salicylates. The differentiation between the chronic form and tuberculous arthritis was more difficult. In chronic gonorrheal arthritis many joints were involved, the joints were more swollen, more painful, with some redness, had large effusions, and had more tendinous involvement, and more edema, etc., than in the tuberculous cases; in the latter the joints were often white and glazed in appearance, and the trouble was more central, often involving the epiphyses of the bones. The tendency of the profession to call all joint troubles rheumatism was far from correct. After considering the prognosis, he said that the treatment was as varied as unsatisfactory. In the acute type rest in bed, fixation of the joint, local applications of heat or cold, etc. The internal administration of drugs rarely helped the matter, and was not advisable except to meet symptomatic conditions. In the chronic cases general reconstructives were used and potassium iodide. All surgical interference should not be condemned; aspiration was advised in some cases, and where there was suppuration, incision and drainage constituted the only treatment. He then referred to the remarkable cures that had been reported by Dr. Eugene Fuller of New York City, who insisted that the infection came from a gonorrheal vesiculitis, and by opening and draining them secured an immediate amelioration of the arthritis.

Differential Diagnosis of Rheumatoid Joint Affections.—Dr. James B. Herrick of Chicago said that he would narrow his discussion and not consider such conditions as sarcoma of the joint, monarticular tuberculosis, sprains, and other traumatic arthritides, nor would he do more than mention the arthritides occurring in connection with definite infectious diseases, such as scarlatina, pneumonia, epidemic meningitis, septicemia, pyemia, etc. Here diagnosis was comparatively easy. Laying these aside, there remained a goodly number of joint troubles whose exact recognition was no easy task. Such conditions were gout, arthritis deformans, gonorrheal arthritis, some of the

arthropathies of nervous diseases, the joints of hemophilia, scurvy, the purpuras, some cases of tuberculous polyarthritis, etc. Their exact recognition was difficult, because there was no accurate etiological classification, because differentiation on the basis of post-mortem anatomy was none too clear, and the anatomical changes in life were not always recognized, and were liable to be confused with one another. One must depend in these on a study of the symptoms and signs, mode of onset and advance of the disease, temperature, pulse, number of joints and which joints involved, lesions in other organs and tissues, tendency to relapse, influence of therapy, *x*-ray examination, etc., in order to reach a reasonable probability of truth. Such a thorough study usually resulted in a diagnosis as near accurate as our imperfect classification would admit. In arthritis deformans there were three notions partially wrong, namely, that arthritis deformans was always chronic in onset and course, did not cause fever, and began in the small joints. In the more acute type of arthritis deformans there was not the shifting of the process from one joint to another, as in acute rheumatism. Even in the chronic cases a pulse of 90 to 110 was common. The profuse sweats of acute rheumatism were lacking, endocardial and pericardial complications were scarcely ever seen. Salicylates were comparatively inert. The acute process was slower to subside than in acute rheumatism. Arthritis deformans was more likely to attack the temporomaxillary, sternoclavicular, and vertebral joints than was true rheumatism. Some hesitated to declare a case arthritis deformans because of the evident presence of a considerable amount of fluid in a joint. This could often be found, as in the knee, elbow, and wrist. Sometimes atrophic, not hypertrophic, changes were met with. Localized spondalitis might simulate tuberculosis of the vertebræ, with pain and other cord symptoms, due to pressure, and thus be hard to recognize. In some of these cases of local spondylitis careful research might reveal a stray joint here and there in some other part of the body involved in a typical manner, that would betray the nature of the vertebral disease. Some of the earlier symptoms described by patients sound like the stories of a neurasthenic or hysterical individual, as burning in the hand, sudden weakness in the hand, tenderness along the carpus, sudden chilliness, sudden weakness, etc. He had been deceived in one case of a hysterical woman who gradually developed one of the worst cases of arthritis deformans. The diagnosis was often helped by the *x*-ray revealing the bony nature of the deformities or the atrophic changes in the joints. He had never seen arthritis deformans helped by visits to springs, baths, etc. One should not forget that polyarticular deforming arthritis occurred in children, often with glandular and splenic enlargement. The early diagnosis of arthritis deformans was of great importance from the standpoint of prognosis and therapy. Too often a diagnosis of rheumatism or gout led to a restriction of diet that was useless and a deluging of the system with salicylates, etc. In differentiating arthritis deformans from gout, one should take into consideration the following points: Gout was apt to be found in people of all classes; tophi should be watched for; the big toe history should be taken from the beginning; examination should be made for cardiovascular accompaniments of the disease; the uric and phosphoric acid output should be studied; an *x*-ray would generally confirm the diagnosis. Without tophi there were cases that were baffling and where a provisional diagnosis might be temporarily made.

Joint Affections in Nervous Disease.—Dr. Lewellys F. Barker of Baltimore read this paper. He said that leaving out certain joint affections, the most important fell into the following groups: (1) The intermittent joint effusions (hydrops articulorum intermittens). (2) The arthropathies of tabes and dementia paralytica (arthropathia tabetica). (3) The syringomyelic arthropathies (arthropathia syringomyelica). (4) The painful joints of the psychoneurotics (arthralgia psychoneurotica. He considered in detail the symptoms and diagnosis of these, and briefly dealt with the treatment.

The Treatment of Chronic Nontuberculous Arthritis.—Drs. Edwin A. Locke and Robert B. Osgood of Boston presented this communication. They classified chronic nontuberculous arthritis into villous arthritis, infectious arthritis, atrophic arthritis, hypertrophic arthritis, and chronic gout. The treatment was essentially the employment of methods influencing general metabolism and the local treatment of the affected joints. There were certain general régime for all cases, with special methods for the various types. First there was the general treatment for all cases, treatment of the disturbances of the general health, *i.e.* malnutrition, nervous debility, anemia, emaciation, obesity, etc.; treatment of the organic disturbances, *i.e.* circulatory, respiratory, renal, etc.; treatment of infective foci, *i.e.* of middle ear, tonsils, genitourinary tract, pyorrhea alveolaris, salpingitis, etc.; treatment in connection of deformity by operative measures and apparatus. Then there was the diet. Again, there was the physical therapy, the treatment by hyperemia—active to lessen the pain, increasing motion, favoring the action of the circulation so as to produce increased nutrition to joint with absorption of exudates; passive, lessening the pain, reducing the inflammation, overcoming the infection. Then they considered massage, hydrotherapy, and rest. Secondly, there was the special treatment.

Dr. Joel E. Goldthwait of Boston contrasted the papers just read with those read four or five years ago; at this meeting the term uric acid had only been mentioned once, and that only as a feature of the disease and not as a cause. Apparently the physicians in the country were working intelligently and honestly in trying to unravel the many features in these diseases, about which so much uncertainty existed. He emphasized the importance of making a very thorough examination in every case, using every method available. It was the pathology that underlay all treatment. He pleaded with them that they all do their best and contribute even a mite to the knowledge of a large subject which represented the cause of more of the helpless cripples than any other disease with which they were confronted. In watching cases of gonorrheal arthritis, it was his experience to observe the joint exudate and distention, a serous effusion in the joint, occurring during the first two, three, or four weeks, and then came the purulent cases, with much joint destruction. Or polyarticular infiltration would occur, which led to the formation of adhesions, making the manipulative treatment of these joints very difficult, and almost impossible in the severer forms of gonorrheal arthritis. Therefore he believed that if the acute symptoms did not subside at the end of three or four weeks, operation should be performed to get rid of the effused material. With greater knowledge came fewer diagnoses of hysterical joints.

Dr. George W. McCaskey of Fort Wayne, Ind., said that acute rheumatic arthritis was of infectious origin, and that to this poison, whatever its nature was, special susceptibility was given on the part of joint structures. He called attention to the dangers attending operative interference upon the urethra during an active gonorrhea, and reported such a case, the patient afterwards developing a gonorrheal endocarditis.

Dr. James J. Walsh of New York said that the term rheumatism should be gotten rid of. Acute arthritis might be traumatic or infectious. In Paris he saw 160 soldiers with mumps, and 11 of them developed a mumps arthritis.

Dr. John Rogers of New York spoke of the use of antigonococcal serum used in 45 cases of gonorrheal rheumatism. There were 83 per cent. of cures in the acute cases, 84 per cent. in the subacute cases, while in the chronic cases, numbering 13, only 4 were cured. This antigonococcus serum seemed to be valuable in gonorrheal septicemia.

Dr. Woods Hutchinson of Redlands, Cal., said that last winter he had had under his care from 60 to 70 cases of

chronic rheumatism, so-called, and out of this number more than 60 per cent. of them could be traced clearly to some acute infectious disorders, such as influenza, pneumonia, typhoid fever, etc. Salicylates did not diminish the number of complications, nor did they shorten the disease.

Dr. Charles E. Skinner of New Haven called attention to the treatment of arthritis deformans with hot air and static and high-frequency electricity.

Dr. Conner said there was no doubt but that many of these cases of acute articular rheumatism were due to toxins.

Dr. Witherspoon considered serum therapy in its embryonic state as yet, and said we were not warranted in recommending it now.

Dr. James B. Herrick recognized the importance of early aspiration in those cases of gonorrheal rheumatism.

Dr. Lewellys F. Barker said he was glad to hear it said that rheumatism was of infectious origin. The serum treatment should not be too strongly advocated until we knew more about the disease.

(To be continued.)

A Case of Typical Tetanus Observed in a Monkey.—Henry Labonne observed this case. The writer had owned the animal four years and as it was about a year old at the time when it was purchased, it was about five years old when attacked by tetanus. The writer first noticed a suppurating wound at the umbilicus which had been caused by injury with a piece of iron attached to the strap which fastened the monkey. A dressing of menthol was applied to the wound which closed up the next day, but the monkey would not touch his favorite food. Great depression was followed by the development of trismus. The jaws could not be opened sufficiently for the introduction of a spoon between the teeth. Opisthotonos developed and the monkey dropped to the bottom of his cage. From this time the least jar gave rise to violent paroxysms, the muscles twitching as if they were under the influence of electricity. The animal died with its intelligence undulled. The body assumed the classic position of this disease, touching the ground with its two extremities only. It is interesting to recall the fact in this connection that negro infants not infrequently suffer from tetanus consecutive to an injury of the umbilical cord.—*Gazette des Hôpitaux Civils et Militaires.*

Medical Gymnastics in the Treatment of Pleurisy.—L. Bernardo says that pleurisy, exudative or serofibrous, is very common in the Italian army: during twenty years there have been 42,035 cases, the maximum in any year being 1,390, the minimum, 294 cases. Many of them are of tuberculous origin; others produced by the diplococcus of Fraenkel and the streptococcus. In general, while there is fever, the liquid exudate is not absorbed because the pleura and the lymphatic channels are affected by the inflammatory process. After the fever is over, absorption begins and is rapid in proportion as the lymphatics become quickly pervious or no. The breathing exercises increase expansion and this facilitates absorption. By making use of the muscles of forced respiration, instead of only those that have become atrophied by non-use, the circulation is much improved and absorption increases. The lung dilates thoroughly in forced respiration, and each day inspiration is deeper. The exercises used are raising the arms with inspiration, lowering them with expiration, raising them with external rotation on inspiration, and all movements that tend to erect the trunk and produce lateral and posterior movements of the vertebral column. The treatment was given to forty-eight soldiers in all. There was a less number of recurrences of pleurisy; convalescence was more rapid, pulmonary respiration returned more rapidly, the muscles increased in volume, and general health was quickly regained. All cases were discharged from hospital sooner than usual.—*Giornale Medico del Regio Esercito.*

THE SCIENCE AND ART OF FITTING GLASSES.*

By A. EDWARD DAVIS, A.M., M.D.,
NEW YORK.

PROFESSOR OF DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, ETC.

Since this is the centennial meeting of our society, a brief historical sketch of the progress made in the last hundred years in the science and art of fitting glasses, or of the progress of ophthalmology itself, did time and space permit, is a fitting introduction to my paper. And I may venture to assert that in no branch of medicine in the last hundred years has there been so great an advance as in that of ophthalmology, and particularly in this branch of it, embraced under the term, Errors of Refraction and Accommodation. In fact, it is conceded that the science and art of fitting glasses comes nearer to being an exact science than any other branch of medicine. The laws of physics as regards the refraction of light and the correct focussing of the same on the retina of the eye, so as to form clear images of objects, can be applied with almost mathematical precision. With the eye, however, as with other organs and members of the body, we must reckon with variations within the organism itself, and it is in dealing with this phase of the subject that our skill as oculists is called into action. We need to be more than mere mechanics, trained simply in the laws of optics, but must be thoroughly trained physicians, with a special and complete knowledge of the anatomy and physiology of the eye, in order properly to correct errors of refraction.

In the last one hundred years, yes, less than one hundred years, the science and art of fitting glasses has been developed into almost, if not quite, an exact science. It is true that spectacles were invented as early as the thirteenth century by Salvinus Armatus, or Roger Bacon, it is not certain which; but these were simply convex spherical glasses for the correction of presbyopia, or old sight. At the International Congress of Ophthalmology of 1904, G. Albertotti presented a reproduction of a portrait with spectacles, painted by Tommaso of Modena in 1352 (middle of the fourteenth century). The Emperor Nero is said to have worn concave glasses made of precious stones, to witness the gladiators in the Coliseum. Dr. John Green argues that he had compound myopic astigmatism. However, but little science and less art were used in the selection of glasses at this early date, and the same criticism holds good until about the middle of the nineteenth century, and that even after the invention of the ophthalmoscope, in 1851. As late as 1855, a standard text book, "A Practical Treatise on the Diseases of the Eye," by William Mackenzie, M.D., advises: "When a near-sighted person wishes to be fitted with concave glasses the simplest and surest plan is to try a series of them at an optician's shop." And the same author advises against young people wearing too strong plus glasses for fear that when they grow older they will have to wear entirely too strong glasses. Some rules were given for the tests for glasses, but as the patient himself in a great measure selected the glasses, and as the patient and the optician both were ignorant of the anatomy and physiology of the eye, the science used in such a procedure was mere guess work and the art employed was rank empiricism. Yet, under the circumstances, what more could be expected, when we remember that the art of fitting glasses is a very young one compared with other branches of medicine. It was not until 1801, just 105 years ago, that astigmatism was discovered by that illustrious savant, Thomas Young, who we are told was a celebrated physicist mathematician, and general scholar. But he was something more, *he was a physician.* He studied medicine at London, Edinburgh, Goettingen, and Cambridge, but did not practise his profession. However, in making this one discovery in medicine he has made the human race his debtor.

It remained for Sir George Biddell Airy, the noted English astronomer, to take advantage of this discovery of Thomas Young and to correct his own astigmatism with cylindrical glasses, in 1837. Here indeed was applied for the first time the remedy, cylindrical glasses, for the defect or error of refraction, called astigmatism. It was not until fifteen or twenty years later that oculists had awakened to the fact of the great value of this discovery and began to look for this error of refraction and to apply the proper glasses to correct same. Pertinent to the history of the discovery of astigmatism and its correction by cylindrical glasses, Roosa, in his "Treatise on Diseases of the Eye," page 534, says: "Donders found it remarkable that astigmatism up to his time was almost exclusively treated of in English literature. In Mackenzie's illustrated treatise he found all that was known on the subject, and this had been discovered by Thomas Young and the Royal Astronomer, Airy. The latter had a high degree of compound myopic astigmatism in his own eyes which he carefully investigated. Stokes, also an Englishman, invented a lens for determining the degree of astigmatism. Dr. Goode also reported some cases, one of them, like Airy's, in his own eye. After Goode, Thompson reported cases, also in England. In our own country, Dr. Isaac Hays recorded two cases in an American edition of 'Lawrence on the Eye,' for which the optician McAllister made correcting glasses." He concludes his remarks as follows: "Since but one Continental observer of astigmatism appeared until Donders' time, and he long after the reports of Young and Airy, the credit of preparing the way for the full revelation of the diagnosis and correction of astigmatism, made in Holland, must be given to Great Britain and our own country."

Hypermetropia, that is, far-sight, was discovered in 1812 by James Ware (*Philosophical Transac-*

*Read before the New York State Medical Society, January 31, 1906.

tions) for the Royal Society, London, 1813, and after him, though several years had elapsed, such men as Sichel, Ritterich, Bohm, and Cooper, investigated this condition in a scientific, though imperfect, manner, as must have been the case without the use of the ophthalmoscope. The observations of Professor Dewey of Union College should be given credit here. In an article in the *American Journal of Science and Arts,* Volume III, page 443, November, 1849, hypermetropia is described, in a somewhat imperfect manner, it is true, under the name of *neomacropia.* Prof. Dewey says that the causes of this condition are to be sought in the structure of the eye, and may be due: "First, to too little convexity of the crystalline lens; second, its position too near the retina; or, third, its too little density." The true cause of hypermetropia, shortening of the anteroposterior diameter of the eyeball, he failed to recognize. However, the necessity for wearing convex glasses in such condition was recognized, and attention was called to the frequency of this error of refraction. It was not until after the discovery of the ophthalmoscope, in 1851, and a few years later of the ophthalmometer, both by Helmholtz, that scientific and exact measurements of the different errors of refraction could be made and properly classified. What had previously been guess work and assumption now became a matter of scientific accuracy in diagnosis and rational treatment for the defects found.

And with a proper classification of refractive errors, the necessity for accurately testing the visual power was recognized. Accordingly, in 1854, Eduard Jaegar in Austria, and Alfred Smee in England arranged a set of test types or letters which served fairly well for this purpose. But they were not entirely adequate, as they consisted simply in the arrangement into separate paragraphs of different-sized printed type, from the finest to the very coarse print. No standard was given as to what should be seen by the normal eye, consequently the tests were not very satisfactory. It was not until the year 1868, when Snellen of Holland printed his test types, which were made on scientific calculations, that a strictly accurate record of the visual power could be easily made. These letters were made on the plan of finding the smallest angle in which the form of a given object could be accurately recognized.

In this early stage of the development of this branch of ophthalmology, we are indebted to such men as Brewster, Bowman, Beer, Lawrence, Mackenzie, Stellwag; and, later, to Liebreich, Wecker, von Graefe, Knapp, Landolt, Helmholtz, Donders, and to many other notable men of this period, for much scientific and original work. Donders' epoch-making book on "Accommodation and Refraction of the Eye," in 1864, placed this branch of ophthalmology on a thoroughly scientific basis. And I may remark that Donders' great work is really the Blackstone of this branch of ophthalmology. It is amazing how well he covered the ground in his investigations, and we of later years have but amplified and refined the tests; but no new principles or truths, of history-making importance, have been discovered. Donders clearly showed the causative relation existing between errors of refraction and headaches, and cited cases by way of illustration. (Donders' "Accommodation and Refraction of the Eye," page 233.) The publication of Donders' work created a great stimulus for the study of refraction, both abroad and in this country, but especially so in America. In America, E. Williams of Cincinnati, H. W. Williams of Boston, H. Derby of Boston, Knapp of Heidelberg and later of New York, Agnew, Noyes, Roosa, Loring, Bull, Pooley, Gruening, Callan, Webster, all of New York, William Thompson and Norris of Philadelphia, Noyes of Detroit, John Green and Arlt of St. Louis, Hotz of Chicago, Burnett of Washington, Miles Standish of Boston, Conner of Detroit, Howe of Buffalo, Randall of Philadelphia, and many others whose names, even, space forbids mentioning, we are indebted to for the elucidation and solution of many problems in refraction. To the many younger men who have done excellent work in this line I shall not even refer, first, because their writings are fresh in the minds of my readers; and, second, their number is so great that time will not permit. Suffice it to say, their work is so good that America to-day stands at the forefront in this branch of ophthalmology. And we should not fail to record the fact here that it was Benjamin Franklin who first suggested bifocal lenses—which are often called Franklin lenses. This was in the latter part of the eighteenth century, about 1784.*

Abroad, the most notable advance in the science and art of fitting glasses since Donders' time was that made by Javal and Schiotz, when they rendered the ophthalmometer a practical office instrument. The use of this instrument has practically revolutionized our methods of fitting glasses, at least it has for a great many American ophthalmologists. Instead of using cyclopegics in almost every patient under forty years of age, as was necessary before the ophthalmometer came into use, we are now able to dispense with cyclopegics almost altogether. The perfecting of this instrument for daily use in the office is the one great advance made in fitting glasses since Donders' time. Reid, Leroy, and Dubois have given us ophthalmometers also, but they have not come into wide use. Tscherning has contributed largely to the subject of refraction and physiological optics, *Physiological Optics,* The Keystone Press, Philadelphia, 1900; and Panas, Meyer, Galezowski, Bull, Fuchs, Wallaston, Snellen, and many other notable continental writers, together with Priestly Smith, Nettleship, Story, Lawford, Berry, Hardy, and other notable men whom space alone forbids my naming, all have contributed largely to the subject of refraction.

Ophthalmoscopy.—To Dr. E. Williams of Cincinnati belongs the credit of introducing the use of the ophthalmoscope into this country and also into England. And just here, it is well to mention the fact that the discovery of the ophthalmoscope was fruitful in much more than in placing the subject of refraction on a sound basis. It enabled us, for the first time, to examine the interior of the eye and determine if the media were clear; to discover atrophic states, or grave inflammatory conditions, and to institute correct and prompt treatment for such conditions, to the end that the sight of many eyes has been preserved. But more yet, we are often able, by looking into the eye with the ophthalmoscope, to diagnosticate the presence of the gravest general diseases of the body. For instance, Bright's disease is often first manifested by characteristic changes in the retina of the eye; gray atrophy of the optic nerve is not infrequently the first symptom of tabes; while characteristic changes in the retina are often the first symptom of lukemia, and so on. In brain tumors and brain abscess the ophthalmoscope is often of the greatest value in making or confirming a diagnosis. And in many other diseases, as in arteriosclerosis, the findings of the ophthalmoscope are of the greatest help in arriving at a correct diagnosis. So in every sense of the word the invention of the ophthal-

*Cited by Roosa, from the writings of John Bigelow: The Works of Benjamin Franklin, New York, 1888, p. 55.

moscope can be truly said to be one of the greatest benefactions to mankind.

Ophthalmometry.—Another instrument of the greatest practical importance in fitting glasses is the ophthalmometer. To the same savant, Helmholtz, who invented the ophthalmoscope, we are also indebted for the invention of this instrument, which in importance ranks next to that of the discovery of the ophthalmoscope itself. Helmholtz, as early as 1854, published a description of the ophthalmometer, together with his conclusions as to the exact form of the cornea as measured by this instrument. Donders and Knapp also made careful measurements of the cornea with the instrument. Dr. Swan N. Burnett of Washington was the first American to use the Javal ophthalmometer. As early as 1885 he published a paper in the *Archives of Ophthalmology*, Vol. 14, under the title of "Ophthalmometry with the Ophthalmometer of Javal and Schiotz, with an Account of a Case of Keratoconus." Dr. Henry D. Noyes of New York began using the instrument at about the same time. Both of these instruments were old models. In 1887, Dr. Burnett gave a description of the old model instrument in his "Treatise on Astigmatism," and in the same year, 1887, in the "Reference Hand-Book of the Medical Sciences," Dr. John Green of St. Louis gave a description of the instrument, with a cut. The instrument remained comparatively unknown, however, in this country until 1889.

When the new or "1889 model" came out, it found among its advocates Dr. D. B. St. John Roosa of New York, who was taught its use by Javal himself and George J. Bull of Paris, and who, by his earnest and persistent advocacy of the instrument, especially in the classroom and in the hospital, where practical demonstrations of its use and value were given, did much to bring it into general favor. Other writers in America who have helped to bring the ophthalmometer into esteem are: Speakman, Koller, Ring, Weiland, Van Fleet, Wurdeman, Swasey, Woodward, Valk, de Schweinitz, Norris, myself, and many others. Although very accurate in its measurements, the instrument, as constructed by Helmholtz, was not a practical one. In order to use it the patient was placed six feet in front of it, and from fifteen to twenty readings made; then, before the astigmatism was ascertained, mathematical calculations had to be made. As such, it was used in the laboratories of only a few men, and for strictly scientific purposes. The late E. Dyer of Philadelphia demonstrated the original instrument in America.

It was not until 1880, when Javal and Schiotz made alterations and improvements in the instrument, that it became practical for office use, and it was not until 1889 that they perfected the instrument into its present model. It is an instrument designed to measure the radius of curvature of the cornea in its various meridians. By its use the presence or absence of corneal astigmatism is ascertained; and, if present, it gives the amount and axis of the astigmatism. While it is true that the ophthalmometer measures only the corneal astigmatism and not the total, yet those of us who are most familiar with the use of the instrument have found out by actual, everyday experience in our offices that the corneal astigmatism comprises almost the total amount of the astigmatic error present in the eyes. We know by experience in thousands of cases that the amount of corneal astigmatism corresponds, as a rule, to within .50D of the total astigmatism, and this difference can be found out with the subjective tests, that is, with the test letters and trial lenses, and with the objective tests, with the ophthalmoscope, and without the use of a cyclopegic, except in the very rare cases in which there is spasm of accommodation and in children under ten years of age. And this is one of the greatest virtues of the ophthalmometer, in that it enables us to fit glasses in the great majority of cases without the use of cyclopegics of any kind. Furthermore, ophthalmometry is the most accurate method yet devised for determining the exact axis at which cylindrical glasses shall be worn, which, in my opinion, is one of the most, if not the most, important factor in the art of fitting glasses.

Retinoscopy.—Bowman (Ophthalmological Hospital Reports, 1859-60, page 157) was the first to use the retinoscope for diagnostic purposes, which he did in 1859, in cases of astigmatism and keratoconus. But to Cuiguet of Lille belongs the credit of introducing this method of determining refraction into practice, and without being acquainted with Bowman's observations on this subject. Mengin, Parent, Forbes, Morton, Loisseau, Chernly, were early writers and advocates of this method. This method of determining the errors of refraction was, and is now, extensively employed in England and to a great extent on the Continent, but has not been used in America extensively until within the last few years. The simplicity and cheapness of the instrument are in its favor, also the fact that the total refractive error is measured by its use. Nevertheless, because of the difficulty of acquiring the method of accurately using the instrument, the time it requires to determine each case of refractive error by placing the lenses in front of the patient's eyes to arrive at the correct diagnosis, and, above all, because it requires the eye to be under the influence of a mydriatic before it can be used to the best advantage, it has not met with the widest favor.

Muscle Insufficiencies and Functional Neuroses.—To a thorough study of the ocular muscles and their insufficiencies we are indebted, first, to von Graefe, and after him to Wecker, Javal, Knapp, Maddox, Noyes, Landolt, Roosa, Stevens, Ranney, Worth, Howe, Priestley Smith, Gould, and Savage, together with many other notable workers. Some of these, it is true, especially in this country, made extravagant and unconfirmed claims in reference to the importance of muscular insufficiencies in the production of asthenopia, functional neuroses, and even to constitutional diseases. Of these functional neuroses and other ailments supposed to be due to errors of refraction and insufficiencies of the ocular muscles, a brief notice by way of the history of the subject is necessary here.

Dr. George M. Gould of Philadelphia (*Journal American Medical Association*, January 16, 1904) gives the credit to Savage as being probably the first to call attention to ocular headaches. Following Savage, Heberden (1803) speaks of ocular headaches in connection with overwork with the eyes. Priorry, in 1831, came nearer to describing the true nature of headaches originating from use of the eyes. Many writers after Priorry, as Lawrence, Mackenzie, etc., described the true clinical picture of migrainic headaches, following the use of the eye, but did not recognize them as the true and underlying cause of it, as that of hypermetropia and astigmatism. Donders was the first to recognize the causative relation of hypermetropia and hypermetropic astigmatism to headaches, and to prescribe glasses accordingly, and he cites such cases in his book, "Accommodation and Refraction of the Eye," page 233. Dobrowlsky (*Archiv für Ophthalmologie*, 1868) reported like results, and this same author was the first to call at-

tention to dynamic astigmatism, caused by irregular contraction of the ciliary muscle. In 1869, in this country, Carleton, in an article on the "Use and Abuse of Spectacles" (*Proceedings Connecticut Medical Society*, 1869) cites such cases, and the possibility of cure with correcting glasses. Dr. S. Weir Mitchell of Philadelphia (*Medical and Surgical Reporter*) called attention to ocular headaches which came from some intraocular disorder, or disorder in the motor muscles of the eyeball, and cites cases from the Case Book of Dr. Wm. Thompson, one of hypermetropia and one of myopic astigmatism, in both of which headaches were prominent symptoms, and in each instance relief came with the proper glasses. In the case of hypermetropia the headaches were migrainic in character, beginning with blindness over one-half of the field of vision and ending in nausea and vomiting. In 1868, in the *Journal of Medical Science*, Mitchell again forcibly called attention to the fact that headaches migrainic in character, nausea, vomiting, and vertigo were due to errors of refraction and accommodation, and also that muscle insufficiencies might cause headaches. He says in this article: "What I desire, therefore, to make clear to the profession at large is: (1) That there are many headaches which are due indirectly to disorders of the refractive or accommodative apparatus of the eye. (2) That in these instances the brain symptoms are often the most prominent and sometimes the sole prominent symptom of the eye trouble, so that while there may be no pain or sense of fatigue in the eye, the strain with which it is used may be interpreted solely by occipital or frontal headache. (3) That the long continuance of eye trouble may be the unsuspected source of insomnia, vertigo, nausea, and general failure of health." In 1879, Dr. Wm. Thompson of Philadelphia reports cases in which headaches, nausea, vomiting, and twitching of the muscles of the face were due to errors of refraction, and which symptoms were cured by proper correcting glasses. Many other writers have reported such cases, and emphasized the importance of refractive errors in the production of the same.

It remained for Dr. George T. Stevens of Albany, now of New York, to make the claim that chorea, epilepsy, etc., and functional nervous diseases were due to anomalies of refraction and accommodation, and to difficulties in adjusting the eyes in the act of vision. In his earlier writings (*Transactions New York Academy of Medicine*, Vol. II, page 440) he claimed that it was hypermetropia chiefly that was responsible for these functional nervous troubles; but later ("Functional Nervous Diseases," George T. Stevens, M.D., 1887; also *New York Medical Journal*, page 428) he shifted to muscle insufficiencies as the chief cause, and advised prism exercises, the wearing of prisms, and graduated tenotomies, with which methods of treatment he claimed to cure such functional neuroses. Some of his pupils and others have claimed to cure not only functional nervous diseases, but even grave constitutional diseases. Dr. St. John Roosa and Charles Stedman Bull of New York were the earliest writers to combat Stevens' views. Bull (MEDICAL RECORD, Vol. 12, page 239) as early as 1877 read a paper before the New York Medical Journal Association, entitled "The Connection Between Chorea and Errors of Refraction." In this paper he reports thirty-one cases of chorea, and is unable to trace the causative relations between the errors of refraction or muscle insufficiencies and the disease. Roosa made observations along this line in the same year, and in 1880, in a paper entitled "The Cure of Constitutional Diseases by the Use of Glasses," repudiates the claims made by Stevens. Roosa's views on this subject are so well known it is necessary for me to make but a brief quotation from him, giving his past and present position on this subject: "The belief in any morbid constitutional condition of more than passing nature, being dependent upon an error of refraction or a latent insufficiency of an external muscle of the eye, I could never accept, and my views upon this subject were placed before the profession at a very early date. Time and added experience have deepened my conviction that the cures accomplished by tenotomies and prisms in such cases were mainly suggestive and many of them were illusory, occurring in neurotics who came into the world with an abnormal nervous system, and in whom symptoms are as variable as the changing of the wind." ("Treatise on Diseases of the Eye," page 520.)

In a recent article upon "The Symptoms of Ammetropia,"* Dr. H. F. Hansell of Philadelphia has this to say: "Perhaps the strongest argument that can be brought to weaken the claims of ophthalmologists that many of the functional nervous diseases are due to errors of refraction and muscular anomalies is that the ophthalmologists do not see their failures as often as nerologists see them, and the failures are never published. We read of cures of all kinds of reflexes by glasses, but we do not see records of failures to cure." And again: "We read that 80 percent. of all headaches are ocular. This means presumably that 80 per cent. of the cases of headache applying at the oculist's office are relieved by ocular treatment, and 20 per cent. are not benefited. Of the other cases of headache, those that do not seek ocular treatment, no account is taken."

Another recent writer (Max Talmey, *New York Medical Journal* and *Philadelphia Medical Journal*, December 2, 1905) says: "Certain devotees of ophthalmology surpass those of any other specialty with their wonderful therapeutic achievements by the most simple means. Severe diseases that have persisted for years have been cured by a little operation lasting about fifteen minutes. Cutting of the external eye muscles has removed many ailments. In some instances the simplicity of the remedy for the cure of obstinate diseases that have baffled the skill of the internist and neurologist is nothing short of marvelous. The patient does not even need to undergo the discomfort of swallowing an unpalatable medicine. One prescription for glasses after a short examination suffices to cure a wide variety of grave symptoms, of such diseases even that formerly nobody would have considered as having any relation to a defect of the eyes." And this same author quotes three eminent neurologists to the following effect: "Not less marvelous is the report of the cure of general paresis obtained by the correction of errors of refraction." Dr. Edward D. Fisher, in his illuminating article on "The Value of the Recognition of Errors of Refraction in Functional Diseases of the Nervous System," says: "General paresis is a disease with a known pathological history, inflammatory in character . . . ; and yet cases are recorded of cures of this disease by correction of errors of refraction."

Dr. Charles L. Dana concludes his article on "Eye Strain and the Psychoses" with the following words: "Perhaps, after all, the most real psychosis connected with eyestrain is that shown by a group of enthusiastic oculists who have become obsessed with the idea that eyestrain forms the background of

*Ophthalmology, January, 1906.

most pathological conditions, and, like Bishop Berkeley and his tar water, think that the whole material universe is nothing and eyestrain is everything. With due respect also to my learned colleagues, I should suggest that 'glassing' has become something of, at any rate, a minor psychosis." Similarly flattering to a sort of oculists is the judgment of Dr. B. Sachs. He says: "The relationship between ocular affections and epilepsy, chorea, and convulsive tic may be a close one in the minds of some 'faddists,' but it must remain a very remote one in the minds of those who have no special axes to grind and no particular therapeutic territory to exploit."

But perhaps the position of American ophthalmologists upon this subject is best presented in a very recent paper by Dr. Howe of Buffalo in *Ophthalmology*, January, 1906. Dr. Howe sent out 198 circular letters, 162 of these to members of the American Ophthalmological Society, 8 to oculists not members, and to 28 others, some of whom did not claim to be ophthalmologists, but whom the writer of the "New Ophthalmology" had named as being advocates of the so-called advanced views. The questions were as follows:

1. How many, or about how many, cases of diseases of the eye have you recorded as seen in private and in hospital or dispensary practice altogether?

2. Among them all, how many have you recorded in which "eyestrain" can justly be considered in any way a cause of any one of the following diseases or conditions? (The diseases are selected from the articles on the New Ophthalmology.) Keratitis? Iritis? Glaucoma? Cataract? Choroidal diseases? Hyperemia of the retina? Diseases of the macula in any form? Pigmented retinitis? Other retinal diseases? Sinus diseases? Pharyngitis? Laryngitis? Aphonia? Common colds? Influenza? Pneumonia? Tuberculosis? Anorexia? Denutrition? Intestinal fermentation? Constipation? Disorder of the liver? Dyspepsia? Loss of appetite? Nephritis? Cardiac palpitation? Chorea? Epilepsy? Insomnia? Scoliosis?

Dr. Howe received 150 replies; 24 of these were complete in every particular, while 47 were fairly complete (enough so to draw conclusions from), while the remainder were so incomplete that they could not be made use of.

Of the 24 who made complete replies, 20 had not seen a single case in which the diseased conditions or reflexes mentioned in the circular letter were apparently due to eyestrain. Four of these observers, however, reported that the following were apparently the result of the eyestrain, namely: Choroidal diseases, 3; diseases of the macula, 1; hysterical laryngitis, 1; chorea, 1; epilepsy, 5; insomnia, 12. That is to say, these are all of the diseases or reflexes which were found by these 24 men among about 350,000 cases of refraction or muscular anomalies. What has been said thus far of the results relates only to twenty-four observers. But there were forty-seven others whose testimony is not to be left out of account. They gave approximately their total experience in figures, but they did not answer the other questions with figures. Instead, they were in doubt as to having seen some of these conditions or reflexes (as can occur to any of us), or they reported simply "a few cases" or "many," etc. Evidently it is impossible to make a statistical classification of these replies. But it is possible to classify the doctors themselves. That is to say, it is possible to state how many of the entire eighty-one saw examples of this or that disease or symptom in the list cited, and also what that experience was. This is shown in the following table. "In this the first column gives the number of observers who have not seen any of the reflexes or conditions mentioned in the list. The second column gives the number of those who were doubtful if they had seen any such. The third column, the number who were quite sure that at some time they had observed some such symptoms or conditions; the fourth column, 'A,' the number who had seen 'a few'; the fifth column, 'B,' the number who had seen 'several' or 'some,; the sixth column, 'C,' the number who had seen 'a number' or more.

	None.	Doubtful.	Yes.	A.	B.	C.
Keratitis	64	4	1	2	..	..
Iritis	66	2	..	3	..	..
Glaucoma	60	7	1	3	..	..
Cataract	60	4	1	5	..	1
Choroidal diseases	58	2	3	8	..	..
Hyperemia of retina	46	4	4	14	..	3
Macular changes	60	3	3	5	..	..
Anorexia	67	1	3	..	..	..
Denutrition	66	..	3	2	..	..
Intestinal fermentation	69	..	1	..	1	..
Constipation	67	..	1	3	..	..
Disordered liver	68	..	1	1	..	1
Dyspepsia	60	..	4	7	..	..
Loss of appetite	60	..	4	7	..	..
Nephritis	69	2	..	..	..	..
Cardiac palpitation	65	..	3	3	..	..
Chorea	46	2	4	18	..	1
Epilepsy	55	2	1	13	..	..
Insomnia	49	2	8	10	..	2
Scoliosis	69	1	..	1	..	..

"These data and a more careful study of the answers show: 1. That the personal equation enters largely into these reports. Only comparatively few individuals have seen many such reflexes, while most have observed only a few or none at all. 2. This large experience shows, beyond question, that in the future it will be impossible for anyone to repeat the claim that these reflexes or conditions, or any of a similar kind, are considered by most American ophthalmologists to be the result of eyestrain. That is simply the assumption of a few enthusiasts. 3. An important cause of our confusion is the lack of definition of the morbid conditions under discussion—such terms as intestinal fermentation, disorders of the liver, nephritis, etc., having no definite meaning. 4. Another cause is the lack of exact diagnosis of the condition or the symptom which is suspected to be the result of the eyestrain. One man may call a hyperemia of the retina what another would call normal eye ground."

I have made these rather long quotations to show just how we in America to-day stand on this important matter of refraction. It shows that, while we have a few altogether over-enthusiastic members in the specialty, the great majority of us are on a sane and safe basis and have the correct understanding of the subject. As Hansell aptly puts it: "We have not yet advanced to that stage when we study diseases of the body in relation to ocular defects, and fail to consider diseases of the eye in relation to general diseases." (*Ophthalmology*, January, 1906, page 210.)

The Present Status of the Science and Art of Fitting Glasses.—It may be said without fear of contradiction, I think, that America to-day stands at the head of the medical profession in the science and art of fitting glasses. Abroad, with a few conspicuous exceptions, the oculist devotes most of his energies to the study of the inflammatory and pathological conditions of the eye, and to the operative procedures on that organ. And oculists have given so much time and endeavor to these studies and to the collec-

tion of microscopic and macroscopic specimens that they have neglected in a great measure to give due attention to this less attractive but equally important and practical branch of ophthalmology—the art of fitting glasses. Javal and Bull of Paris and the two Snellens of Utrecht are among the brilliant exceptions. In America, on the other hand, especially in the last fifteen or twenty years, the closest attention has been given to the study of anomalies of refraction and accommodation. Much consideration has also been given to the subject of muscle insufficiencies, not only relative to the eye symptoms present, but to their bearing on the general health and comfort of the patient. To such men as Knapp, Roosa, Loring, Noyes, Stevens, Bull, Gruening, Agnew, John Greene, H. Derby, William Thompson, Gould, Burnett, Myles Standish, Alt, Jackson, etc., and to many younger men, whom space forbids to mention, though they have done much good and conscientious work in this line, we owe the present advanced and perfected state of this branch of ophthalmology.

To the neurologists we are indebted, too, especially to S. Weir Mitchell of Philadelphia, who, though not an oculist, was one of the very earliest observers to call attention to the fact that in many instances headache, insomnia, vertigo, nausea, and other nervous symptoms were caused either by refractive errors or ocular insufficiencies. It is true that in some instances a great deal too much has been claimed for the rôle played by the so-called eyestrain as a cause of functional nervous troubles and of other ailments of the human body. But these extravagant claims are soon shown not to be based on fact, and although temporary harm may result, in the end it is only the truth which prevails.

In America we are divided as to the importance of the rôle which muscular insufficiencies play in the production of asthenopia and functional neuroses. Individually, after giving it thorough study and trial, I place but little importance to the insufficiencies of the ocular muscles in the production of asthenopia, and for that reason shall give it but little space in this paper, but shall direct my efforts to the proper technique in the correction of errors of refraction and accommodation.

In this country, too, it may be stated that there is a division of opinion as to the necessity of the use of cyclopegics in testing for errors of refraction. I am one of that number who believe their use is seldom called for in patients over ten years of age. I have come to this conclusion after thoroughly testing both methods, that is, with and without cyclopegics. In children under ten years of age, the mentally deficient, and in rare cases in which spasm of the accommodation is present, I use a strong cyclopegic, but in no other cases. I have better results and change fewer glasses when following this method than when I used cyclopegics as a routine practice. And we must be guided by our experiences and results, for it is results after all that we are looking for. If we are to arrive at a proper conclusion as to which is the best method, we should report our failures as well as our successes for the different methods, which I propose to do in this paper. Furthermore, I shall try to tell the truth, that my confreres may compare these results with their own, to the end that the most direct method may finally be adopted.

The Different Tests Usually Employed in Fitting Glasses.—These are twofold: Objective and subjective. The objective tests are, first, the use of the ophthalmoscope; second, the use of the ophthalmometer; third, the use of the retinoscope. The subjective tests are made by means of test letters and test types (Snellen's and Jaeger's are standard), astigmatic charts and letters, with the assistance of trial lenses and prisms, kinescopy, and tests based on Schreiner's experiment.

After the refractive error has been corrected, and with the trial lenses in position in the trial frames, tests for insufficiencies of the ocular muscles are made by means of a candle for the distance, or a dot on a sheet of white paper for the near point, and with the aid of prisms, the phorometer, or tropometer. My own method of procedure in the ordinary refractive cases is as follows: First, use the ophthalmometer; second, use the trial lenses and test cards; third, use the ophthalmoscope; fourth, if after two tests on different days the result is still unsatisfactory, employ a cyclopegic and use the retinoscope in addition to the other tests. The reason that I do not, as a rule, use the ophthalmoscope before testing with the trial lenses is that if light is thrown into the eye for a prolonged time, it dazzles the sight and impairs the value of an immediate test with the trial lenses. If I have much trouble, however, in finding the proper glass, I do not hesitate to use the ophthalmoscope to find the nature of the error of refraction, or if any pathological condition of the eye exists; then let the patient wait a short while before the subjective test with the trial lenses is again undertaken.

Simple cases of hypermetropia and myopia are usually easily fitted with glasses; but a certain definite method should be followed even in these cases. It is the astigmatic cases that give most trouble, and among these, as is well known, the compound hypermetropic and mixed astigmatisms are the most difficult to fit. Astigmatism is the thing of most importance in the correction of errors of refraction, and I invariably correct the astigmatism first, unless there is a large amount of spherical error present, with only a small amount of astigmatism. In such cases, part of the spherical error is first to be corrected, in order, if possible, to bring up the vision sufficiently, so that the eye will appreciate any further change in acuity of vision when a weak cylindrical glass is placed in front of it.

I always begin my test by putting on plus glasses; plus cylindrical glasses if astigmatism is present, plus spherical glasses if astigmatism is absent, and for the following reasons: first, because we do not know if the patient is hypermetropic or myopic. If the patient happens to be hypermetropic, and minus glasses are first tried, the patient many times accepts them, especially if the error is of low amount, though the patient is really hypermetropic. The eye instinctively makes an effort to overcome minus glasses when placed in front of it, the ciliary muscle is thrown into a spasm of accommodation, producing an artificial myopia, which the minus glass partly or wholly corrects, and in this way apparently improves vision. The mere fact that a patient accepts minus glasses is no indication whatever that he has myopia. Furthermore, minus glasses should never be tried until plus glasses have been tried, unless we know beforehand that the patient is really myopic, for they tend to incite a spasm of accommodation, which is the very thing we wish to avoid.

The thing of next importance to plus glasses in beginning a test is that we shall begin with the weakest lenses in the trial case, and go up gradually. I do this also to avoid spasm of accommodation, for by adding a quarter of a diopter at a time the eye accustoms itself to it, and the ciliary muscle relaxes gradually, if it is only given a chance. Should all, or almost all, of the correction be put on at once, however, the change for the eye is so sudden and marked that it will not adjust itself to it;

whereas, had the glasses been gradually increased in power, the ciliary muscle would have relaxed. This is my experience, and I believe it accords with that of the great majority of observers. By following this plan, spasm of accommodation, if present, can, in the great majority of cases, be overcome, and, if not present, the liability of causing it be avoided.

After using the trial lenses, I next take the patient into the dark room and examine with the ophthalmoscope. If this test confirms approximately the test with the ophthalmometer and trial lenses, I then, with the glasses in position, test for muscle insufficiencies, by the simple prism test—that is, for adduction, abduction, circumduction. In this way the relative strength of the muscles is shown, and if insufficiencies are present the indication for treatment is suggested. If the simple prism test is not satisfactory, I find the amplitude of convergence, after Landolt's method. For functional insufficiencies of the ocular muscles I rely wholly on correcting refractive errors properly, general tonics, and rest, for a cure. If not relieved in this way, and the insufficiency progresses into a strabismus, I perform a complete tenotomy of the opposing muscle. I have long since given up graduated tenotomies, prism exercises, or even the prescribing of prisms in these cases. As a matter of fact, I remove almost daily glasses with prism combinations in them prescribed by other oculists, and place in their stead simply the correction of the refractive error; and these glasses, with the proper constitutional treatment, give relief in the great majority of cases. Prisms do not afford, but for a brief space of time, relief in functional ocular insufficiencies. On the contrary, they only make matters worse. In my experience, in those cases in which prisms have been of benefit—and the number is exceedingly few—the insufficiencies were not functional, but, in my opinion, were due to anatomical anomalies, or to a true paresis of the muscle. The anatomical anomalies were an actual shortening of a muscle or a faulty attachment.

If, after two tests for glasses without the use of cyclopegics, the tests are unsatisfactory and do not correspond—that is, if there are evidences of spasm of the accommodation—manifested subjectively by the patient first accepting a certain glass and then rejecting it, by the patient being able to read certain letters at one time, and in a few minutes having them fade from vision; or, objectively, when the ophthalmoscope shows a large amount of latent hypermetropia, which was not manifested by the subjective test, I use a cyclopegic, a strong one, and employ retinoscopy in addition to the other tests. Retinoscopy is a thoroughly reliable test after a cyclopegic has been used, but not before. As I now seldom use cyclopegics, for that very reason I rarely employ the retinoscopic test. Formerly, when I used mydriatics in all cases under 40 years of age, I made use of this valuable test. It can be practised with a concave or a plane mirror. The plane mirror with a small sight-hole, two millimeters in diameter, not cut through the glass, is the best one to employ. One meter distance should separate the observer and the patient, and the light should be as near the observer as possible (4 or 5 inches). The whole test depends on finding the point of reversal of the fundus reflex or illumination. If this point of reversal is not within the meter distance separating the patient and the observer it should be brought there by placing convex glasses in the trial frames which are on the patient's face. The glass required to just reverse the motion of the shadow expresses the nature and degree of the error of refraction, after adding one diopter negative glass to the findings. For example, if it takes a + 4 D. to reverse the image in a certain case we have but three diopters of hypermetropia, as minus 1 D. added to + 4 D. gives + 3 D. On the other hand, if it requires a minus 4 D. to reverse the image we really have a myopia of 5 D. present, as minus 1 D. must be added to the glass already found. A good plan, as Dr. Thorington suggests, is always to add minus 1 D. to the neutralizing glass found in the dark room. When the concave mirror is used in retinoscopy, the light must be placed beyond the patient's head; and in this instance the motions of the shadow in the different refractive errors are just the reverse to those observed when the plane mirror is used. The advantages of retinoscopy as an objective test are: First, cheapness of equipment; second, it measures the total refractive error; third, in common with the other objective tests, in the mentally defective, illiterates, etc., we do not have to depend on the answers of the patient. Its disadvantages are, first, a mydriatic must be used in most cases in order that the average observer may use the test correctly; second, uncertainty of finding the exact axis of the cylinder to be worn, which is a very serious objection. Dr. Thorington's axonometer does away with this objection to a certain extent; but in this respect—that is, finding the axis at which cylinders are to be worn—the retinoscope is far inferior to the ophthalmometer. I have found the most important thing in correcting astigmatic errors is to find the correct axis at which the cylinder should be worn. The amount of astigmatism, as a rule, can be found out without the use of a cyclopegic. The ophthalmometer is superior to the retinoscope in these two important respects: First, in finding the correct axis at which the cylindrical glass is to be worn; second, in that it enables us to fit glasses without the use of a mydriatic or a cyclopegic in the great majority of cases; third, in a minor respect that the test for glasses can be made much more rapidly with the use of the ophthalometer than with the retinoscope. A no inconsiderable advantage, however, when we remember the value of time to the busy practitioner.

The ophthalmometer is inferior to the retinoscope: First, in respect to cost, it being an expensive instrument; second, in not indicating the total refractive error present. Relative to the last disadvantage, in my experience, it is only in exceptional cases that we need to take into account the total refractive error in order to give the correct glasses. These are cases of spasm of accommodations, mentally deficients, and amblyopics, and in these exceptional cases the retinoscope is of the greatest advantage, and it is in just these cases that I make use of it; because here we must use a cyclopegic. But in the great majority of cases it is necessary to correct only the astigmatism and the manifest spherical error, in order to obtain relief from asthenopic symptoms. Astigmatism is the most important factor in the causation of asthenopia, and with this properly corrected, together with the manifest spherical error, the latent error may be neglected without harm, and to my mind with benefit. All the tests must be used in such cases, especially the objective tests. And this brings me to a consideration of the use of mydriatics, and cyclopegics in fitting glasses.

Shall We, or Shall We Not, Use Cyclopegics as a Routine Practice in Fitting Glasses?—In answer to this question, my reply is emphatically in the negative. It is neither necessary or desirable to use cyclopegics as a routine practice; they should be

used only exceptionally. I have come to this conclusion after having thoroughly tried both methods. As I have already said earlier in this paper, we must judge of the efficacy of any method by the results obtained, and my results have been better without the routine use of cyclopegics than with them. That is, I have changed fewer glasses and given better satisfaction to my patients without than with the use of cyclopegics. If I am compelled to change a pair of glasses within six months after having prescribed them, I count it as a mistake made by myself. When using cyclopegics, the tendency was always to overcorrect the spherical error of refraction, that is, to give too strong plus glasses in hypermetropia, with the result that the glasses at times had to be weakened, at least the spherical part of the glass. And this same error or mistake is now being made by my confrères who use cyclopegics as a matter of routine, if I may judge of cases that come to me with unsatisfactory glasses. Nine-tenths of these cases have too full a correction. Perhaps my patients, whom I now fit without the use of cyclopegics, and who go to someone else, must have their glasses increased in strength. All I can say is, the unsatisfied ones of my own fitting, who come back to me, even where I fit without the use of a cyclopegic, have been over-corrected, as a rule, and not under-corrected. I have taken the trouble to inquire of a few of the leading opticians in New York City what was the nature of the change most frequently made in the glasses when they were not satisfactory to the patients. Not in the patients of any one oculist, but of them all, just as they were sent to the stores. The answers of these men were to the effect, to use the words of one of them, "Almost invariably we have to reduce the strength of the glasses." Especially in this so with plus glasses. In other words, when a mistake is made in fitting glasses it is usually by ordering too strong a glass.

Then we must consider the danger of using cyclopegics, even the milder ones, in people over forty years of age, as is recommended by many oculists. Now and then the use of a cyclopegic brings on an attack of glaucoma, rarely, of course, but nevertheless it does. Why, therefore, should we unnecessarily sacrifice vision, even in a single instance? The use of cyclopegics for refractive purposes, in people over forty years of age, is not only absolutely unnecessary, but is not without danger. Furthermore, consider the inconvenience to the patient with his eyes disabled from three to ten days. Picture the clerk, the seamstress, the business man, the professional man, disabled this length of time. Then we wonder why patients go to opticians, not poor patients alone, but people who do not have to consider the oculist's fee, but who *will not* submit to the discomforts of cyclopegics. Perhaps one-half of all patients with refractive errors go to opticians to be fitted for glasses; and cyclopegics, unnecessarily used, in my opinion, more than all other factors combined, are the cause of this anomalous state of affairs.

The Adjustment of Glasses.—All the good work of a carefully conducted examination may be brought to naught by having the glasses poorly or improperly adjusted on the patient's face. The prime considerations in the adjustment of glasses are: First, that the lenses should be properly centered in front of the eyes, the center of the glasses corresponding with the visual line (the center of the pupils will do), if the glasses are to be worn for distance; or with the centers of the glasses slightly to the nasal side of the center of the pupil (one to two millimeters) if for reading or near work. A compromise between these two positions should be made if the glasses are to be worn all the time; second, the plane or face of the glass should be perpendicular to the visual line. In distance glasses the face of the glass should be perpendicular, while in reading glasses it should be tilted forward from the perpendicular from five to ten, or even fifteen, degrees; third, the nearness of the glass to the eye must be considered. Glasses should be worn as close to the eye as possible, not to touch the eyelashes. A wider field of vision is obtained in this way. The diameter of the glass should be large enough so that the patient does not see through the edge of the glasses. Spectacles are usually to be preferred to nose glasses, if the patient can be induced to wear them.

Bifocal lenses require a special care in their adjustment, and often then patients are unable to wear them. Of late years invisible bifocals have been introduced. These are made by grinding out of the distance lens a certain amount of glass near its lower border, and in setting into this space a glass of higher index of refraction. In this way a greater refractive power is obtained, which serves for reading purposes. I may say that the cosmetic effects of these invisible bifocals are very good indeed, but the price of the glass is greatly increased.

50 West Thirty-seventh Street.

WHAT HAS SURGERY LEFT TO MEDICINE IN THE TREATMENT OF PERITONITIS IN ADULTS AND CHILDREN?*

By HENRY W. BERG, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS; ADJUNCT PHYSICIAN TO MT. SINAI HOSPITAL, INSTRUCTOR IN INFECTIOUS DISEASES, COLUMBIA UNIVERSITY.

Those who have practised medicine for the past score of years have seen the domain of surgical therapy constantly enlarging, with a corresponding restriction of the field of purely medical treatment. In most cases, however, it will appear on investigation that surgery has not supplanted medicine in cases in which the latter was therapeutically effective, but in only those diseases in which it offered but faint hope of a cure. In no condition has this been more marked than in the treatment of peritonitis. The hesitancy with which the surgeon invaded the peritoneal cavity twenty years ago is more than equaled by the readiness with which he explores, repairs, and removes therefrom diseased and offending structures at the present time. The peritoneum is no longer "forbidden ground." Aseptic surgery and improvements of surgical technique have done so much in the successful prevention and treatment of peritonitis that a discussion of the medical treatment of peritonitis should properly be limited to a discussion of such treatment as applied to non-surgical forms of peritonitis and such types of peritonitis as, while amenable to surgical measures in their inception, have progressed beyond the aid of surgery.

But even in these cases so little does medicine offer, in effective therapy, that the physician frequently permits the surgical exploration of a given case of peritonitis in the hope that it may after all be a type of peritonitis amenable to surgical measures. To-day the physician keeps from the surgeon cases of peritonitis with far more hesitancy than was shown in the invasion of the peritoneum by the surgeon twenty years ago.

What, then, are the types of peritonitis which are

*Read before the Medical Association of the Greater City of New York, April 10, 1906.

not amenable to surgical treatment and what can we do for these medically?

In this connection it will be profitable to classify the various forms of peritonitis occurring clinically into diffuse and circumscribed, acute and chronic. To these most obvious factors in the clinical recognition of a peritonitis it is of importance from a therapeutic standpoint to recognize in a given case whether the pathological process is aseptic or nonpurulent, otherwise known as a fibrinous or serous peritonitis, or whether the process is a septic peritonitis with the presence of pathogenic bacteria as more than an active factor in the inflammation. Finally, belonging to a class by itself and especially interesting from a medical standpoint, the peritonitis due to a specific organism—tuberculous peritonitis. But even when a peritonitis has been classified in accordance with these factors there remains still to determine the point of origin of the peritonitis. From a therapeutic standpoint this factor is perhaps the most important, for its solution, when practicable, carries with it the determination as to whether the case be one in which surgical and operative procedures are the only logical therapeutic measures, at least at the beginning of the peritonitis or even as a prophylactic measure to prevent a peritonitis, or whether the case is properly a medical one, the inflammation to be combated by medical means, surgery in such case offering nothing in prevention or cure of the inflammatory process. Such an etiological classification, if I may call it so, would include:

1. Peritonitis due to rupture or perforation of the hollow viscera—stomach, intestines, appendix, bladder and gall-bladder. This includes gunshot and other wounds as well as autochthonic perforation.

2. Peritonitis due to the spreading of an inflammation by contiguity from localized inflammations of the hollow viscera. A prominent example is the peritonitis accompanying non-suppurative and nonperforative appendicitis, and non-suppurative disease of the gall-bladder.

3. Peritonitis due to (a) suppurative disease of the liver, including echinococcus, cysts, (b) nonsuppurative disease of the liver, such as malignant liver, etc.; (c) subphrenic abscess.

4. Peritonitis due to suppurative or nonsuppurative disease of the kidney and ureters.

5. Peritonitis due to suppurative and nonsuppurative diseases of the pancreas and its ducts.

6. Peritonitis originating in septic or nonseptic diseases of the uterus, Fallopian tubes, ovaries, and vagina, including pelvic peritonitis as far as it affects the peritoneum.

7. Peritonitis due to neoplasms, aneurysms, and ruptured blood-vessels.

8. Peritonitis secondary to surgical operations in which the peritoneal cavity has been invaded.

9. General peritonitis, primary or complicative, of hematogenous origin, *e.g.*, the peritonitis of scarlet fever, pneumonia, rheumatism, gonorrheal peritonitis, etc.

10. The chronic peritonitis due to a specific organism, of which the chief example is tuberculous peritonitis originating in the lymphatic glands and vessels of the abdomen, or at some local site.

It will be seen that in by far the largest portion of these kinds of peritonitis, the mere recognition of the point of origin of the peritonitis at its inception necessitates surgical intervention, and even at any stage, provided the condition of the patient is such that surgical interference still offers a faint hope of success. Thus I believe that a peritonitis due to a perforation of a hollow viscus, provided the diagnosis be beyond question, is to be treated surgically. Of this there is no question, and reports of an occasional case of recovery from such perforation, under medical treatment, as for instance in the case of a peritonitis following a typhoid perforation, should not serve as an excuse for advising or keeping such patient under medical treatment.

But medicine has a legitimate and important function even in these typically surgical types of peritonitis, and that is the prophylactic one—the prevention of the perforation.

It has frequently been a source of surprise to me that perforations of typhoid ulcers are so much rarer in private practice than in hospital work. In a large private practice extending over almost twenty years, in which I treated at least the average number of typhoids, peritonitis due to the rupture of a typhoid ulcer has occurred very rarely. Indeed I can recall it only in about five cases. On the other hand, some years ago out of about 36 typhoid cases seen in hospital practice in a period of two months, four cases of perforation occurred. I suspected that possibly there might be a physical reason for this. I wondered how important an etiological factor in the rupture of these ulcers the examination of the abdomen of a typhoid by the many physicians connected with the house might be. I hinted at such a suspicion to some of the house officers; it was scouted. I was reminded that these perforations were occurring all over the world; that all institutions were reporting large numbers of them; that the reason they were recognized in hospitals was because the means of accurate hourly observations were at hand; that the rise in the leucocyte count so characteristic of a perforation was there readily appreciated even when pain and severe shock were absent; that the frequent examinations and charting of the area of liver dullness in a hospital record enabled us to appreciate the diminution of the liver and splenic dullness long before they had entirely disappeared, as would be the case in private practice. All this and more. But, nevertheless, keeping in mind the thinness of the floor of some typhoid ulcers which I have seen at autopsy, I have steadfastly and firmly interdicted the indiscriminate palpation of the abdomen in typhoid cases. The spleen once palpated and recognized by the fingers of the attending and house physicians, no others should be permitted to palpate the abdomen of a typhoid case, which needs but infrequent and then only the most expert percussion and palpation. The recognition of other abdominal conditions in these cases is best accomplished by the sensitive tactus of the experienced physician, and even this only when absolutely necessary. Typhoid patients as far as their abdomens at least are concerned, are not to be exploited for the furtherance of medical education. I think it will be found that hospitals connected with teaching institutions both at home and abroad, are apt to encounter this complication far more frequently than others not so favored and very much more than patients treated in private practice.

While we are upon this subject of prophylaxis it is well to remember that in this, medical means play an important part in the timely recognition and cure of conditions which would ultimately lead to virulent types of peritonitis if allowed to develop and go untreated. Thus the recognition and cure of ulcers of the stomach, duodenum, colon, and rectum, the early recognition of an appendicitis and the submission of it to a surgical operation before a suppurative peritonitis has developed; the recognition of cholecystitis in its early stages, of impacted calculi, of hepatic abscess—of all these when recognized by medical diagnosis and sent to the surgeon

in time are operated without the likelihood of the development of peritonitis. Prophylaxis in obstetric practice in accordance with the principles of asepsis has made puerperal peritonitis an exceptional instead of a frequent disease. The medical means used in the prevention of general toxemia and sepsis in acute types of pneumonia, scarlet fever, diphtheria, and rheumatism, and other infectious diseases, are prophylactic as well as curative in the prevention of septic and toxic peritonitis as a complication of these diseases. A great factor in such prophylaxis lies in the conservative use of saline cathartics, such as the sulphate of magnesia. The intestines are emptied, meteorism is to that extent prevented, autointoxication does not so readily occur, the pressure of tympanitic intestines against the diaphragm with the interference in the functions of the lungs and heart is obviated, and the return circulation through the veins to the right heart is not impeded—all of these benefits, with many others, accomplished by such simple means as catharsis.

The types of peritonitis included under the second group—those due to the spreading of a peritonitis by contiguity from more or less general or localized inflammations of the hollow viscera, such as for instance the peritonitis common in infants and children, complicating gastroenteritis or enterocolitis—are, as a rule, examples of acute diffuse peritonitis of a nonpurulent type, and such cases are to be treated by the medical means of which I shall speak later, and are in no sense a field for surgical interference. Nonsuppurative local peritonitis complicating nonsuppurative chlelithiasis, and nonsuppurative hepatitis are not necessarily surgical types of peritonitis, although many surgeons believe that every case of cholecystitis due to cholelithiasis should be treated by removing the calculi. And yet this practice has only developed in the last decade; before that we constantly saw such nonsuppurative inflammations subside under the influence of local and general medical measures. And even to-day it occasionally happens to me to see appropriate cases in which I have advised a cholecystotomy or cystectomy refuse to submit to such operation and recover under the medical means that I apply under protest, or some colleague applies with or without protest. They get well of the peritonitis and the cholecystitis and retain their lithiasis. Indeed peritonitis due to nonsuppurative disease of the liver, kidneys, spleen, and even pancreas, subsides under appropriate medical measures if the inflammatory disturbance in the originating viscus is amenable to such measures. Suppurative diseases of these viscera, however, require surgical interference.

I believe that puerperal peritonitis should not be treated by laparotomy. I am sure from a large experience in the medical treatment of such cases that the results even in very severe cases are better than the results reported by laparotomists. The disease is eminently a general septic disease with a local origin. When peritonitis has developed, the removal of the uterus does not diminish the general septicemia. I think the consensus of opinion is in favor of treating puerperal peritonitis with or without septicemia by medical means. I would not exclude from such measures the medication and curetting of the endometrium. By purely surgical measures I mean laparotomy and removal of the uterus or uterus and adnexa.

Peritonitis secondary to surgical operations, as well as peritonitis which has not been relieved by surgical operations looks to medicine as its *dernier resort*. However hopeless the outlook, measures of a medical nature can be applied for alleviation and sometimes an unlooked-for cure. Peritonitis hematogenous in its origin, generally nonsuppurative, complicating infectious diseases, must be treated medically. And finally, tuberculous peritonitis is by many considered a surgical affection; by others of equally competent authority it is claimed that results are better from nonsurgical interference. When we have arrived at a specific for tuberculosis I think that there is no question that this type of peritonitis will be purely medical. At the present time even those who laparotomize cases of tuberculous peritonitis do not recognize in this operation *per se* any curative effect such as that readily appreciated in the purulent peritonitis complicating purulent appendicitis for instance. The surgeon simply finds empirically that cases thus laparotomized, at first under a mistaken diagnosis, mysteriously improve and some get well. I believe that the best explanation of such surgical cures of tuberculous peritonitis is on the basis of Metchnikoff's theory of immunity and cure in infectious disease processes. The incision through the abdominal parietal peritoneum in these cases brings to the field of operation a large excess of leucocytes, which exercise their phagocytic activity, destroying the tubercles and bacilli and setting up a reparative process.

Now as to the question of what medicine can do for the nonsurgical types of peritonitis.

First of all, as to serum therapy in these hopeless cases of peritonitis. In this connection it will be interesting to remember that the bacterial organisms found in various types of peritonitis are very numerous. In some cases and stages of the process the bacteria are found in almost pure culture, but in by far the larger majority they are present as examples of mixed infection. The most frequent bacteria found in peritonitis, whether of the adhesive or of the purulent type, are the *Streptococcus pyogenes*, the *Bacillus coli communis* and the *Diplococcus pneumoniæ;* in chronic peritonitis the tubercle bacillus. In very young children there is an extremely fatal type of peritonitis in which immediately after death the *Diplococcus pneumoniæ* can be isolated from the peritoneum in almost pure culture. This is a type of peritonitis which does very badly when submitted to surgical interference. Such cases when operated under a mistaken diagnosis of appendictis generally die. I have no doubt that many of the cases of peritonitis in infants that recover under medical treatment are of this type in which the bacteriological diagnosis has not been made. This form of peritonitis often occurs in such children independently of pneumonia, is more frequent in girls than in boys, and this is accounted for by the ease of entrance of the organism into the peritoneum through the vaginal-uterine-Fallopian route. The cases are frequently mistaken for appendicitis because this type of peritonitis is generally limited to the lower regions of the abdomen. *Streptococcus pyogenes* is found in almost every kind of acute purulent peritonitis and is especially of importance in puerperal peritonitis; while *Bacillus coli communis* is almost omnipresent in the peritonitis of intestinal origin, including appendicitis, the peritonitis accompanying wounds and ruptures of the intestines, volvulus, intraabdominal and hernial intestinal strangulation, etc.

The types of the peritonitis due to the streptococcus, especially puerperal peritonitis, have been treated in recent years quite generally with an antistreptococcus serum together with other means. Some authorities believe there is some efficacy in such treatment. I do not think that we have any

reason logically to expect that any of the bacteriolytic sera have much curative power, depending as do they for their action not only upon the antibodies which they contain but also on the presence of the unstable alexin or complement present in limited amounts in the body of the patient. The bacteriolysis is therefore so limited that but small amounts of bacteria are destroyed by even the largest possible doses of such sera, which are insufficient to cure the bacterial infection. Nevertheless such antistreptococcus serum in the treatment of general peritonitis of the puerperal variety I have used, and have seen cases recover. I am disposed to think that they would have recovered from the other means instituted as well. I generally inject this serum (Marmorek) in doses of 20 c.c. twice a day until I have injected 150 to 200 c.c. As far as the other two bacteriological types of acute peritonitis are concerned, the coli and the pneumococcus type, I know of no cases having been treated by serum therapy. The tubercular peritonitis might logically be treated by the modified tuberculin of Koch. I have seen no cases thus treated. For diagnosis the Koch tuberculin can be used in doubtful cases with no temperature or very slight temperature. An acute rise in temperature after the injection would speak in a diagnostic way in favor of tubercular peritonitis.

The purely medical treatment of peritonitis is best considered from the standpoint of the treatment of acute general peritonitis. First then in a given case is the diagnosis. By that I do not mean the recognition of the fact that a peritonitis exists, but as far as possible the cause in the given case of the peritonitis that is present. In what organ or at what site did it originate? The patient's history will frequently be of but little assistance. In infants the complicating type, and the independent pneumococcus type are frequent. In young women peritonitis from the internal sexual organs is not rare, and some of them carefully conceal this etiological factor. A general inquiry as to the causation of every case is absolutely essential, for upon this determination depends to a great extent the important fact as to whether the case should be treated surgically or by medical means. Having determined that the case is a proper one for medical treatment, we are immediately confronted with the prime necessity, as far as the patient is concerned, of relieving pain. For this purpose I use morphine by hypodermatic injection. I give sufficient to control the pain, but no more than this. I am cognizant of the fact that this by no means answers the requirements of the old-fashioned opium treatment of peritonitis, with which the name of Clark was identified, in this city, more than a score of years ago.

My admiration for Alonzo Clark does not blind me to the fact that the treatment of peritonitis in the presurgical days included the treatment of a vast number of cases of perforative peritonitis complicating the unrecognized suppurative appendicitis, and that in such cases the pushing of opium to the point at which all peristalsis ceased was all-important. It prevented the further soiling of the peritoneal cavity by the pouring out through the perforation of intraintestinal contents and pus, and the breaking of the adhesions by which nature attempted to close such perforations. But at the present time such perforative cases are treated surgically, and for the medical cases of acute general peritonitis the absolute cessation of *all* peristalsis to the point of paralysis is not of unmixed advantage. It increases the constipation, intensifies the paralytic condition of the bowels, aggravates the meteorism, encourages the vomiting, and it paralyzes by the pressure of the inflated intestine the diaphragmatic movements. Absorption of pathological products from the peritoneum depends upon the capillaries, lymphatics, cellular activity of the peritoneal endothelium, and pneumatically upon the excursions of the diaphragm. So that the absolute paralysis of peristalsis and great diminution of the extent and frequency of the diaphragmatic movements discourage the absorption of pathological products from the peritoneum.

I would not, however, be understood as claiming that it is desirable in peritonitis to increase peristalsis. Far from this. But we must face the problem, weigh the dangers and the advantages of the effects which we desire to produce in a given case and employ the means capable of accomplishing them. I feel, however, that the opium treatment as pushed to the extreme has no place in the modern therapy of peritonitis. Nevertheless the intestines must be kept quiet, for increased peristalsis due to catharsis spreads the pathological process through unaffected areas of peritoneum, breaks up adhesions and does infinite harm. So that cathartics, except in the first and incipient stage of the peritonitis, are contraindicated. In this respect my experience has shown a decided improvement following the use of a brisk cathartic in the threatening peritonitis complicating any ileocollitis. I have already referred to the admirable effect of cathartics at the incipience of a pelvic peritonitis and sometimes of a puerperal peritonitis. I repeat, however, that such measures are to be used only at the very beginning of the peritonitis. The best cathartics for this purpose are the saline cathartics—Epsom and Rochelle salts, in divided doses. In adults 1 dr. every 15 minutes in hot water until 4 to 6 doses have been taken, or a calomel series of ½ gr. every quarter hour until 5 grs. have been taken. This method of treatment of incipient peritonitis has many advocates in this country and England.

In cases of peritonitis which I have believed rheumatic in their origin and also in other cases of acute, general nonsuppurative peritonitis in adults and children, I have used in the past few years rectal injections of sodium salicylate; in adults 1 dr. once a day in a half pint of warm water injected high up in the rectum; in children a year old, 3 to 5 grs. in one ounce of water. I have seen cases of this type improve remarkably under these injections, and while in rheumatic peritonitis the etiological connection between the remedy and the beneficial result is evident, the well known antiseptic powers of the salicylate salts might explain the beneficial effects in the other cases.

As far as the general septicemia and toxemia are concerned we can do as little here as we can do for these conditions in other diseases. My friend, Dr. Alfred Meyer, is fond of using the unguentum Credé in septic diseases of various nature—pneumonia, cerebrospinal meningitis, etc. In two cases of peritonitis (puerperal) recently seen by me daily inunctions of appropriate doses (ʒss. twice a day for four days in thighs and buttocks) were ordered as part of the treatment. One of the patients recovered. It is a remedy easily applied and surely does no harm. On the other hand I am disposed to be more enthusiastic concerning hypodermoclysis with physiological salt solution into the breasts and thighs, especially in septic peritonitis, and more especially when it complicates the infectious diseases such as scarlet fever, pneumonia, etc. As to the modus operandi of this remedial measure let us not inquire on this occasion too closely. Does it dilute the poisons in the blood? Does it enable the kidney by diuresis to excrete more of the toxic materials from

the body? Does it act as a heart stimulant? All of these suppositions might explain the undoubted beneficial effects of the measure. Such hypodermoclysis, or venous infusions are also frequently made use of by the surgeons in the treatment of their cases of suppurative general peritonitis before or after operation, with markedly beneficial results, and some surgeons recommend the performance of such transfusions immediately before operating for peritonitis.

I need scarcely mention that patients with peritonitis are treated by absolute rest in bed and are to be kept on fluid diet. Indeed if there is much vomiting they are best maintained by rectal feeding. I have been in the habit of further alleviating the pain of peritonitis by the application of the Leiter Coil with ice water. The ice bag is absolutely contraindicated on account of its weight and bulkiness. I have tried in former years hot applications and poultices over the abdomen, and find that they make most patients uncomfortable besides weakening them by the perspiration which they encourage. I do not, however, think that the cold coil has any antipyretic effect, and I am sure it has no prophylactic action in the prevention of a peritonitis. Blistering the surface of the peritoneum is of doubtful efficiency. Although where the area affected is limited, as in pelvic peritonitis (lower abdomen) I use blisters I believe with benefit. The theory of phagocytic action explains the undoubtedly beneficial effects which they exert upon inflammatory processes.

The measures I have mentioned are intended to antagonize this disease as a disease. But certain of the individual symptoms through their urgency require especial attention. First of these is vomiting. If the vomitus is alkaline in reaction I give minute doses of morphine with a drop of aromatic sulphuric acid in a little chopped ice. If the vomitus be acid in reaction I give small doses of the carbonate of magnesia combined with minute doses of morphine frequently repeated. In adults this is given in pill form: in children as small powders in chopped ice. The most valuable agent, however, for excessive vomiting in peritonitis is lavage of the stomach, the quantity of water and the duration of the process depending upon the strength of the patient. So also tympanitis and meteorism which cannot be relieved by the passage and keeping *in situ* for a half hour of a high rectal tube, is best treated by lavage of the bowels with warm water to which some salt or sodium salicylate has been added. Owing to the fact that the phrenic nerve distributes sensitive fibers to the peritoneum, hiccough is a frequent and distressing symptom of this disease, for which we have no really effective remedy. Of occasional efficacy is Siberian musk in small doses, gr. ¼ hourly, or this drug combined with small doses of morphine given by the needle. For the fever, limited hydrotherapy, applied in such a way that the patient is not disturbed, is most desirable. Antipyretic drugs are absolutely contraindicated. Hypodermatic medication should be used wherever practicable. Digitalis (strychnine is to be avoided because it stimulates peristalsis), adrenalin, chloride, whiskey, and caffeine are the appropriate cardiac stimulants.

Although I fear that the preponderance of opinion is in favor of the treatment of tuberculous peritonitis by surgical measures, some cases certainly improve under ordinary medical régime suitable for tuberculous patients. This includes the usual dietetic, hygienic, and climatic recommendations. Added to this, tonics such as iron, arsenic, etc., iodine applied to the abdomen and the inunction of the abdomen over the tumor masses with mercurial ointment. These methods should certainly be used in cases of advanced pulmonary tuberculosis to the exclusion of surgical methods. When, however, tubercular peritonitis is the prominent lesion, with or without fever, especially if there be a fluid or semi-fluid effusion or if the tumor masses are seriously incommoding the patient, laparotomy with removal of the tubercular focus, whether it be in the peritoneal glands, ovaries, or where it may, is the proper method of treatment. I have seen no cases treated by radiotherapy, but the accessibility of the lesion in tuberculous peritonitis would encourage the trial of this mode of treatment.

The title of this paper obviates the necessity of an apology for its discursive character. Its object has been to show that while surgery is the stronghold in the therapy of peritonitis, medicine with the basic knowledge as to diagnosis, pathogenesis, and etiology which it has developed in the past few years concerning this affection, has laid the ground work for the successful surgical therapy and has amplified the purely medical curative resources to an appreciable if more limited extent.

THE EXAMINATION OF THE SPINAL FLUID IN DEMENTIA PARALYTICA.

By PAUL B. BROOKS, M D.,

BUFFALO, N. Y.

A great deal has been written of late relative to the cytological and chemical examination of the cerebrospinal fluid as an aid to diagnosis in various diseases of the cerebrospinal system. There seems still to be ground, however, for question as to its actual value. The following is a résumé of work done during the past winter, in the wards and laboratory of the Buffalo State Hospital, by Dr. Alfred H. Clark of this city and the writer.

Our efforts have been directed principally to the cytological examination of the fluid as a diagnostic measure in dementia paralytica. We have in each case made the usual tests for seralbumin and for a copper reducing substance said by certain writers to be present in the normal fluid; but have gone no further into the chemical characteristics. At the outset we met with numerous difficulties arising both from our own inexperience in the technique and from the fact that the methods of procedure are still unsettled, each worker modifying the technique to make it conform to his own ideas. We have followed in the footsteps of our predecessors and established our own method of procedure.

The method first recommended to us, and which is still in vogue to some extent, was as follows: 5 c.c. of fluid, having been secured, is placed in the centrifuge for a given time, varying from ten to forty-five minutes. The fluid is then carefully withdrawn and the tube inverted to drain off any that may remain. With the tube still inverted, a capillary pipette is introduced and any sediment and fluid adhering to the bottom of the tube are allowed to run up into the pipette, which is then withdrawn and the contained mixture divided as equally as possible among three cover-glasses. The drops are allowed to dry and are stained for counting.

After having tried this method in three or four examinations we concluded, as we were prone to feel before undertaking it, that the method was crude and unreliable. With the cells unevenly distributed by the centrifuge over the bottom of the test-tube, the thinness of the layer depended largely on the caliber

of the tube, and after scraping the bottom it did not seem reasonable to us to suppose that there could still be any uniformity despite the attempted equal distribution of the material thus collected upon the cover-slips.

In our own work we have devised a method of procedure, which follows. While it is still crude, it seems to us to be a step toward greater accuracy. It differs from the method above described in that we used graduated tubes, and after centrifuging for twenty-five minutes, withdrew all the fluid excepting 0.2 c.c. This fluid, with the sediment, was then stirred thoroughly with a platinum loop, and drops of the mixture placed on slides. Then, always with the same pipette, all excess of fluid was withdrawn from the drops by capillary attraction. The advantage was gained by having a uniform dilution and drops of practically equal thickness. We found that different drops, made from the same specimen, showed essentially the same number and distribution of cells, thus differing from those with the method first described.

After drying, the drop was stained and always examined with the same objective and eye-piece, in order that the fields should be of uniform size. Various stains are recommended, but we have found the Jenner very satisfactory, the entire staining process requiring only two or three minutes.

In our later examinations we have resorted also to the use of the Thoma-Zeiss blood-counting chamber, using uncentrifuged fluid, in conjunction with the other method. We have thus been afforded absolute accuracy, with the additional demonstration of the character of the cells by means of the staining process. In comparing the results obtained by the two methods, in the same cases, we have found them always uniform in their relation to each other.

We have found it quite difficult to compare our results with those of others, on account of the lack of uniformity of technique, but have finally reduced them as nearly as possible to the same terms, and feel that we can safely compare them.

When using the centrifuging and staining process, with the dilution recommended, we have counted from 30 to 50 fields in each case and have looked upon the presence of one or more lymphocytes to a field as indicating a lymphocystosis, while the normal fluids have usually presented one lymphocyte to from 5 to 20 fields. With the counting chamber we have considered anything over 14 or 15 to a c.mm. as an increase, while the normal fluids presented from 1 to 4, or less, to the c.mm.

We have made satisfactory examinations of fluid in 29 cases, 13 of which have been typical paretics, 3 probable paretics, and 13 suffering from other conditions, from which paresis could be absolutely excluded.

Of the 13 typical paretics we found an abnormal increase in the number of lymphocytes in 8, or practically 61½ per cent. If to these we add the three probable paretics, in all of whom there was a lymphocytosis, the result is 68¾ per cent. increased.

Of the 13 cases other than paretics, 11, or practically 84 2-3 per cent., presented a normal lymphocyte count. Of the other two, one gave a history of syphilis, some twenty years before, and the other was evidently suffering from a syphilitic and inflammatory condition of the meninges, which condition was cured by treatment with potassium iodide. To recapitulate: 68¾ per cent. of our paretics showed an abnormal lymphocytosis, while in 84 2-3 per cent. of the cases other than paresis the lymphocytes were normal in number.

The seralbumin present in the fluid we found to be a variable quantity, and, so far as we were able to determine, bore no particular relation to the number of lymphocytes present or to the presence or absence of dementia paralytica. It was markedly increased, in two cases giving evidence of meningeal inflammation (showing polynuclear leucocytes in the fluid) and in a case of dementia paralytica associated with tabes.

Quincke, Farrar, and others state that sugar is present in the normal fluid. Certain other writers mention the presence of a substance, probably not sugar, which reduces copper from Fehling's solution. Deroubais reports a constant sugar reaction in normal fluid, but was unable to get a reduction in cases of dementia præcox. In spite of our careful and persistent efforts we have been able to get a reduction of Fehling's solution in but one case, and that one of the catatonic form of dementia præcox.

To conclude, while it does not seem to us, judging from our own observation and from a review of the literature, that it is yet possible to make a positive diagnosis of dementia paralytica from the cytological examination of the spinal fluid, as a few writers have asserted, we feel that it bids fair to become a valuable aid to diagnosis in some doubtful cases of this condition.

Aside from its value in paresis, it is not infrequently of service in other conditions. In the case of meningeal syphilis, associated with meningitis, referred to above, the character of the cells in the spinal fluid (an increase both of lymphocytes and polynuclear leucocytes) established a diagnosis which had been undetermined for weeks, previous to admission. Proper medication, administered on the strength of this examination, resulted in early and complete recovery, whereas, before this time, the patient had been failing gradually, but surely.

The fact that in the hands of the inexperienced the operation necessary for the withdrawal of fluid is attended with some difficulty, would probably limit its use to institutions, or to those who had acquired some experience in the operation and technique. Our experience has led us to believe that with reasonable asepsis the withdrawal of not more than 5 c.c. of fluid, which is all that is necessary in any case, and the detention of the patient in bed for three or four days, the operation is attended with no danger. We are not prepared to discuss the dangers said to exist in brain tumor, having had no experience with this condition. In 38 punctures (9 beside the 29 satisfactory for cytological examination) we have had no mishap, and apparently the operation has been without ill effect of any kind. By taking the necessary precautions it may also be made nearly, if not quite, painless.

New York State Hospital.

PRECISE DEFINITIONS FOR MANY DISEASES.

By JAMES FARQUHARSON LEYS, M.D.,

SURGEON U. S. NAVY.

While engaged recently in reference work at the Library of the Surgeon General's Office in Washington I had occasion to compare the definitions of infectious diseases given by various writers of dictionaries, text-books, and works of reference, and was struck with the vagueness and verbosity which characterize nearly all of them.

Thirty years ago it was not possible to give an exact definition to any disease, and in the case of most diseases it is still impossible. Diseases, the essential natures of which are unknown, because

their causes are unknown, cannot be defined, and in lieu of a definition it is customary to give a brief and imperfect description. In our imperfect knowledge of any disease in question we content ourselves with an enumeration of its most prominent characteristics and symptoms. Such substitution of description for definition is not only unobjectionable, not only desirable as representing the best we can do in the circumstances; it is of positive value to the student, who needs, at the outset, a few pegs on which to hang the more extended knowledge which he is about to acquire by further study of the subject.

Concerning many diseases we may labor yet for a long time, perhaps always, under this disadvantage of not being able to define them exactly. In the production of medical literature, as in the practice of the medical art, we are to some extent condemned to inexactness. The incompleteness of our knowledge in many matters of theory and practice, fully realized by ourselves, is often more painfully evident to the laity than to us. Our inability to give exact and satisfying answers to physiological, etiological, and therapeutic questions, which are put to us in an intelligent and sincere desire for enlightenment, often causes us to be regarded by laymen as a profession hopelessly condemned to inexactness and empiricism. Even in anatomy, which is, of all the vital sciences on which our art rests, the one made up entirely of fact to the exclusion of theory, there is so much variation in the size and form of bones, in the branching and distribution of arteries, nerves, etc., that we cannot avoid an elastic form of description and the admission of many exceptions. As a first-year student I remember well how this impressed a classmate who had been a mechanical engineer before taking up the study of medicine, how unsatisfactory he found the study of the human machine and its functions at first, and with what difficulty he was obliged to change his whole habit of thought and study and content himself with indefinite and elastic statements where he had been accustomed to exactness.

Because at many points we have recourse to speculative opinion in the absence of knowledge, because we know that many of our statements which are now accepted as founded on reasonable probability are open to refutation in the light of new discoveries, and because we have to deal so much with variable quantities, the profession has formed a habit of stating facts in a manner elastic and approximate rather than precise.

No profession welcomes discoveries of truth more gladly than ours, or labors harder to make plain by such discoveries what has been obscure. Nor are we usually slow in making use of newly discovered truth to revise and simplify our teaching, and substitute precision for vagueness of statement. Yet we have been very slow to do this in the definition of the infectious diseases. We have been more than slow, we have not even begun. It is thirty years since Robert Koch, in 1876, demonstrated the precise nature of anthrax, identifying in the diseased tissue the bacillus which is its cause, growing the bacillus in pure culture outside the body, after several removes of such pure cultures producing the disease by inoculation of a healthy animal with them, and demonstrating the proliferating bacilli again in the diseased tissue of the inoculated animal; thus satisfying all four of the postulates laid down by him and accepted by the entire profession as necessary to establish proof of the causative relation of a bacterium to a disease. For thirty years, then, it has been possible to give a precise and accurate definition of anthrax within a dozen words, and no other definition is exact or admissible.

Yet it is doubtful if this exact definition can be found in any dictionary or text-book. Most writers seem still to prefer a vague description by no means calculated for the accurate instruction of the student, and incomprehensible to the layman.

The following so-called definition of anthrax is taken from an exhaustive and much-consulted work of reference, recently published: "Anthrax is an acute, exogenous, facultative, parasitic, infectious disease, which is never general in its extension, but invariably finds its locus of primary origin in telluric and caloric conditions of certain localities which supply the pathobiological necessities of its specific cause—bacillus anthracis; and which is extended from such primarily infested localities by animals infected thereon to other localities, either by means of their natural excretions or by materials derived from such animals when dead—wool, hair, hides; and occasionally by floods."

A student or layman, desirous of knowing what anthrax *is*, might plunge into this collection of words, flounder through it to the end, and be excusable if he emerged with a vague idea that anthrax is a ghost which walks in certain haunted places.

We do not question the general truthfulness of this statement, but we must object to its being called a definition. It strikes us as an *indefinition*, a thing in every way the contrary of a *definition*. We venture to suggest here that the word *anthrax* can be defined with the same exactness as the words *iron, water, quinine*, and *triangle*, and that the following statement which defines it precisely is the only one admissible as a definition. To define the name of any thing is to tell as precisely as possible what the thing *is*. Anthrax is *the disease caused by an invasion of Bacillus anthracis*.

We will ask the reader to scan this definition deliberately, before we proceed to support our contention that it cannot be varied in a single word without destroying its precision. For we hold that each one of the words of which it is composed is necessary to make it correct and complete, and that no other word can be substituted.

To begin, the definite article must be used if we would define *the* thing. The so-called definitions of our text-books are apt to begin with a statement that anthrax is "*a* disease," or "*an infectious disease, caused by, etc.*" The indefinite article *a* or *an* means, *any, any one of many*. Anthrax is not any one of several diseases caused by the invasion of *Bacillus anthracis*. It is *the* one single definite disease caused by the invasion of that bacillus.

Anthrax is the *disease*. *Disease* is, according to Webster, "a derangement of any of the vital functions in which their natural action is interrupted or disturbed; morbid or unhealthy condition; sickness." The word is essential to our definition. Anthrax is not the organism itself, nor is it the invasion of the organism. It is the derangement, the morbid or unhealthy condition of the body, the *disease*, therefore, which is *caused by* such an invasion. And let us remark here, in passing, the superfluity of any adjectives inserted before the word *disease* in a definition. Apart from the confusion involved in the application of such terms as *infectious, contagious, communicable, inoculable*, etc., the impossibility of clear distinction between *acute* and *chronic*, and the superfluity in any case of the word *specific*, it is well enough understood now, not only by the profession, but by the intelligent laity who care enough for accurate knowledge of these matters to consult a dictionary or any other work of reference for information concerning a dis-

ease, that every bacterial or other parasitic disease is specific and infectious. To state that the disease is caused by an invasion of a certain bacterium is to say that it is specific and infectious and to insert those words in the definition conveys no additional information.

And before the word invasion we require the indefinite article: we must say *an* invasion, for that is just what we mean; *any* invasion of any part of the living body; skin, lung, or intestine; of man or any other animal. Further than that, if it should ever be proven by botanists that *Bacillus anthracis* invaded, lived, and multiplied upon, or in, any form of plant life, causing a blight or disease of the plant, the vegetable disease so demonstrated would be anthrax; we should not require any new name for it. If anyone is still inclined to say that anthrax is caused by *the* invasion of *Bacillus anthracis*, let him ask himself to what particular invasion he refers.

Invasion is, according to Webster, "a warlike or hostile entrance into the possessions or domains of another; the incursion of an army for conquest or plunder; a raid; the approach of any foe, or anything hurtful or pernicious; as, the *invasion* of a disease." The fathers of medicine who chose this word *invasion*, applying it in a figurative sense to the stage at which there was the first tangible evidence of the onset of an infectious disease, chose better than they knew. Its literal application in diseases now known to be caused by the entrance and spread of bacteria in the body is so appropriate and exact that we cannot improve upon it.

Lastly, as to the insertion or omission of the definite article before the name of the organism, it is better usage to omit it. Careful writers who once used it have since dropped it. It is not some one particular bacillus of the species to which we refer as the invading organism, but to the species, as a species, collectively. Thus man, as an animal, is *Homo sapiens*, not *the* Homo sapiens; quassia is the wood of *Simaruba excelsa*—that is to say, the wood of the species as a whole, not of some individual tree of the species. The article being omitted, the generic name should always be begun with a capital and the specific one with a small letter.

Let us now scan the definition again. To the question, *"What is anthrax?"* our definition makes answer: *"Anthrax is the disease caused by an invasion of Bacillus anthracis."*

Not only is there no other way to give a satisfactory answer to the question, not only will any enumeration of the signs and symptoms of anthrax fail to answer it, but our definition gives the only answer that dictates the question. Question and answer can be transposed. *"What is the disease caused by an invasion of Bacillus anthracis?" "Anthrax"* is the only answer possible.

Since a precise knowledge of the nature of anthrax was gained in 1876, bacteriological discovery has constantly enlarged the list of diseases which can be defined with a similar precision, thus:

Actinomycosis is the disease caused by an invasion of *Actinomyces bovis.*

Tuberculosis is the disease caused by an invasion of *Bacillus tuberculosis.*

Diphtheria is the disease caused by an invasion of *Bacillus diphtheriæ.*

Malleus (*Glanders*) is the disease caused by an invasion of *Bacillus mallei.*

And so on.

Including the various forms of malarial fevers, the invasions of the blood by many other animal parasites now clearly identified, the animal parasites for which the intestine is the usual site of invasion, and the skin diseases caused by invasions of the true fungi, the method of precise definition here suggested is already applicable to a large number of diseases. Nor is it necessary to distinguish in the definition itself between local and general invasion. The invading germs may remain as strictly localized in *diphtheria* or *anthrax*, with grave constitutional symptoms, as is the case in *favus*, with local manifestations only. These distinctions should be left for the subsequent description of the disease.

This manner of concise and exact definition can be "understanded of the people," and is as fit for any general dictionary as for the exclusively medical one. As it is desirable to give, in general dictionaries, as much descriptive information as limited space will admit, and to make it as simple and clear as possible, such information may be added after the definition itself without interfering with its unity.

Styles of definition suitable for general dictionaries would be the following:

Anthrax.—The disease caused by an invasion of *Bacillus anthracis.* One of the infectious diseases. Epidemics of it are frequent among sheep and kine, and man is occasionally inoculated. The disease is also called Siberian cattle plague, splenic fever, malignant pustule, or wool-sorters' disease.

Malleus.—The disease caused by an invasion of *Bacillus mallei.* One of the infectious diseases; chiefly affecting the horse and other solipeds, but occasionally communicated to man. The lungs, nasal passages and skin are chiefly affected. The disease is often called *glanders* when the nasal lesions are prominent, and *farcy* when the lesions are chiefly in the skin.

Glanders.—See *Malleus.*

Farcy.—See *Malleus.*

For medical dictionaries and for text-books on human pathology and practice, in which, in addition to a strict definition, a brief description is desirable, to give the student his bearings for further study, such forms as the following are suggested:

Anthrax.—The disease caused by an invasion of *Bacillus anthracis.* It is characterized by a specific lesion at the site of inoculation in the skin, with local edema and lymphatic inflammation; or by intestinal or pulmonary lesions with general infection; splenic enlargement, grave constitutional symptoms, and high mortality.

Malleus.—The disease caused by an invasion of *Bacillus mallei.* It is characterized by nodular, pustular, or ulcerative lesions in the lungs, nasal mucous membrane, or skin; with secondary lymphatic involvement, deep abscesses, fever, grave constitutional disturbance, and a high mortality.

It has been the purpose of this article to point out to medical lexicographers and writers of text-books the desirability of substituting precision, where precision is possible, for a wandering and floundering verbosity in defining the names of infectious diseases. Let our profession be exact so far as discovery has made exactness possible for us. Let us be done with *indefinition* where *definition* is as easy as it is desirable. Where this precision is possible, as it has been for a long time in many bacterial and other parasitic diseases, nothing should be allowed to intervene between the definition and the word defined; and no statement should enter into the definition itself which is indefinite or which requires subsequent modification. Additions of synonyms, descriptions of signs and symptoms, and details of zoological or geographical prevalence, are often desirable and proper, but this additional information should not be confounded with *definition*, or so inserted as to obscure the definition itself.

Bureau of Medicine and Surgery, Navy Department, Washington, D. C.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, June 30, 1906.

THE FINANCES OF THE A. M. A.

IN many respects the recent meeting of the American Medical Association in Boston was the most remarkable in the history of this body—remarkable not only in size (over 4,500 registered members were present), but also in the perfection of the local organization (due to the remarkable executive ability of Dr. Burrell and his efficient aids on the Committee of Arrangements), in the enthusiasm felt and expressed by all present, and, finally, in the bitter condemnation by some of the most prominent men in the Association of the arbitrary methods of the Secretary-Editor. Never has the Association been so prosperous as it is to-day; it has a membership of over 20,000—one-sixth of the estimated number of physicians in the country; it has a surplus of over a quarter of a million dollars, and this surplus is increasing at the rate of more than $25,000 a year. All loyal members of the Association, *quorum pars sumus*, must rejoice in those signs of prosperity and must give due credit for the same to the Secretary-Editor, to whose genius for organization this increase is largely owing. Since he assumed control of the Association, the membership has increased, in round numbers, from 8,000 to 20,000 and the outside subscribers to the *Journal* from 2,500 to 17,500, which should have brought an increase of $140,000 per annum to the treasury of the Association. Credit must also be given to the Treasurer of the Association, a practical financier and a bank director as well as a popular physician, whose wise investments of the surplus funds have apparently added not a little to the balance in the treasury. To the salaried organizer of the Association, sometimes dubbed the "walking delegate" by the disaffected, praise is also due from those who approve of the present system of organization of the American Medical Association. It is true the methods which he has thought wise, or has temperamentally been compelled, to adopt have made many bitter enemies of himself and of the body which he is assumed to represent; yet the fact remains that he has succeeded in the creation of many county societies and has thereby increased the potential membership in the Association.

So far, so good. The American Medical Association to-day is larger and richer and *quoad hoc* more powerful than ever before. But is it stronger in itself, and assured of continued progress? "Let him who standeth take heed lest he fall." This saying applies to organizations as well as to those who rule the organizations. Less than two years ago there were three enormously rich and powerful life insurance companies in the United States; their surpluses were in the neighborhood of $100,000,000; the men in control of them were among the financial magnates of the country, respected and envied, and anyone who had ventured the suggestion that there was danger to the companies in this prosperity would have been scouted. To-day these same companies are putting forth every effort to regain the confidence of the public by instituting investigations, suing their former chiefs to enforce restitution, and reducing salaries (including those of the medical examiners), and the pitiable condition of those who brought them to this state of seeming prosperity by their deceitful methods is known to all. The cause of the spectacular *débacle* is also known. The fall was the logical and inevitable consequence of the policy of concealment so long followed by those in control. The published reports dealt in generalities and studiously avoided details. The members of the mutual companies, who were theoretically part owners with a right to know how their money was being spent, were kept in ignorance of the facts and "jollied" by the magnificent totals into believing that they were coining money by living and would make more by dying.

The financial reports of the American Medical Association are disquietingly analogous to those of the insurance corporations. They deal in glittering generalities—and the surplus increases at the rate of $25,000 annually. But what are the items of expenditure? In the report for 1905 the expenses of "organization" are set down as $7,797.04; organization of what? The sum given away in salaries and wages was $78,874.79; whose salaries? For "medical legislation" there was spent $1,234.90. Under the item "Association" we find $10,062.30 expended. The average circulation of the *Journal* was 38,006, and the income therefrom should have been in the neighborhood of $192,000: but the total amount received from dues and subscriptions was only $147,651.61, leaving over $44,000 unaccounted for. And so on. What the members of the Association want is frank publicity in the financial reports—not indefinite items which defy analysis. Herein lies danger to the Association. Such a report as that published in the *Journal* of June 16 is worthless and worse—it is not frank. What the members have a right to know is what "organization" means, what "salaries and pay roll" means, what "association" means, why more than 23 per cent. of what should have been received in dues and subscriptions remains unaccounted for, and so on. Every member of the Association is the owner of an undivided fraction of the property of the Association, and he should be told how this property is being managed; he wants something more than the assurance of a retiring president, in virtue of his office a mere figure-head, that everything is all right and that the rulers are honorable men. There may be no "ring" or "clique," in the evil acceptation of the terms, but there is want of frankness on the part of those who control the Association which is disquieting and tends in these days of "graft" to arouse grave suspicions. These may be, and we believe are, unjust. They are, however, bound to grow so long as those who have charge of the money of the Association make unsatisfactory reports which suggest a desire for concealment. The only way for them to purge themselves

of suspicion is to take all the members into their confidence and to publish a clear and definite itemized report of receipts and expenditures, and then have the report audited by a committee of members, not by a local firm of expert accountants.

THE PATHOLOGY OF BURNS.

There are apparently two leading factors concerned with primary death from burns. When this follows immediately upon the reception of the injury, shock is probably the only factor with which we have to deal, but when the fatal issue does not come on at once and is preceded by focal hemorrhages and necroses in one or more organs, by hematuria, hemaglobinuria, and other evidences of violent intoxication, it seems likely that we are dealing with something essentially different from shock. Among the explanations which have been offered to account for these phenomena the most prominent have been the following: suppression of the cutaneous functions in the involved areas, changes in the nervous system due to reflex disturbances, the formation of toxic substances in the blood, the destruction of the blood elements, and the absorption of toxic materials from the injured area. Experimental evidence has been adduced to show that poisonous substances are circulating in the blood after the infliction of extensive burns, and it may be reasonably assumed that these are directly concerned with the fatal issue. But their exact origin and character are by no means certain.

The degenerative and necrotic changes which have been described in various organs, particularly in the liver, the kidneys, and the lymphatic system are strikingly similar to the effects of some of the infectious diseases such as diphtheria. There are changes in the blood which also seem to be due to the action of some toxic material, and both the urine and the blood serum have been shown to be poisonous. It has been found in addition that if the flow of blood to the affected region can be temporarily prevented, a prophylactic effect is secured and the immediate removal of the burned tissues also seems to prevent a fatal issue. The facts just noted have been quite conclusively demonstrated, but we are still very much in the dark regarding the production and action of this toxic substance if such it be, and considerable interest attaches therefore to any new communication on this subject. Herman Pfeiffer has made some careful experiments in animals in an attempt to solve this problem and his findings, detailed in an article in *Virchow's Archiv*, Vol. 180, No. 1, are very instructive. After anesthetization he scalded various portions of the body and then collected and studied samples of the blood and urine. It was found that the pathological changes increased in intensity the longer the time which had elapsed between the injury and death. The urine was at first hemorrhagic and later albuminous in the burned animals, and if introduced into normal animals by subcutaneous injections, either death or extensive necrosis and ulceration resulted. A like effect was obtained with the blood serum. The toxicity of these body fluids increased until about the fifty-sixth hour, when it began to grow less. It seemed to be entirely independent of the amount of hemoglobin dissolved, and the poisonous principles appeared earlier in the urine than in the blood serum. An intense paralytic action on the central nervous system was usually noted, but in some cases a local necrotic effect was more prominent. Sometimes the intestinal canal was particularly affected. The toxic substance was destroyed by exposure to sunlight or ordinary daylight and disintegrated by heat. It also seemed to have no effect on the unbroken skin.

Pfeiffer does not believe that there is any agglutinin or hemolysin present in this body, neither is it a ptomain or one of the pyridin bases. In some respects it resembles the snake poisons and the nucleoproteids, but as to its exact composition he is ignorant. Where the poison originates he is unable to state, as he failed to recover any from the immediate vicinity of the burn or from the tissues. These experiments, although not by any means conclusive, are in thorough accord with the modern ideas as to the pathology of burns. Whether further research along this line will result in any new ideas as to the treatment of the condition remains to be seen. It seems reasonable to suppose that in addition to local and general supportive measures as hitherto employed we may expect the treatment to be developed along the lines indicated by the trend of the experiments of this and other recent observers.

THE ALLEGED EPIDEMICITY OF APPENDICITIS.

Theories innumerable and of various degrees of complexity have been adduced to account for the pathogenesis of this disease, and among them the idea that appendicitis was possibly of an infectious origin has become especially prominent. A closer anatomical study of the vermiform appendix has shown that in its structure lymphoid tissues constitute an important element, and this feature, together with its topographical relations, offers a most favorable condition for an invasion by infectious processes. It is quite natural that the development of this idea would soon lead to the thought that appendicitis might also prove to be epidemic in character, and the adherents of this theory call attention to the fact that during the past fifteen years the disease has become particularly frequent. It has been claimed moreover that the greater frequency of the complaint has been coincident with that of influenza and that both of these conditions could be traced to an increased consumption of meat.

A more reasonable view of this question, according to Cheinisse (*La Semaine Médicale* 1906, No. 10), would take cognizance of the fact that perhaps improved methods of diagnosis and a more complete knowledge of the clinical history of the disease during recent years have tended to define many cases as appendicitis which formerly went unrecognized or were called by some other name. This applies particularly to the early diagnosis and undoubtedly in many instances the

symptoms of beginning appendicitis were attributed to disturbances in the stomach, intestines, or liver, and the acute cases were formerly commonly designated as peritonitis of unknown origin. This point is well illustrated in the statistics presented by Villaret dealing with the situation in the French army, to which Cheinisse calls attention. Here the number of appendicitis cases was found to have increased about 70 per cent. in recent years, but in contrast to this the affections of the liver and the peritoneum, as well as chronic gastric complaints underwent a corresponding decrease. This demonstrates that the increase in the former is only apparent, and other carefully compiled statistics will no doubt bear out this statement. It is evident therefore that the theories dealing with the epidemic nature of the disease do not receive very much support from a study of these figures, and the relation between appendicitis and influenza has likewise never been confirmed by facts. The statistics upon which the latter assertion is based do not comprise an amount of material sufficiently large to exclude the possibility that the connection between the two diseases was anything more than accidental; this lack of evidence invalidates also the claim that the complaint is more prevalent during certain seasons than during others. A natural sequel to the assumption that appendicitis occurs in epidemics is the fact that the disease is apt to be diagnosed as being present without sufficient cause for such a claim. Thus it has been shown that in certain cases of pneumonia the pain may be entirely localized in the right iliac fossa, and during an attack of influenza a similar clinical picture may be due to a neuralgia or a neuritis. Certain forms of intestinal spasm may closely simulate the clinical features of appendicitis and unfortunately continue after the organ has been removed by operation; and the same is true of colitis.

Anesthesia for the Wounded.

It has been claimed that the introduction of the small caliber weapon has diminished to a large extent the horrors of the battlefield, but the experience gained in the South African and the Russo-Japanese wars has afforded ample confirmation of the fact that the term "humane" as applied to these instruments of death is a misnomer. The unfortunates who may have been hit by the projectiles from these weapons are known to have been subjected to great suffering, as great as in the days when bullets were not made with humanitarian intentions. There is one circumstance which largely increases the suffering which the wounded are compelled to endure, and that is the long time which must necessarily elapse in many instances before proper surgical aid can be extended to the unfortunate victims. This is an aspect of the question which has not apparently been thought of very often, but its importance is nevertheless quite evident and we must therefore regard with some interest the suggestion for relief advanced by Prof. Schleich, whose name is so closely associated with the subject of infiltration anesthesia. In a recent pamphlet (Berlin, Julius Springer) Schleich proposes that every soldier in the field be provided with a means by which, in case he is wounded, it may be possible to produce a narcotic sleep which would alleviate his sufferings until other help arrived. The remedy most suitable for this purpose is believed to be a mixture of chloroform, ether, and ethyl chloride with a boiling point closely approximating that of the temperature of the body. This combination has been used as a general anesthetic by Schleich and others in all classes of cases with good results. It is claimed to possess an anodyne action and the power of producing sleep without inducing a true narcosis, and therefore seems particularly adapted to the purpose for which it has been recommended. For practical use the remedy is to be carried about in small aluminum capsules containing absorbent cotton which has been saturated with the narcotic mixture. Each soldier is to be provided with three capsules, and when wounded he is directed to withdraw the cork from one of these small receptacles and simply inhale the narcotizing vapor. Or he may act as the ministering angel to some other unfortunate who may be unable to perform this feat himself. We have seen how efficacious the first-aid packages supplied to the Japanese soldiers could be made, how hemorrhages, suppuration, and other wound complications could be controlled to an extent in many cases sufficient to save life. This personal anesthetic scheme is even a step further, but a step which will certainly seem to many fraught with considerable danger, and we may expect to hear comments, both acrid and otherwise. To a limited extent the procedure may perhaps be applied with success, but practical experience will afford the only means by which we can hope to gain any knowledge as to the real value of Schleich's suggestions. There is, of course, no suggestion of "euthanasia" in this scheme. The life of the soldier is too valuable to be thrown away prematurely. It is intended that the dose of the anesthetic shall be narcotic only, not lethal.

A New Method of Diagnosis in Tuberculosis.

Among the various methods employed for the purpose of confirming or of making a diagnosis of tuberculosis, the most constant and reliable has been found to consist of the inoculation of certain animals with the suspected morbid material and then to await the production of a similar pathological process in their tissues. Guinea pigs are usually chosen for this purpose because the lesions of experimental tuberculosis as they occur in these animals are well known and spontaneous cases of the disease are very rare. One of the disadvantages connected with these methods of subcutaneous or intraperitoneal inoculation is the fact that a definite result cannot be expected in a period of less than eight weeks. This objection is apparently overcome in the procedure recommended by Larier and Ronzoni (*Gazzetta medica Italiana*, 1906, No. 4), in which it is proposed that the suspected morbid material be injected directly into the mammary glands of guinea pigs which are still suckling their young. The method referred to is based on the fact that experiments made in cows have demonstrated that the mamma provides an excellent medium for the growth of the tubercle bacillus. The writers injected specimens of sputum in cases of doubtful tuberculosis into the mammary glands of guinea pigs who had given birth to young from twenty to twenty-five days previously, and in all cases which were later proved to be positive by other means, the bacilli were found

in the milk of the animals in from five to ten days after inoculation. In order to eliminate any possibility of abscess formation, the sputum was exposed to a temperature of 54° C. for an hour, and then on the following day again for another twenty minutes before being injected into the animal's glands. As a result the virulence of all the other germs was practically destroyed; that of the tubercle bacillus was inhibited, but not to a sufficient degree to prevent the production of both splenic and hepatic tuberculous foci. The advantage of such a method as that here referred to is obvious, for above all other things it will effect a great saving of time, and in certain cases this may be a factor greatly to be desired. The mammary gland of the guinea pig is particularly well adapted for this purpose because it does not harbor any acid-fast bacteria and does not afford a favorable soil for the growth of other organisms.

A Salt-free Diet in Scarlatina.

There has been considerable discussion lately regarding the advantages of a diet free from salt during scarlet fever, and interest attaches to certain comparative tests made by Pater (*Wiener klinische Wochenschrift*, No. 13, 1906). The patients in one group were kept on an absolute milk diet, the others were given bread, rice, potatoes, eggs, butter, sugar, and milk, all without any trace of salt. It was found that the latter course was entirely free from danger and seemed to constitute a better prophylactic measure against nephritis than the exclusive milk diet. The initial febrile albuminuria which is often present rapidly disappeared under this régime. An increase in body weight was also observed and the variety of food presented was greatly appreciated by the patients. Convalescence was invariably more rapid and immediately succeeded the period of defervescence. The improved condition of the patient also favored resistance against secondary infections. This is evidently but another step in the more liberal dieting of certain classes of patients which has lately been adopted and an exclusive milk diet is no longer considered by many to be the *sine qua non* of medical treatment in many of the febrile diseases, of which typhoid fever is another example.

News of the Week.

California Legislation.—A special session of the California Legislature, made necessary by the catastrophe at San Francisco, enacted these laws of interest to the profession: A bill appropriating $25,000 for the building of temporary houses for the insane while permanent buildings can be put up to replace those of the Agnew State Insane Asylum at San José, destroyed by the earthquake; three bills providing for the reproduction of the registers of the State Boards of Examiners in Medicine, Pharmacy, and Dentistry; a bill providing for the issuing of duplicate certificates to physicians, pharmacists, and dentists who lost the original papers in the fire at San Francisco; a bill appropriating $83,800 for the University of California, about $8,500 of which is to restore buildings and apparatus damaged in the Medical and Veterinary departments; a bill appropriating $2,500 for the restoration of the property of the State Board of Pharmacy, and a bill of equal amount to restore the property of the State Board of Medical Examiners.

Contract Practice.—The referendum on the protest raised by the Douglas Branch of the Chicago Medical Society against the practice of physicians "contracting" their services showed that 358 members were against such a practice, and that 201 thought it should not be interfered with. The vote was not decisive, inasmuch as the bylaws require that 50 per cent. of the members must engage in a referendum in order to make it imperative. With a total membership of 1,928, the referendum fell considerably short.

Degrees Conferred on Drs. Moyer, Allport, and Steele.—Drs. Frank Allport and Harold N. Moyer of Chicago received the degree of LL.D. at the annual commencement of Notre Dame (Indiana) University, on June 14. Dr. D. A. K. Steele likewise received the degree of LL.D. at the commencement exercises of the University of Illinois, Champaign, June 13. Dr. Steele is President of the College of Physicians and Surgeons of Chicago.

Fruit and Candy as Fomites.—A recent investigation of the fruit and candy in the shops by the Bacteriological Department of the Board of Health at Los Angeles, Cal., revealed the presence of so many bacteria conveyed to them by the wind that legislation has been asked for requiring of dealers that such articles be exhibited for sale under glass.

Medical Department of the University of California.—The regents of the University of California, at a meeting held in the Cooper Medical College, San Francisco, June 12, decided to transfer the work of the first two years of the Department of Medicine and Dentistry to the university buildings at Berkeley, in order to give more room in the college building for clinical work.

International Congress for the Promotion of Hygiene and Salubrity in Dwellings.—The second annual conference of this association is to be held in Geneva, Switzerland, on September 4 to 10, 1906. The purpose the promoters of the congress have in view is to appeal to the most competent professional men of all countries—to doctors, hygienists, and architects—to deliberate in common on the problem of how best to ameliorate the salubrity of dwellings. The general secretary is M. Albert Wuarin, 1 Rue des Moulins, Geneva, Switzerland.

Swedish Hospital in Brooklyn.—The new Swedish Hospital, at Sterling place and Rogers avenue, Brooklyn, was dedicated and opened on June 24. The hospital is a large brick building, which has been remodeled to suit the purpose at a cost of about $65,000. It is equipped to accommodate seventy-five patients, and, while specially intended for Swedes who speak only their own tongue, it is also free to all without distinction of race. It will be ready to receive patients July 15.

The New Homeopathic Medical and Surgical Hospital and Dispensary of Pittsburg, Pa.—This institution, after forty years of existence in the business district of Pittsburg, has bought a site for a new building in the residence section. The plans, which are the work of Mr. C. Emil Müller of Pittsburg, include many original features in hospital construction whereby a maximum of light and air is secured to each ward and the expenses of maintenance are greatly reduced. The building is to provide for two hundred and fifty patients and will cost about $1,000,000.

Faculty of the University of Chicago.—Dr. Valdemar Koch has been appointed to the chair of Physiological Chemistry in the University of Chicago. Prof. Alexis Carrell has resigned and will go to the Rockefeller Institute in New York. Prof. G.

C. Muthrie has also resigned and will go to St. Louis University.

Ordinance Relating to Hospital Removals.—An amended form of ordinance relative to the transfer of patients from one hospital to another has been passed by the Board of Aldermen. As amended, it provides that patients shall not be transferred from one hospital to another unless suffering from an infectious disease or requiring treatment specifically out of the range of the hospital in question. Hospital superintendents violating the ordinance are to be subject to a penalty not exceeding $100 for each offense.

Illegal Practitioners Convicted. — The Medical Society of the County of New York on June 23 secured the conviction of three persons for practising medicine illegally. One was an alleged osteopath; another, a man of seventy-six years, was fined for practising the "cup treatment," and the third was a "hypnotic healer."

New Nurses' Training School for Bellevue.—The Board of Estimate has authorized an appropriation of $628,000 for the erection of a building for the training of nurses for Bellevue Hospital. The building is to be part of the new Bellevue Hospital and will stand between Twenty-fifth and Twenty-sixth streets, facing the East river. The cost will be borne in part by subscriptions from the patrons of the now existing training school. The trustees of the new institution will comprise the twenty directors of the present school and ten others to be appointed by the Mayor.

Contribution for St. Mary's Hospital.—The sum of $6,000, the largest in sixteen years, was secured at the annual garden party in Brooklyn for this hospital.

Free Outings for the Sick Poor.—The New York Association for Improving the Condition of the Poor will send this notice to the physicians in the city: When your patient needs a fresh-air outing, special institutional care, extra nourishment, or other material relief, we may be able to help, if you will send (by 'phone, 348 Gramercy, or by post card or letter addressed A. I. C. P., 105 East Twenty-second street) the name and address, with a simple diagnosis and statement of need. Similar notices were sent to the teachers of the public schools some time ago—with excellent results, it is said.

Smallpox at Catskill.—The Secretary of the State Board of Health has informed the City Health Department that there have been between forty and fifty mild cases of smallpox at Catskill-on-the-Hudson, and that of this number fourteen or fifteen cases are still remaining. Dr. Darlington believes that the public should be advised of the conditions, so that all persons who intend going into that region for their summer vacations may be revaccinated. If that precaution is taken there will, of course, be no danger.

Dr. Woodbury Sustained.—The counsel for the aldermanic street cleaning investigating committee submitted his report and findings, including a recommendation for the dismissal of Commissioner Woodbury, to the committee on Tuesday morning. After some discussion his recommendations were rejected by the majority of the committee.

The Yellow Fever Situation.—One case of yellow fever and one suspected case have been reported from Havana, and another patient, ill with the disease, has been detained at the Mississippi River Quarantine Station, ninety-seven miles below New Orleans. This is the first case of yellow fever reported in Louisiana this year. The patient is a Cuban sailor who arrived on the steamer *Holstein* from Havana.

Deaths from Wood Alcohol.—Two deaths occurring in Brooklyn last week are attributed to cocktails adulterated with wood alcohol. The saloon keeper who sold the compound has been arrested on a charge of homicide. A ten-gallon keg of wood alcohol was found in his place of business.

Commission to Investigate Harbor Pollution.—A commission to devise means for keeping the waters of New York harbor from becoming polluted has been appointed by Mayor McClellan. It will consist of Dr. Daniel Lewis, ex-president of the State Board of Health; Prof. Olin H. Landreth of Union College, Dr. George H. Soper, A. J. Provost, and Matthew C. Fleming. The commission is directed to invite the cooperation of the State authorities of New Jersey and must make its report within two years.

Pure Food Bill.—The House of Representatives on June 23 passed the Pure Food bill by a vote of 240 to 17. In its present form the bill differs in many respects from the original measure proposed by the Senate. Several amendments were adopted, but one designed to prevent the blending of whiskey was rejected.

Reception Hospital for the Insane.—The Board of Estimate and the Aldermen have authorized the purchase of the property between Seventy-third and Seventy-fourth streets, with a frontage of a block on Exterior street overlooking the East River, as a site for a State Reception Hospital and Dispensary for the Insane. The land will cost $146,000 and the plot will be 200 x 250 feet. It will be leased to the State, and the State Commission in Lunacy will erect the necessary buildings at a cost of $300,000.

Oklahoma State Medical Association. — The new organization resulting from the amalgamation of the medical associations of Oklahoma and Indian Territory will be known as the Oklahoma State Medical Association. The list of officers of the new society may be found on page 841 of this volume of the MEDICAL RECORD.

Officers of the Chicago Medical Society. — At the annual meeting of this society, held June 20, the following officers were elected: *President*, Dr. George W. Webster; *Secretary*, Dr. Robert T. Gillmore; *Councilors*, Drs. W. A. Evans, C. S. Bacon, Frank Billings, L. L. McArthur, and F. Henrotin; *Alternates*, Drs. William E. Quine, Henry F. Lewis, W. S. Harpole, Brown Pusey, and Theodore Tieken.

Harlem Medical Association.—The list of the newly elected officers of this society is as follows: *President*, Dr. W. H. Stewart; *Vice-President*, Dr. Charles Clinton; *Secretary*, Dr. Martin Cohen; *Treasurer*, Dr. John Remer; *Trustees*, Drs. Henry Heiman, E. L. Cocks, and P. Fridenberg.

Obituary Notes.—Dr. KARL EDUARD BEHN, surgeon of the Hamburg-American liner *Graf Waldersee*, died suddenly on June 16 and was buried at sea. Dr. Behn had been a surgeon with the Hamburg-American for eight years. Prior to that he had been with the North German Lloyd Line for two years. He was single and he lived in Bremen.

Dr. WILLIAM DUFF BULLARD of this city is dead, at the age of thirty-four years. He was graduated from Amherst College in 1892 and from the College of Physicians and Surgeons three years later. Dr. Bullard served as interne in the Post-Graduate Hospital and was an adjunct Professor of Surgery there until 1900.

Dr. Herbert James Liddle of this city died at his residence, 63 West Thirty-seventh street, on June 25, after a short illness. He was born thirty-two years ago and was graduated from the Long Island College Hospital Medical School in 1896. He was a member of the Medical Society of the County of New York, of the Society of Dermatology and Genito-Urinary Surgery, of the American Urological Association, and of the Polyclinic Clinical Society.

Dr. David Clark Strachan, an interne in the Flower Hospital, New York, died on June 23, at the residence of his father in East Orange, N. J., of sarcoma. He was born in Chicago in 1882.

Dr. Charles S. McKnight of New York City died suddenly at his summer home in Saratoga on May 21, at the age of fifty-three years, after a long illness.

Dr. Charles F. Faber died at Philadelphia on June 23, at the age of forty-one years. He was graduated from the Medical department of the University of Pennsylvania in the class of 1866. He had for ten years pursued the practice of his profession in Cairo, Egypt.

Dr. J. F. Scoresby Eastgate of Ellenville, N. Y., died on June 2, at the age of forty-nine years. He was graduated from the College of Physicians and Surgeons in New York and had practised in Ellenville ever since.

Dr. Tighlman Hunt of Plainfield, Ind., died on June 12, at the age of sixty-eight years. He was born in Friendship, N. C., and was graduated in 1866 from what is now the Medical Department of Purdue University at Indianapolis. He had practised in Coatsville and Greencastle until twelve years ago, when he removed to Plainfield.

Dr. Oscar L. Dales of Grand Rapids, Mich., died on June 11, at the age of fifty years. He was born in Uhrichsville, O., and received his medical education at the Western Reserve University at Cleveland, O.

Dr. Alexander R. Shaw of Philadelphia died on June 13, at the age of seventy-one years. He was graduated from the Hahnemann Medical College in 1856 and began the practice of medicine in Chambersburg. He then moved to Newark, Del., and from there to Philadelphia.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

METCHNIKOFF ON HYGIENE—THE "CHRISTIAN SCIENCE" CASE—ILLEGAL PRACTITIONER CONVICTED—CHICAGO MEAT—THE LATE SIR WILLOUGHBY WADE.

London, June 5, 1906.

Professor Metchnikoff has been here and delivered the Harben lectures. I congratulate the Royal Institute of Public Health on having secured his services and on the success of the reception held to meet him. The first lecture was on "The Hygiene of the Tissues," and of course referred to the very latest researches. On the strength of these he postulated that the phagocytes were able to elaborate and excrete into the blood substances which attached themselves to microbes and made them more easily destroyed by the body. Acquired immunity is due to an extra activity of the phagocytes, giving rise to increase of immunizing substances and increased capacity for enveloping microbes and destroying them intercellularly. Immunity being then the result of phagocytic action, that is to say, a function of cells, leads to the conclusion that to fight the germs of infection we should stimulate the action of the cells, and that is the way in which vaccination against infectious diseases is effectual. Anything likely to weaken phagocytic action must be avoided. Opium and other poisons do this even in small doses. Alcohol also, as shown by the slighter resistance to infectious diseases, particularly pneumonia, exhibited by those who indulge in it freely. Quinine, so valuable as a prophylactic against malaria, is also a poison to the white cells. As a rule drugs were best avoided and hygienic measures trusted to check the outbreak of infectious diseases.

More than ten years ago it was proved that the resistance of guinea-pigs to pathogenic microbes could be increased by injections of certain liquids, and this plan has been tried in practice. Mikulicz injected subcutaneously a solution of nucleinic acid twelve hours before operations. Petit used heated horse serum in abdominal and pleural operations, and the lecturer thought this preferable. To increase the phagocytic reaction in the protection of tissues subjected to operations is the first step in the hygiene of the tissues of which the foundation stone has now been laid. This is that the phagocytes are the defence against infective germs.

Prof. Metchnikoff devoted his second lecture to the "Hygiene of the Alimentary Canal," his main point being the necessity of preventing the consumption of foods that have been contaminated with microbes or entozoa. In regard to this he offered suggestions which to many will appear to be counsels of perfection, *e.g.* the proposal to eat strawberries only after boiling, which reminds me of another eminent bacteriologist, who, when questioned about the best way to secure the purity of ice-water to drink, replied, "Boil the ice." But, to return to the lecture, it was pointed out that leucocytosis may occur as a normal process. After a meal microbes pass through the intestinal wall and are found in the blood. It may be that the wall has been injured by the passage of hard particles, for which reason when an animal is to be used for providing serum it should fast before being bled. Probably in conditions referred to intestinal intoxication, the blood has already been invaded, so that the intestinal wall demands further attention as to its hygiene. Intestinal worms are known to be often present without causing inconvenience to their hosts, but it is just as certain that their bites might give rise to mischief. The lecturer cited the fact that entozoa had often been recorded as present in appendicitis, and referred to the success which had attended the use of vermifuges in the intervals of acute attacks. It had been suggested the entozoa might carry the typhoid bacillus to the mucous membrane, and the suggestion deserved investigation. Worms believed to be of intestinal origin have been found in the center of tumors in mice. All these data, the lecturer held, go to show that it is time to begin a campaign against entozoa such as is being waged against mosquitoes. Naturally, the first preventive is to secure that no contaminated food or drink should be consumed, and to this end the lecturer said all should be boiled, for, although a temperature equal to boiling water is not sufficient for sterilization (spores of *Bacillus subtilis* and others resisting it), yet it would kill the ova of parasites and almost all pathogenic microbes. Salads and raw vegetables are dangerous from this point of view. They are so likely to carry entozoa or microbes they should always be scalded with boiling water, or, better still, be themselves boiled. The same precaution applies to fruits. Strawberries, as I have already mentioned, the lecturer said, should be boiled. They grow so near the ground the berries are contaminated by the soil, except perhaps the fine variety caprouel, which grows higher. It would be safer to eat such fruits in jam. But assuredly those who like them fresh will pronounce jam a mawkish substitute. The lecturer said that until hygiene becomes generally understood it is necessary to insist on people boiling whatever they drink and adequately cooking their solid foods, for thus they might secure themselves against many diseases of the digestive system. Perhaps they might also by that means escape some diseases for which we have at present no remedy. It had long been held the use of raw food should not be permitted in infancy, but the direction was equally suitable for all ages.

Another method of meeting the danger was mentioned by Prof. Metchnikoff, viz., the attempt to acclimatize useful microbes in the alimentary canal. Lactic bacilli have been proved to serve this purpose. They produce lactic acid and prevent butyric and putrefactive ferments developing. They seem to assist in regulating the functions of the bowels and kidneys. Intestinal putrefaction, being a cause of general wear and tear in the body, its prevention must be beneficial.

In the "Christian Science" case the magistrate has committed Adcock for trial for manslaughter by neglect, and accepted bail, defendant in £1,000 and two others in £500 each. As the coroner's jury found the same verdict, it may seem to you that some of the proceedings are rather unnecessary, these preliminary ones having no effect until the full trial. But that is the way of the law.

The Defence Union on Tuesday obtained a conviction for illegal practice against a man calling himself Mr. Le Grand Denslow. An advertisement stated that a gentleman had been cured of locomotor ataxia after fifteen years' suffering, and offered to send the address of the doctor.

It was obtained for the union and the defendant was seen, who said English methods were too slow and old-fashioned. The defence was that Denslow was an American doctor. The magistrate fined him £30 and costs.

Our newspapers are inculcating some very horrible accounts of the Chicago meat scandal. Some doctors have a special interest in the revelations, as they have often advised their patients to buy the preserved foods. But there is no novelty about the alleged misdoings, for more than a year ago some most unsavory details were published in the *Lancet*, but its readers do not seem to have been alive to the importance of the matter, or perhaps they fancied their leading authority was slightly exaggerating. A similar story was given last year about the method of picking strawberries, etc., but it did not seem to trouble the consumers, who for the most part would know nothing of the contents of medical journals until the general newspapers quote them—and then, well, not a few doctors will be blamed by patients for not telling them.

Sir Willoughby Wade, M.D., Consulting Physician to the General Hospital, Birmingham, died on the 28th ult. in Rome, aged 79. He had lived in Italy for some years. He took his B.A., Dub., in 1849; his M.B., 1851, and in 1896 was made M.D. Hon. Causa, in which year also he received the honor of knighthood. He wrote "Observations on Diphtheritis" (1858) and a further work on the subject, "Clinical Notes on the Pathology and Treatment of Diphtheria," in 1863; next year "Notes on Rheumatic Fever," followed in 1893 by "Gout as a Peripheral Neurosis."

THE ETIOLOGY OF RICKETS.

To the Editor of the Medical Record:

Sir:—In your issue of March 31, 1906, on page 518, in the paragraph on Rachitis, Hansemann is stated to believe that "the chief factors involved are the absence of a sufficiency of fresh air and freedom of motion for the young, and the validity of this argument is attested by the fact that rachitis is practically unknown in Japan, where babies are exposed to the fresh air to a much greater degree than is the case in other countries, and where their clothing is such as to permit of the greatest possible freedom of movement." Living here under much the same conditions as would prevail in Japan as noted above, I can testify to the fact that these surroundings alone do not prevent rachitis, of which we see a fair amount. Children here go practically naked for the first year or eighteen months of their life. They are also reared in bamboo houses, the sides being made of loosely woven matting and the floors of split bamboos, so that on every side air can and does enter. Added to this, the life is essentially an open-air one. Yet many children from the age of two to three years suffer from rickets. I ascribe it to the diet of the Shans. The staple is rice, with almost every kind of thing, from the grubs of insects and many kinds of young leaves up the scale to beef and pork, used as a relish. The poorer classes live very largely on rice and green stuff of one sort or another. Children too are nursed all through pregnancy and after the second child has arrived, so that there is every chance for them to suffer from a lack of fats in their food. That they respond very readily to an emulsion of cod-liver oil and lime-water, seems to bear out my theory of the cause here.

A. H. Henderson.

Mongnai, S. Shan States.

CAUSATION OF THE STIMULUS OF THE HEART—A SUGGESTION.

To the Editor of the Medical Record:

Sir:—In his article in the *Journal of the American Medical Association*, June 2 and 9, 1906, W. H. Howell carefully weighs the pros and contras for the myogenic or neurogenic origin of this stimulus, basing his conclusions upon the results of evidently very careful and new observations. As important factors in the causation are demonstrated calcium chloride and potassium salts, the latter being one of the constituents of an unstable, probably organic, compound that easily disassociating should thus supply the stimulus. But, considering the well-known chemical properties of calcium chloride, may not this alone constitute the important factor? Some of it upon or within the endothelium would come in contact with a blood stream heavily laden with carbon dioxide. As result insoluble calcium carbonate would form first, rapidly changing under the influence of more carbon dioxide into easy soluble calcium bicarbonate, this then being carried away. The other component, chlorine, *in statu nascenti* would at once appropriate sufficient hydrogen for becoming, as hydrochloric acid, the irritant or stimulus. The latter in turn would unite with the potassium salt. This, when remaining *in situ*, would delay the next beat, as described, but when carried off would open the way for a renewed supply of the calcium chloride. In a well equipped laboratory proof of this theory by color reaction would not seem impossible. But the writer is in no way situated to do this, nor can he look up the literature upon the subject.

C. Am Ende, M.D.

New York.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 21, 1906.

Multiple Ulcers of the Gall-Bladder.—E. A. Locke and S. B. Wolbach report the case of a woman of fifty-six years suffering from varicose ulcers of the leg. There was a sudden onset of severe abdominal symptoms suggestive of appendicitis. Operation was finally deemed advisable, but nothing was found. Later an abscess formed in the wound and was followed by peritonitis. Twenty-three days after operation a terminal pneumonia supervened. Autopsy showed the entire gall-bladder lined with chronic ulcers, two of which had apparently penetrated, causing a general peritonitis. The general condition of the patient was not at all good at any time, there being arteriosclerosis, myocarditis, chronic bronchitis, and emphysema. According to the authors this case of ulcerative cholecystitis not occurring in association with gallstones and leading to a perforation and peritonitis is unique in literature. The cause of the sudden onset of abdominal symptoms they are unable to determine. Two possible explanations are suggested for the post-operative peritonitis: first that a local sepsis at the wound may have been the point of origin, and second (more probable), the perforations in the gall-bladder. Perforation occurred probably spontaneously, although it is evident from the extremely thin floor of many of the ulcers found at autopsy that the emptying of the gall-bladder by pressure at the operation might have caused them to give way.

New York Medical Journal, June 16, 1906.

The D'Arsonval and Other High Frequency Currents; What They Are and What They Will Do.—H. G. Piffard describes the physics of these currents, which are three in number (D'Arsonval), the derived or shunt current, the autoconduction and the autocondensation current, the essential feature connected with their conduction being (1) a suitable capacity, such as Leyden jars, or a flat condenser and (2) a solenoid or a spiral. The general effects of these currents on the human organism are described. The author considers the high frequency currents more efficient owing to their higher amperage. The general indications for their employment are conditions characterized by impaired metabolism. Contraindications are acute visceral inflammations, eruptive and continued fevers, marked cardiac or vascular disorders, and advanced pulmonary tuberculosis. A limitation to their use is that the patient must be able to attend on the physician as the apparatus is not easily transported. In early tuberculosis these currents have proved to be extremely useful. Weight increases, appetite improves, cough lessens, and night sweats cease. Other diseases in which beneficial results have been obtained are gastric dilatation and locomotor ataxia. Locally obstinate acnes, localized eczemas, genital pruritus, lichen planus, hemorrhoids, and fissures have all been markedly relieved. Malignant or semimalignant lesions of the skin, such as epithelioma, lupus, and sarcoma have, in many instances, been destroyed by the caustic sparks from a metallic electrode connected to one terminal of a coil transformer, the other terminal being grounded or connected with the patient. As a means of aborting furuncles, the author knows of nothing better than the plan just referred to.

Treatment of Acute Otitis Media Purulenta and Mastoiditis by Means of an Artificially Induced Hyperemia (Bier's Method).—After allusions to the general development of Bier's ideas, S. J. Kopetzky gives the result of his personal experience in six cases of acute purulent otitis media with mastoid involvement. Duration of treatment varied from one to eleven days. All but one case were relieved without operation, the ear becoming normal in about a week. The author does not believe in the application of the Bier principle by means of suction cups, but prefers the use of the bandage in the conditions named in his title. The mode of application is thus described: The patients are put to bed after the performance of a paracentesis, and receive about their neck the application of a rubber slightly elastic bandage, one to one-half inches in width (children one-half inch), and suitably long to fit snugly around the neck. This is fastened at the ends by hook and eye. The pressure maintained must be sufficient to cause only a slight cyanosis of the

face, but not so tight that pain is felt in the congested region, which should be warm to the touch. The regulation of this pressure is soon learnt by experience. During the course of treatment, the rubber stretches and therefore the bandage must be frequently inspected, and if necessary tightened. The bandage is placed in position in the morning and remains in place twenty-two hours; after a pause of two hours it is again replaced. The induction of hyperemia of the head is facilitated by raising the foot of the bed so that the patient's head shall be lower than his feet. The author finds that this aids considerably, and the bandage need not be applied as tightly as when this procedure is omitted. Where pus is evidenced superficially over the mastoid region, Bier's method demands incision into the suppurating mass only large enough to afford egress to the purulent contents of the abscess; no packing is introduced into the cavity.

Value of the Blood Count in Sepsis.—Observations in nearly two thousand surgical cases have convinced F. E. Sondern of the value of the blood count in sepsis. The usual findings are, an increase in the relative proportion of polynuclear cells on differential count above 85 per cent., and the higher the proportion, the more virulent is the pyogenic process. This is associated with a greater or lesser degree of leucocytosis; and the higher the leucocytosis with a given percentage of polynuclear cells, the better ordinarily is the body resistance toward the infection at the time the blood examination was made. A slight polynuclear increase with pronounced leucocyte increase indicates slight infection and well-marked body resistance. A pronounced polynuclear increase associated with a pronounced leucocytosis indicates a severe infection and good body resistance. A pronounced polynuclear increase and little or no leucocytosis indicates a severe infection and little or no body resistance. The observation is not recent that an absence of leucocytosis in severe inflammatory lesions is a bad prognostic sign. If a differential count is made the high relative polynuclear percentage will also be found. An increasing polynuclear percentage and stationary or decreasing leucocytosis indicates an increasing degree of infection and decreasing body resistance. A decrease both in the polynuclear percentage and in the leucocytosis denotes improvement. If pus is confined by dense pyogenic or fibrous membranes, there is no absorption of toxins, and consequently no leucocytosis or polynuclear increase. These may occur in pneumonia, erysipelas, scarlatina, and occasionally in malignant disease, and here the blood count would be of little value in differential diagnosis. Experience also teaches that a septic condition occurring as a secondary or mixed infection with tubercle bacilli, typhoid bacilli, and possibly a few others, presents a lower relative polynuclear percentage than we would obtain if the staphylococcus or streptococcus infection was a primary one

Journal of the American Medical Association, June 23, 1906.

A New Supplementary Color Vision Test.—N. M. Black remarks on the defects of the color vision tests usually employed, the inability of the Holmgren test to detect all forms of color defects, the failures of the lantern tests, especially in color myopia, etc., and describes a device of his own in which are utilized the optical laws that reduce the apparent size of an object when looking through the wrong end of a telescope. The apparatus consists of a tube with a dead black lining mounting a combination of biconcave lenses and fixed in a screen so as to prevent the subject of the test from seeing the source of the illumination, which consists of three standard semaphore lanterns arranged in a right-angled triangle at a given distance from the tube. These are fitted with frames in which the various colored glasses used for the tests can be placed. An attempt to produce the effects of fog, smoke, steam, rain and lowered intensity due to different atmospheric conditions, is made by interposing ground glass, smoked glass, etc. The person examined sits behind the screen and looking through the tube is asked to say what the different signals indicate, according as the lenses are adjusted to produce the effects of distance and the various conditions met with in actual railroad practice. The test, he says, "fits exactly the conditions found in practice. The objects used in testing are the same used in actual practice, the person tested is required to designate what he sees, either by name or to indicate its meaning, which he does in practice. The fault of all lantern tests is overcome by simulating distance by a relative reduction of the size of the image. The factor which gives the success to the Holmgren worsted test, that of comparison, is followed, the impression of distance is maintained, and the test may be used as an office test. The only thing we cannot do is to produce a gale of wind or a rain storm or the roar and noise of the engine for the benefit of the candidate while being examined." Formulas are given for the lens adjustments for apparent distance, also figures of the apparatus.

Meningitis in Infancy.—In the forty cases analyzed by J. L Morse, the diagnosis was made in every case by autopsy or lumbar puncture. A marked predominance of mononuclear cells in the spinal fluid was considered diagnostic of the tuberculous form, and of polynuclear cells of the cerebrospinal form. The meningococcus was found in all but three of the cerebrospinal cases. His careful analysis of the symptoms shows quite a different picture from the usual one given in the text-books; in only four of the cerebrospinal type was there the usually looked for sudden onset, and in seven of them there were no symptoms pointing directly to the nervous system until after several days or two weeks. On the other hand, the onset was sudden, with convulsions or stupor in four of the tuberculous cases. The short duration in many of the tuberculous cases and the long duration of many of the cerebrospinal cases was also very striking. The tuberculous form has a more sudden onset and a shorter course than in the adult, and the symptomatology of the two types is essentially the same, there being only a slight predominance of signs of spinal and to a less extent of cerebral irritation, in the cerebrospinal form, but not enough to justify a differential diagnosis. A positive diagnosis between the two forms is impossible by the symptoms alone, and can be made only by examination of the cerebrospinal fluid obtained by lumbar puncture. A high leucocytosis may be present in tuberculous meningitis, as well as in the other form, though not so characteristic. The history of the case is of value in making the diagnosis, but it is often wanting. Lumbar puncture has no curative value in cerebrospinal meningitis, but is very useful for the relief of symptoms in both forms. Twenty cases of each form, all in patients in the Infant's Hospital, Boston, furnished the material for the study.

Joint Manifestations in Hemophilia.—E. W. Ryerson says the possibility of hemophilia should be kept in mind in doubtful joint affections, and a thorough study of the case will then lead to a correct diagnosis. In the first stage aspiration of some of the fluid may be necesssary, and the procedure is harmless if done with a very small needle and with all proper precautions. The principal conditions likely to cause confusion in this stage are acute synovitis and intermittent hydrops or hydrarthrosis. In the former there is usually a history of more severe injury, more local pain and tenderness, and the effusion disappears more slowly. Intermittent hydrops is a very rare disease, characterized by intermittent mild joint effusions occurring without antecedent traumatism, and each attack followed by complete recovery. The various infectious forms of arthritis are much more painful and persistent and attended with more constitutional disturbance; the antecedent disease also suggests the diagnosis. In the hemarthroses of the hemorrhagic diseases, such as purpura, etc., the accompanying petechiæ are indicative of the cause. In the second stage of hemophilic hemarthrosis, with its thickened capsule, limited motion and beginning flexion, tuberculosis is suggested, but the absence of true spasticity, of free fluid in the joint and of local tenderness, together with the lack of temperature, help to exclude that disease. Arthritis deformans is distinguished by its slow onset, multiple involvement of joints, and the presence of bony or cartilaginous exostoses. In the third stage the clinical picture may be exactly that of an old tuberculous joint, with complete ankylosis and without evidence of suppuration and a complete history of the case may be required. Before operating on any old ankylosis in which hemophilia cannot be positively excluded, a test of the coagulability of the blood should be made. For treatment of the first stage, Ryerson advises aspiration with a fine needle, followed by injection of adrenalin solution and a bandage for six hours. Use of the joint and massage are advised if aspiration cannot be done. No fixation should be used after the first day. In the later stages, with a tendency to flexion, traction, followed by a splint or cast is advised. Ankylosis in flexion might be corrected by forcible measures, but any cutting operation must be sedulously avoided.

The Lancet, June 9, 1906.

Cannabis Indica in Tetanus After Childbirth.—Two cases successfully treated are reported by A. M. Smith. A third case similarly treated died. Of the two former, Case 1 was not seen until ten days after labor. The woman, a Mohamedan, was thirty years old. She was put on tincture of cannabis indica, 15 minims of the tincture q. 3 h. for twelve hours, and then the same dose, q. 4 h. for three days. The dosage was gradually reduced, until the ninth day, when she was taking 6 minims t. i. d. Tetanus was well marked when the treatment

began, but the latter at once alleviated the spasm, and by the fourteenth day the patient was practically well. Case 2 occurred in a Hindoo woman of twenty-five years, in whom tetanic symptoms first appeared sixteen days after delivery. Cannabis was given freely, as in Case 1, and on the sixth day the patient was up and able to walk. The uterus was not curetted in Case 1, but was so treated in Case 2, though not till the fifth day (twenty-fourth after delivery), after admission to the hospital. In both cases the child did well.

Deep Alcohol Injections in Facial and Other Neuralgias and in Histrionic Spasm.—From this method, F. Ostevath claims entirely satisfactory results in more than 90 per cent. of all cases. He employs about a dram of 80 per cent. alcohol containing a sixth of a grain of cocaine or stovaine. He is able to reach, by injections, not only the third, but also the second and first branches of the fifth cranial pair at the very points where they emerge from the apertures at the base of the skull. Full anatomical directions are given in regard to these matters and must be consulted in the original paper. The effect of the injections is felt not only in anesthesia, but there is also a paralysis in which the masticatory muscles incompletely share. This is temporary, however, though it may last two or three months. These results show that the alcohol produces an actual nerve degeneration, which is recovered from, though fortunately the condition of pathological irritability which produced the neuralgia rarely returns with the recovery of nerve function. Relapses are apt to occur in about one-third of the cases, and then, as a rule, about five months after the first treatment. The author has observed no accidents from his several hundred injections. The same plan of treatmet has been applied to cases of histrionic spasm and sciatica.

Pneumococci Peritonitis in Children.—Summarized histories of sixteen fatal cases are given by W. F. Annand and W. H. Bowen. They say that prognosis depends on the following factors: (1) Whether the peritonitis is local or diffuse; (2) whether an operation is or is not performed and, if performed, whether or not at a suitable time; (3) the previous presence or the onset of a severe complication. Whether the peritonitis is primary or secondary, providing there is no other complication, does not appear to affect the prognosis to any material extent, according to the results in 91 cases tabulated. Of this number 45 had encysted peritonitis, of which 44 were operated on, and of these 37 recovered and six died; in two the result is uncertain. The other 46 cases were of the diffuse variety, of which 18 underwent operation. Of the 18 cases operated on, 6, or 33.3 per cent., recovered, whereas all those not operated on died. The one case of the local variety not operated on recovered by spontaneous evacuation of the pus. The above table shows that recovery occurred in 86 per cent. of those with the encysted form, while only 14 per cent. of the cases with the diffuse variety survived. The authors present the following summary of their views: (1) Pneumococcic peritonitis is a comparatively rare disease in children, but in the past many cases have not been recognized; (2) it is in about a third of the cases secondary to some remote pneumococcal lesion; of these affections of the lungs and pleuræ are by far the commonest, the middle ear being the next most common site. The infection is carried to the peritoneum in the blood stream. (3) In the remaining two-thirds the peritoneum is probably infected from the bowel in the vast majority. No microscopic lesion is, as a rule, found. (4) In half the cases the pus is encysted; in these the diagnosis is fairly easy, the prognosis is good, and the treatment is laparotomy and drainage. (5) In the other half of the cases the peritonitis is diffuse, the diagnosis is very difficult, and the prognosis very gloomy. The treatment is laparotomy. (6) The pathological appearances are characteristic.

British Medical Journal, June 9, 1906.

Successful Amputation of the Leg at 94 Years With an Account of a New Operation.—In a West Indian woman of the age stated, who had been knocked down with the result that the lower third of the leg sustained a compound fracture, C. W. Branch did a successful amputation, the patient being discharged well at the end of five weeks without any special complications during healing. The mode of operating is thus described: The left hand seizes the outer side of the leg at the point of section of bone, thumb to the front. The skin over the tibial surface is drawn forcibly outwards, the point of the knife is made to enter at the edge of the tibia, graze the fibula, and emerge as far inwards as possible on the back of the leg, and a flap is then cut downwards. On releasing the leg the front of the incision flies inwards, so that it is now possible to enter the knife and clear the tibia to reach the point of exit behind, and cut the internal flap, which should equal the external. With the catlin a semilunar periosteal flap is cut from the front of the tibia, and quickly stripped upwards, the bones cleared, and the saw entered first obliquely, then straight, in the usual way, so as to take off the front corner of the tibia. This point of bone is in the anterior angle of the wound, but being covered by the periosteal flap, never becomes adherent. Two acupressure pins are inserted between the bones crosswise, so that the anterior and posterior tibial arteries lie in the opposite angles. A stout silk is now wound by figures-of-8 so as to close the pins together and compress the arteries. The pins are slightly withdrawn from their cannulæ, so that the points are hidden, and the tourniquet removed. Two sural vessels in the heads of the gastrocnemius usually require ligature, and nothing remains but to suture, leaving the heads of the pins and the end of their silk protruding from the anterior angle of the wound. The pins are removed about three or four days after, and the silk, then loose, easily comes away.

The Infectivity of Enteric Fever.—W. Wright and W. Archibald relate the histories of a small epidemic of seven cases. The first case seems to have infected the other six. All occurred in the same tenement (Glasgow), all were under ten years of age and were playmates in the lobbies and on the stairs of the building. The view that the water-closets may have served as a source of infection is negatived by the fact that none of the adults (twenty-eight in number) resident in those three flats were attacked, and it is not thought that the situation of the houses in respect of their water supply, some being placed on different sides of the stair, was a factor in the causation. The evidence points strongly to personal infection during play, and, this method of spread of enteric fever being comparatively rare, it was deemed worthy to place these cases on record.

General Convulsions in Early Infancy Induced by the Taking of Food.—Eustace Smith discusses this question in its relation to pyloric obstruction in the infant. He has seen certain cases in which a healthy infant has been thrown into violent convulsions a few minutes after some simple meal without any preceding vomiting or other evidence that the food did not completely agree. All the cases have been in bottle-fed babies. The author brings the matter up because in his view such cases throw a strong light on the mechanism of pyloric obstruction in the newly-born. He believes this condition due, in the beginning, to a reflex spasm of the pyloric wall, caused by the taking of food, and that a continued repetition of the contraction determines a hypertrophy of the muscular layers surrounding the opening. He calls attention to the tendency to local spasm in infants. It may be said that if pyloric obstruction were due to local spasm induced by gastric irritation, the cases of general convulsions here described should all of them have been complicated by spasm of the pylorus, but he declares that such a conclusion does not necessarily follow, and he sees nothing unreasonable in believing that gastric irritation may set up general convulsions without pyloric spasm or pyloric spasm without general convulsions or both together.

Clinical Features of the Several Types of Colitis.—H. A. Caley makes the following decisions of colitis cases: (1) Catarrhal (acute, primary and secondary and chronic, irritative, or atonic and spastic); (2) membranous, (3) parietal colitis and pericolitis, and (4) ulcerative (endemic, epimedic, or sporadic), and his paper is an elaboration along these lines. The various symptoms of each form are taken up in turn and an endeavor made to present contrasting clinical pictures. Of special interest are his observations in regard to the causative relation of influenza to colitis. This relationship may be traced in the following ways: (1) Influenza of the gastro-intestinal type may present symptoms of acute or subacute colitis, though a general enteritis is more common; the colitis may rapidly subside or it may pass into a chronic phase; (2) chronic colitis, catarrhal or membranous, may be much aggravated by an attack of influenza: indeed, the latter is a fruitful cause of relapse in cases of colitis otherwise doing well; (3) colitis may apparently originate in an attack of influenza, the bowel symptoms dating from that time, and in such cases it is highly probable that the lowered nervous tone so conspicuous an after-effect of influenza plays an important part.

Berliner klinische Wochenschrift, June 4, 1906.

The Nasal Treatment of Epiphora.—Meyer states that in many cases of this affection the fault lies with the conformation of the lower turbinated body. This hugs the outer wall of the nasal passage more closely than it should, and obstructs the lower opening of the tear duct. It is undesirable, however, to cut away entirely the turbinated body, as this leads to respiratory difficulties brought on

by the removal of so large a proportion of the mucous surface of the nasal passage. The author's operation, which has been found very effective, consists in forcibly twisting the obstructing ledge toward the septum through an angle of thirty to forty-five degrees by means of a suitable forceps. The bone is fractured in doing this, so that there is no tendency to a return to the original condition, and in proper cases the effect in checking the overflow of tears is very marked.

Observations on the Formation of Leucotoxin Through the Action of the Röntgen Rays.—Milchner and Wolff describe experiments on animals and on exudates which cause them to maintain a conservative attitude in regard to the prevailing view that through the action of the Röntgen rays a toxic substance or leucotoxin is derived from the leucocytes. While they admit that great destruction of the leucocytes is caused in this way, they are not willing to concede that the toxic substance is the result of the breaking down of the leucocytes. The polynuclear cells appear to be more resistant to the action of the rays than the others, and on subjecting living excised spleens to the rays great destruction of tissue was caused and the extract from the organ gave rise to leucopenia when injected into animals.

Münchener medizinische Wochenschrift, June 5, 1906.

A Case of Unexplained Fever With the Highest Recorded Temperatures.—Heller describes the case of a fifteen-year-old girl, who went through an illness of about a week's duration, of which the only objective symptoms of note, in addition to the fever, were moderate swelling of the spleen and a soft systolic murmur. The temperature was remarkable, however, in that on one occasion it reached 44° C. and on several others 45° C., the upper of which limits has, according to the author, never before been reported. In taking the temperature four different thermometers of tested accuracy were used and the readings were checked by three other persons in addition to the author. All of the manifestations usually attending high fever were absent in this case. The tongue was moist and not coated, the sensorium was not affected, the heart was comparatively quiet, and there were no urinary changes.

A Case of Permanent Spinal Paralysis Following Spinal Anesthesia.—Kōnig's patient was a man of thirty-five years, who fell while drunk and fractured his left patella. A week later the fragments were united by suture under spinal anesthesia. The patient did not regain either motion or sensation below the level of the umbilicus; that is, including the bladder and rectum. Death followed three months later, attended by the usual complications of cystitis and bed sores. At the autopsy there was found evidence of a serofibrinous inflammation of the spinal membranes, but there was no meningitis, and cultures made from the spinal liquid, obtained on two occasions by lumbar puncture, remained sterile. The spinal cord itself was found softened in the lumbar and dorsal regions. The author thinks that the possibility of infection can be excluded, and ascribes the unfortunate result to toxic action. At the lumbar puncture, made for the purpose of the original injection, the spinal fluid was slightly pink, and it is suggested that perhaps this indicated some already existing abnormality of the cord, which rendered it more susceptible to damage by the anesthetic agent injected. The author cautions against using the method unnecessarily, or if the spinal fluid is in any way abnormal.

Blood-Pressure Determinations.—Schilling reports clinical observations and experiments on calves made in order to determine the part played in blood-pressure determinations by the width of the armlet used. Most modern authors, including v. Recklinghausen and Janeway, are in favor of the 12 cm. armlet, although Sahli considers that the narrow band gives a more accurate criterion, his point being that the lower pressures obtained with the wide armlet depend on the fact that the pulse wave is forced to perform work in passing under the constriction and therefore becomes extinguished at the periphery before the pressure under the armlet has quite reached the true arterial pressure. The authors, however, agree with those observers who prefer the wide armlet, and state that the 12 cm. armlet is the most accurate one for clinical use. They found that the arterial pressure of the normal male adult lies between 110 and 125 mm.

Deutsche medizinische Wochenschrift, June 7, 1906.

The Treatment of Black Water Fever.—Dammermann considers that the malarial infection is the underlying cause of the development of this complication, which is evoked, however, by the administration of quinine. He describes one case in which three different attacks of hemoglobinuria were caused in the course of a protracted malaria by the administration of even very small amounts of quinine, and others in which death was caused in this way. Contrary to the statements of some observers, he does not believe that the subcutaneous administration of quinine lessens the risk of the development of the renal lesion which consists in the plugging of the tubules with damaged red blood cells. The author's treatment consists in the administration of large amounts of milk and a tablespoonful of two-per cent. potassium acetate solution every hour or two in order to excite diuresis. If milk cannot be obtained or is not retained by the patient, water or large saline rectal injections are to be substituted. Patients with malaria who have already suffered from black water fever after taking quinine should be treated by means of an infusion of the leaves of *Combretus raimbauthii*, a native fever remedy in use on the west coast of Africa, which, in the author's opinion, should be imported into Europe.

The Treatment of Leprosy with Iodoform.—Diesing has treated five patients with leprosy by means of subcutaneous injections of large quantities of iodoform, and considers that a permanent cure has been effected in these cases. The remedy was used in the form of a 30-per-cent. emulsion in olive oil, of which from 2 to 8 c.c. were injected daily under the skin in the neighborhood of the affected areas, and later, when these had become normal, in the subcutaneous tissues of the back, chest, and flexor surfaces of the extremities. He explains the superiority of this form of iodine medication by assuming that on coming in contact with the tissues, the air being excluded, nascent iodine is set free and attacks the leprosy bacilli. He also suggests that the remedy be tried in tuberculosis; the good results obtained in its use locally for joint affections indicating that when employed in more courageous doses it would produce equally satisfactory effects in pulmonary tuberculosis. The large doses employed by the author never gave rise to symptoms of intoxication.

Antiperistalsis in the Stomach.—Jonas says that reverse peristalsis or antiperistalsis of the stomach is not so rare as is supposed, and that if carefully looked for it can often be detected. He describes six cases in which it was clearly demonstrated by direct observation with the fluoroscope after having the patients swallow a mixture of gruel, bismuth subnitrate, and sugar of milk. In five of these cases pyloric stenosis was present, and in the sixth it appeared that pylorus was not normal and was probably responsible for the reversal of motion in the organ. It therefore appears that a connection exists between pyloric stenosis and antiperistalsis, but in view of the many cases of the former condition unaccompanied by the latter it is evident that some further element must also be involved.

French and Italian Journals.

Perforations of the Interauricular Septum.—Bériel divides interauricular communications into two groups: the persistent foramen ovale and perforations proper. It is impossible to say at exactly what time the foramen ovale closes, since its persistence has been noted by different authorities in children of various ages. The perforations proper may consist of a cribriform condition of the septum; simple perforations; or the more or less complete absence of the septum. The sieve-like septum is observed generally in young patients with other cardiac malformations. Cases of simple perforation are more frequent. In extreme cases of absence of the septum there exists only one auricle. In these cases there are generally various other deformities of the different parts of the heart and the blood-vessels. As to the etiology of these formations it is impossible to establish a rigorous classification. It must be admitted, however, that there exist perforations both congenital and acquired. The writer intersperses a number of interesting observations, which, together with cuts, illustrate his statements.—*Revue de Médecine*, May 10, 1906.

A Case of Calculus of the Submaxillary Gland.—G. Alexandre states that cases of this nature are not common. The patient whose history is given here was a woman fifty years old. Her family history was negative. There was little of interest in the personal history. When first seen by the writer she stated that for the last thirteen or fourteen years she had had an enlargement under the left side of the lower jaw. The size of this tumor had gradually increased, although it varied from time to time. There was no discoloration of the tissues. Palpation discovered an indurated and resistant mass movable under the skin and having the form of the submaxillary gland. For years the patient had no pain, but for the last six months she had suffered from this growth. Eating, however, was very easy. Nothing abnormal was noted on examination of the mouth. The gland was removed successfully. On transverse section a calculus as large as a big pea was found. Chem

ical examination showed it to be composed of water, carbonate of lime, phosphate of lime, and organic matter. Bacteriological examination resulted in growth of a pure culture of leptothrix. This microorganism is always found in the mouth.—*Revue de Chirurgie*, May 10, 1906.

Muciparous Epithelial Cancer of the Lung.—Sabrazés and Muratet report the history of a woman fifty-one years old who had all of the physical signs of a large right-sided pleural effusion together with extreme pain, intense dyspnea, and rapid emaciation. A wooden dullness was noted at the summit. There was prosternal edema with distention of the right jugular. Puncture with a fine needle was negative. Death occurred in asystole. The liquid of the effusion was pale yellow and thick, giving the chemical reactions of mucin. The mucus originated in the right lung, which was invaded by a primary malignant tumor, a muciparous epithelial cancer. This tumor was polymorphous. The hypersecretion of mucus was a very striking feature.—*Le Progrès Médical*, May 12, 1906.

Treatment of Tardy Diphtheritic Paralysis.—Comby calls attention to the fact that the successful outcome of the treatment of diphtheritic paralysis by antidiphtheritic serum has been doubted. The writer reports another case as a proof that the results of this treatment are very encouraging. The patient was a girl fourteen years old. An attack of diphtheritic angina which was not recognized at the time was followed by paralysis of the soft palate, strabismus with diplopia, paralysis of the lower extremities with paresis of the muscles of the trunk, nape of the neck, and upper extremities. For two months the only treatment consisted of injections of cacodylate of soda, but the paralysis was only accentuated. After the entrance of the patient into the hospital, however, the writer treated her with injection of Roux's serum. In forty-eight hours the condition began to improve and within a few days recovery was complete.—*Le Bulletin Médical*, May 19, 1906.

Hot Baths in Bronchopulmonary Diseases of an Acute Nature in Infants.—Gaetano Finzil finds great difference of opinion among authorities with reference to the use of hot baths in acute bronchopulmonary lesions in infants. He submits the results obtained by him in the treatment of such cases. Hot baths are more easily permitted by the parents, who fear the action of cold on the lungs. The author uses the bath at a temperature of 37° to 39°, that is, a few degrees less than the temperature of the child treated. If the child is depressed he precedes the bath by a stimulant and adds mustard to the water. After the bath the child is at once wrapped in flannel and is allowed to rest a half hour covered up in bed. The author has treated thirty-two children under one year in this way. The results have been excellent and he refers the benefit to these factors: 1. The increased inspiration during the bath, and the hot vapor which is inspired. This favors elimination of the mucus which lines the bronchi and increases expectoration by lessening the thickness of the mucus. 2. The surface of the skin, after a short period of contraction of the capillaries, presents dilatation of these and the skin becomes very red and covered with sweat. The determination of blood to the surface relieves the bronchial congestion. 3. The profuse sweat favors the elimination of the poisons produced in the system by the disease.—*Annali di Elettricità Medica e Terapia Fisica*, March, 1906.

Injections of Biniodide of Mercury in Syphilis.—Eugenio Sipari records his observations of twenty cases of syphilis treated by hypodermic injections of biniodide of mercury in aqueous solution combined with iodide of sodium. His conclusions are these: The solution acts very favorably on all syphilitic lesions, especially those of the tertiary stage; the rapidity of action is marked; the efficiency is marked, greater in some instances than that of calomel or corrosive sublimate; the injections are not painful; they do not produce nodules of infiltration, or such as are produced are indolent; they are always well borne; they do not produce mercurial stomatitis under the usual conditions. For all these reasons biniodide of mercury in solution with sodium iodide used by hypodermic injection may be regarded as one of the best preparations for the treatment of syphilis, especially in the tertiary stage.—*Giornale Internazionale delle Scienze Mediche*, April 30, 1906.

Prophylaxis and Treatment of Vulvoperineal Lacerations.—C. Morletti discusses the best method of delivery of the head to prevent laceration of the perineum. He considers that the best method which accomplishes the delivery of the head in two separate acts, extracting first the maximum transverse diameter and then the maximum anteroposterior diameter. This is best theoretically and gives the best results practically as well. He discusses the convenience of episiotomy and estimates its advantages and disadvantages, condemning the technique usually made use of in incision of the vulva; he would substitute for the cutaneous incision one on the surface of the mucous membrane, since he believes that the resistance is usually in a situation corresponding with the level of the remains of the hymen. For repair of the perineum he makes use of the method of Bumm, the sutures being horizontal through the entire thickness of the perineum, three or four in number, since it permits of the repair of lacerations of the third grade and gives a fair resistance to the infiltration of the lochia.—*La Riforma Medica*, May 5, 1906.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE PRACTICE OF GYNECOLOGY. By Eminent Authorities. Edited by J. WESLEY BOVÉE, M.D. 8vo, 836 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia. Price, cloth, $6.00, net; leather, $7.00, net; half morocco, $8.00, net.

UBER DAS WESEN UND DIE VERBREITUNG DER WURMKRANKHEIT (ANKYLOSTOMIASIS). Von Dr. LÖBKER und Dr. HAYO BRUNS. Sonderabdruck aus "Arbeiten aus dem Kaiserlichen Gesundheitsamte." Twenty-third Year, Vol. II. 4to, 102 pages, illustrated, paper. Julius Springer, Berlin.

THE SUBCONSCIOUS. By JOSEPH JASTROW, Professor of Psychology, University of Wisconsin. 8vo, 549 pages, muslin. Houghton, Mifflin & Co., New York. Price, $2.50, net.

MANUAL OF DISEASES OF THE EAR, NOSE, AND THROAT. By JOHN JOHNSON KYLE, B.S., M.D. 12mo, 595 pages, illustrated. Flexible leather. P. Blakiston's Son & Co., Philadelphia, Pa. Price, $3.00.

THE AUTOTOXICOSES, THEIR THEORY, PATHOLOGY, AND TREATMENT. By HEINRICH STERN, Ph.D., M.D., etc. 12mo, 222 pages, muslin. G. P. Engelhard & Co., Chicago. Price, $1.00, postpaid.

THE MORPHOLOGY OF NORMAL AND PATHOLOGICAL BLOOD. By GEORGE A. BUCKMASTER, D.M. (Oxon.). 8vo, 244 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $3.00.

GRUNDRISS DER ORTHOPÄDISCHEN CHIRURGIE. By Dr. MAX DAVID. Second Edition, revised and enlarged. 4to, 240 pages, illustrated, paper. S. Karger, Berlin. Price, muslin, $6.00.

ON LEPROSY AND FISH EATING. By JONATHAN HUTCHINSON, F.R.S., F.R.C.S., LL.D., D.Sc., M.D. 8vo, 420 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $3.25, net.

TRANSACTIONS OF THE NATIONAL ASSOCIATION OF UNITED STATES PENSION EXAMINING SURGEONS. Vol. III. Fourth annual meeting, Chicago, July 7 and 8, 1905. 8vo, 93 pages, muslin. Published by the Association at Rochester, N. Y.

ENIGMAS OF PSYCHICAL RESEARCH. By JAMES H. HYSLOP, Ph.D., LL.D. 12mo, 427 pages, muslin. Herbert B. B. Turner & Co., Boston. Price, $1.50, net.

OUTLINES OF APPLIED ANATOMY WITH SPECIAL REFERENCE TO SURFACE LANDMARKS. By RICHARD J. A. BERRY, M.D., F.R.C.S.E., F.R.S.E. 8vo, 244 pages, illustrated, muslin. J. B. Lippincott Company, Philadelphia.

TWENTY-NINTH ANNUAL REPORT OF THE BOARD OF HEALTH OF THE STATE OF NEW JERSEY FOR 1905 AND ANNUAL REPORT OF THE BUREAU OF VITAL STATISTICS. 8vo, 396 pages, muslin. J. L. Murphy Publishing Company, Trenton.

INTERNATIONAL CLINICS. Edited by A. O. J. KELLY, A.M., M.D. Vol. I, Sixteenth Series, 1906. 8vo, 309 pages, illustrated, muslin. J. B. Lippincott Company, Philadelphia.

GENERAL MEDICINE. (The Practical Medicine Series, Vol. I.) Edited by FRANK BILLINGS, M.S., M.D., and J. H. SALISBURY, A.M., M.D. Series 1906. 12mo, 369 pages, muslin. The Year Book Publishers, Chicago. Price, $1.25.

GENERAL SURGERY. (The Practical Medicine Series, Vol. II.) Edited by JOHN B. MURPHY, A.M., M.D., LL.D. Series 1906. 12mo, 583 pages, illustrated, muslin. The Year Book Publishers, Chicago. Price, $2.00.

PRAESCRIPTIONES. Rezept-Taschenbuch für die Praxis. Von Dr. EMIL KANTOROWICZ. 12mo, 190 pages, paper. August Hirschwald, Berlin. Preis M. 2.

ON CARBOHYDRATE METABOLISM. By F. W. PAVY, M.D., LL.D., F.R.S. 8vo, 138 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $2.40.

SECTION ON MEDICINE.

Fourth Day—Friday, June 8.

Value of Tests for Invisible Hemorrhage in Diagnosis and Treatment of Diseases of the Digestive Organs.—Dr. FRANKLIN W. WHITE of Boston said that the methods which till recently had been most used by clinicians were Teichmann's test for hemin crystals, and the spectroscope, but they both must yield in simplicity and delicacy to the recent guaiac and aloin tests, which could easily be carried out by the practicing physician without other apparatus than a test-tube and a few simple drugs. The technique was as follows: 10 c.c. of feces was rubbed up with a little water, or 10 c.c. of gastric contents was shaken with 2 c.c. of glacial acetic acid and then extracted in a test-tube with an equal volume of ether by gently shaking back and forth. The test-tube was allowed to stand until a clear layer of ether separated; the latter was poured off and tested for blood by the addition of 10 drops of freshly prepared tincture of guaiac or aloin, and 30 drops of hydrogen peroxide or well ozonized turpentine. In the presence of blood the guaiac gave a clear blue color and the aloin a clear cherry red. In conclusion he said that (1) the guaiac or aloin test for invisible blood was, in spite of exceptions, the most valuable single clinical method recently developed for the recognition of latent cancer and ulcer; (2) the method was very delicate and yet so simple it could be easily carried out by the practicing physician; (3) the value of the test depended upon the care with which other sources of bleeding were excluded; (4) the test in the stools had greater value; both positive and negative results were significant; positive results in gastric contents were often misleading; (5) never be content with one examination; (6) in ulcer the chief value of the test was to distinguish it from a neurosis, as a premonitory symptom, as a measure of the result of treatment, in prognosis; (7) in cancer, in diagnosis from an acid gastritis, achylia, pernicious anemia, and similar conditions; (8) in general, it had great value in ruling out hemorrhage in a suspected case.

Studies on Cardiospasm.—Dr. BERTRAM W. SIPPY of Chicago reported the history of one case of cardiospasm in detail, and said that he had seen altogether fourteen cases. He showed his dilatating instrument, and demonstrated its use. He also showed a specimen of esophageal dilatation.

Non-Calculous Cholecystitis.—Dr. A. O. J. KELLY of Philadelphia considered the causes of cholecystitis, the infectious agents, and modes of infection, and reported cases illustrative of the different types of the affection. He made an analysis of the symptomatology, based on a study of thirty-five cases operated on by Dr. Deaver at the German Hospital, Philadelphia; he made a contrast of the symptomatology of these cases as compared with one hundred and eighty-one patients exhibiting gallstones at operation. He spoke of the remote consequences of cholecystitis, and made suggestions as to its treatment and the indications for operative interference.

Differential Diagnosis Between Duodenal Ulcer and Gallstone Disease.—Dr. CHRISTOPHER GRAHAM of Rochester, Minn., in summing up his paper, said that pain in cholecystitis was sudden and severe, usually had a wide field of radiation, came with no regularity as to time, was rarely caused by food and as rarely eased by it, nor did the patient often trace his distress to it. There was no stomach history between the short, sharp attacks; spasm of the diaphragm, with dyspnea, was common, vomiting and gas, if present, were so only during the colic, and the relief from eructation and vomiting was not so marked as in ulcer. Nausea and intense retching might be followed by vomiting of a small amount of thin yellowish liquid, mixed with mucus. In duodenal ulcer, the pain came in periods of attack lasting for days or weeks, often were sudden, might be severe, but usually not that intense type of pain met with in gallstones, but rather gnawing and burning in character. It might be irregular as to the time of the separate attacks, but quite regular during the period of the stomach disturbance. The pain was clearly related to food, the intensity often modified by kind and quantity taken; the food eased for a time, but the pain returned two to four hours later. Drinks (hot), soda, and irrigation gave relief. Spasm of the diaphragm was rarely seen except in some cases of perforation. The chronic gallstone case, with impacted stone, ulceration, and adhesions, where no jaundice appeared and where the stomach symptoms, as gas, vomiting, burning distress, sour eructations, impaired appetite, and dilatation, predominated, and where the pain was moderate and followed the taking of food, would too often be diagnosticated ulcer; while the duodenal case, in whose history we could elicit only irregular attacks of sudden, sharp, intense pain of peritonitis or acute spasm (and with no obstruction or hyperacidity, no gas, vomiting, or sour eructations), would be as surely mistaken for gallstones.

Dr. S. J. MELTZER of New York, in discussing Dr. Sippy's paper, said that so far as his knowledge of the literature went Dr. Sippy had seen the greatest number of cases of cardiospasm; no one man had seen so many as fourteen. Out of justice to himself, Dr. Meltzer wished to have it known that the first case of this condition was described by him in 1888, and until that time no one had published any case.

Dr. GARRY DE N. HOUGH of Massachusetts spoke of the abnormal sites of the pain in gallstone disease and said he had seen three cases in which this pain was referred to the left side, a kind of local colic, and in three other cases the pain was in a situation hitherto not described, *i.e.* at the left sacroiliac synchondrosis, one inch below the umbilicus and a little to the right of the median line, but associated with tenderness in the gall-bladder region.

Dr. GEORGE W. MCCASKEY of Fort Wayne, Ind., said that all knew there was no tendency in malignant disease to ulcerative processes in the earlier stages, but this was not so true in ulcer. Dr. McCaskey then referred to the changes and grave anemias that followed minute hemorrhages covering a period of time as from the ankylostomiasis and bothriocephalus. Small quantities of blood removed each day finally would produce a very grave type of anemia.

Dr. Sippy said that in his paper now ready for publication on this subject he had devoted at least two pages to Dr. Meltzer, and gave him credit for having seen and published the earliest case.

The Opsonic Index in Medicine.—Drs. NATHANIEL BOWDITCH POTTER, NORMAN E. DITMAN, and ERNEST B. BRADLEY of New York presented this paper. They said that Denys and Leclef first called attention in 1895 to the effect of blood serum on phagocytosis by leucocytes. They were the first to produce reliable experimental evidence that there existed in the blood serum of immunized rabbits substances which altered microbes in such a way as to permit their being ingested by the leucocytes. From careful experiments *in vitro* they concluded that in an immunized rabbit the leucocytes obtained their power of engulfing the bacteria from some property of the serum. The immunized animal fought the bacteria, first, by the direct action of the serum; second, by its leucocytes. The latter always owed to the serum the commencement of their power. Wright and Douglas in 1903 introduced the word "opsonic" (from the Greek word, meaning, "I prepare the food for") to characterize the substance in normal blood which they believed prepared the microbes for

ingestion by the leucocytes. They were able to show that this substance existed in the serum, that it was partly thermolabile, being largely destroyed at 60° C. in ten minutes, and that it acted upon the bacteria and not upon the leucocytes. An extensive review of the literature here followed. To illustrate the method, if it was desired to obtain the opsonic index to staphylococci of a patient suffering, say from acne, equal parts of washed corpuscles, bacterial suspension, and patient's serum were mixed in the pipette and placed in the incubator. In another pipette equal parts of washed corpuscles, bacterial suspension, and normal serum were likewise mixed and incubated. At the end of fifteen minutes smears were made from each specimen, fixed, and stained. The number of staphylococci per leucocyte was obtained in each case by counting the cocci in the first fifty polymorphonuclear neutrophiles encountered and making an average. If the average for the patient's blood was 6 cocci and that for the normal was 8, the opsonic index to staphylococci would be 6-8 or 0.75. The nature of opsonins was then considered and their relation to amboceptors, to toxins and complements, to "stimulins," to leucocytosis, to virulence of bacteria, etc. A table showing their results in a series of patients with various infectious diseases, the experiments being prepared in the Pathological Laboratory of the College of Physicians and Surgeons, Columbia University, was presented. In thirty-six cases of tuberculosis the tuberculo-opsonic index was below normal (0.73) in 25 per cent. of the cases, and above normal (1.2) in 8 per cent. of the cases; in other words, it was abnormal in 33 per cent. of the cases. Of twenty-three cases with infectious diseases other than with the tubercle bacillus, the tuberculo-opsonic index was below normal in 26 per cent. and above normal in 4 per cent. of the cases. The influence of antitoxins on opsonins and vaccines was then considered as well as the clinical application of inoculation of vaccines controlled by estimation of the opsonic index. To show the diagnostic value of the opsonic index three methods had been devised, obtaining the opsonic index in blood serum, comparing the opsonic index of heated with unheated blood serum, and comparing the opsonic index of blood serum with the index of exudate or transudate from the same case. In reviewing the work that had already been done on opsonins the question of what practical use they might have was one of great interest. The great difficulty would arise from the fact that changes more or less profound were indicated at times by but slight variations of the indices, and that the variation was frequently not far beyond the limits of error in a method where opportunities for small errors in technique were numerous. Some aid in diagnosis might already be had by determining a single index; but before this could be considered a reliable method considerable work must be done to determine the degree of specificity of opsonins. A wider field of application would probably be in the control of inoculation of vaccines to determine the optimum dosage and regulation of the same, but this would be somewhat limited by the clinical difficulties of the method. A field as yet but little exploited which might prove of use was in the determination of susceptibility to infection, especially in the inherited susceptibility to tuberculosis. Perhaps its greatest usefulness would be found in the laboratory, where it might prove to be a convenient and rapid method of testing the virulence of organisms and the strength of sera which were dependent upon opsonins for their beneficial effects.

Discussion on the Causes and Treatment of Chronic Headaches.—A series of discussions took place on this topic.

Affections of the Nose and Adjacent Sinuses as a Cause of Headache.—Dr. Cornelius G. Coakley of New York said that the etiology of these headaches was comparatively simple. In the nasal cavities headaches might be caused from spurs, new growths, deviations, the contact of two mucous surfaces causing pressure upon the terminal filaments of the sensitive fifth nerve. In the sinuses headaches might be caused by retention within those cavities of fluids, possibly gas, causing pressure. It should not be forgotten that other things than those found within the nasal cavity might cause headache. Two patients might present themselves suffering from deviations or spurs, causing marked pressure upon the mucous surfaces. Operation would relieve one patient, but not the other. The difficulty was in looking into the nose and seeing two surfaces in contact to determine whether that alone was causing the headaches. It was difficult, from the location of the pain, to determine what sinus was involved. The pain was, as a rule, of a neurotic character, more severe in the morning and relieved with the discharge of fluid from the cavities. They came regularly every day, and therefore were often treated as though they were malarial in origin. The importance of drainage of sinuses was entered into; if then the headaches persisted another cause should be sought for.

The Relation of Eyestrain to Chronic Headache.—Dr. George M. Gould of Philadelphia said that a vast majority of all cases of headache, certainly nine-tenths, were due to eyestrain. In thirty-one years the members of the American Ophthalmological Society had contributed three papers suggesting that eyestrain was the cause of some headache, and one member had contended that nasal disease, not eyestrain, was the cause of frontal headache. But there had been 122 papers on ocular tumors and many hundreds on ophthalmic surgical subjects. While the Governor of Massachusetts in his inaugural address said that untold numbers of children were becoming ruined in health because of headaches, due to eyestrain, leading members of the great ophthalmic societies ridiculed such folly. While one great diagnostician said that all sorts of gastric diseases were often due to eyestrain and cured by glasses, all the stomach specialists in the world, and 99-100 of the oculists in the world denied the truth. While medical journals were teeming with reports of the world's greatest scientist as to the sleeping sickness in Africa the appalling sleeping sickness of the ophthalmologists at home did not at all interest. While from 40 to 60 per cent. of school children, by actual examination, were suffering from headaches and other systemic effects of eyestrain, and while great school teachers were trying to get the oculists to stop it, famous ophthalmic specialists were pretending to refract without a mydriatic and with the ophthalmoscope alone, and, of course, the spectacles they prescribed were ludicrous blunders; consequently their pet amusement was to guy the "eyestrain faddist." He asked why we were caught in such a set of contradictions and absurdities. The answers were many, but one he emphasized. The single explanation of all this wrangling and misunderstanding was that refraction was not a science; their refraction work was not well done. The country physician should take up refraction work because the great mass of working people simply could not pay the fee demanded by the oculists and were forced to put up with the indifferent work of the so-called opticians. The Superintendent of Schools of New York City ordered his hundreds of thousands to carry their books upon one side one half the time, and on the other side the other half. In this same city great classes of poor children were formed in lines and taught to bend their bodies at command to one side, and then to the other. Better would it be to hold a black cat over the cross roads at midnight and mumble a charm! Osteopathy was a wretched thing. Eddyism was rampant in the land and professionally he said we were largely responsible for Mrs. Eddy, her foolish children, and her million dollar temples. As medical men he said we had neglected the attitude of mind of the patient to himself, and to his disease—especially *her* disease! Again the quacks had made use of our refused quarryings as cornerstones for their healing temples. It was ridiculous bigotry to make fun of the quacks we ourselves allowed or created. These quackeries

were not made up entirely of errors, follies, greeds, and stupidities. Every text-book, and almost every monograph and medical journal article would be revolutionized when the oculists agreed; the oculists would not agree until the general practitioners secured the establishment of at least one refraction school, with a two-year, or possibly three-year obligatory course of post-graduate study.

Headaches Due to Aural Disease.—Dr. Philip Hammond of Boston said that the intimate connection between the innervation of the ear and the central nervous system was clearly established by Zuckerkandl, and later observation had offered further clinical proof of this relationship. In some cases the mere presence of cerumen in the canal had caused a most intense headache. Cephalalgia was quite commonly caused by aural disease. Gradle had observed that children especially were likely to have an almost continuous headache from slight obstruction of the Eustachian tubes. Complete relief almost immediately followed inflating the middle ear. In the more chronic adhesive processes in the tympanic cavity the subjective symptoms were not always so definitely referred to the ear. A feeling of fullness in the head, or pressure in the brain might be associated with chronic dry catarrh of the ear. Headaches were occasionally caused by acute inflammation of the middle ear and was usually relieved by paracentesis. The enduring forms of headache were caused by old chronic suppuration. The exfoliated epithelium and other products of the long-continued suppuration collected in the cavities of the middle ear and mastoid, often forming masses as large as a peach stone. They might assume such proportions that they not only filled the unoccupied spaces inside the temporal bone, but by pressure necrosis caused absorption of extensive areas of the bone. It was an exceedingly common occurrence for an ear that had suppurated at some former time to remain apparently dry for many years, with perhaps a few occasional crusts. The treatment should aim at a complete removal of all the diseased tissue, and, in the more advanced cases, where the disease had invaded the temporal bone, nothing short of a complete operation, a radical mastoid operation, would be curative. In any event cessation of discharge would probably mean relief from headache.

Constitutional Headaches.— Dr. George L. Walton of Boston said there was probably no sharply dividing line between constitutional and reflex headaches. In many cases of so-called reflex headache the reflex cause, *e.g.* a slight error of refraction, was only the exciting cause, the inherent make-up of the individual, the underlying cause rendering him susceptible. At one end of the scale existed certain headaches which could only fairly be termed constitutional. Ocular, nasal, or uterine defects might be present (as well as various other signs of deviation, especially including an exaggerated self-consciousness), but their treatment was unavailing. This headache was probably largely due to the physiological sensation of mental fatigue, made unduly acute by the oversensitized receptive centers, the fatigue itself being increased by the patient's inability to mentally relax. Concentration of the attention increased the pain, which finally seemed to deserve such terms as agonizing and frightful. When a young woman stated that a headache of this degree of violence had been continuous day and night for many years, notwithstanding the fact that she was out and about and showed none of the natural accompaniments of such pain, constitutional headache should be suspected, and the prognosis should be guarded regarding cure by the removal of reflex causes or other therapeutic measures. It was assumed that organic disease of brain, kidney, and other organs had been excluded, and toxic causes eliminated. Constitutional headache might simulate organic disease, but the reverse possibility must also be borne in mind.

Chronic Headache Associated with Pelvic Disease.— Dr. F. H. Davenport of Boston said that headache was not very common in connection with pelvic disease, and in taking 1,000 cases from his notebook, he found it mentioned 98 times, constituting about 10 per cent. In studying these cases he divided them into two groups, first, those connected with the menstrual function, and, secondly, those which seemed to be not especially due to the particular pelvic disorder found, but an expression of the neurasthenia on which the pelvic lesion was one of the predisposing factors. In the first group there were 30 cases, or about one-third, which were directly associated as regards time with the menstrual disorders, and the one abnormality which was constant was a diminution in the amount of blood lost, either from a scanty flow with the periods regular, or from delayed menstruation, the interval being more than four weeks, or again, from both scanty and irregular menstruation combined. The most common type of headache found in these cases came on a few days before the flow occurred, lasting from one day to several, and ceasing promptly as soon as the flow was established. Headaches occurring during the flow were very rare. The treatment of this form consisted first in general measures to improve the patient's health; any treatment that would make blood, improve its circulation, and steady the nerves, would tend to regulate this function. Local depletion should be tried, and the best, in his opinion, followed the use of wool tampons soaked in glycerine. The result was a profuse, watery discharge of blood serum, which relieved the engorged pelvic blood vessels and equalized the circulation. In the second group there were 22 cases where the headaches seemed to be clearly due to neurasthenic conditions, brought on usually by overfatigue, either mental or physical. He said that headache was not a common symptom of pelvic conditions; it was noted in only 14 cases out of 130 retroflexions and versions. There were 13 cases of anteversion, but the most of these had at the time scanty or irregular menstruation, and were probably of a poorly developed type. Some prolapse or enlargement of the ovary was found in 8 cases. Laceration of the cervix was present in 16 cases, and that was significant as emphasizing the fact that lacerations and irritations of the cervix frequently manifested themselves more by reflex disturbances than by local symptoms. In only four cases of fibroid tumors and none of ovarian, was headache present as a symptom. The conclusions he drew were as follows: (1) Chronic headache associated with pelvic disease was accidental, except where it was the most marked symptom of irregular or scanty menstruation; (2) in other pelvic disorders it was usually an expression of the neurasthenic condition, of which the pelvic lesion was merely one factor or accessory predisposing cause; (3) the treatment of the first class of cases was, first, general building up measures and local depletion; (4) the treatment of the second class was the rectification of the existing local trouble, unless specially contraindicated, but the main reliance was to be placed upon prolonged and systematic treatment of the neurasthenia.

(*To be continued.*)

ASSOCIATION OF AMERICAN PHYSICIANS.

Annual Meeting Held in Washington, May 15 and 16, 1906.

(Special Report to the Medical Record.)

Dr. Frank Billings of Chicago in the Chair.

(*Concluded from page 1030.*)

Second Day—Wednesday, May 16.

A Case of Bacillus Coli Septicemia with Hemolysis.—Drs. P. A. D. Blackader and B. D. Gillies of Montreal reported the case of a woman twenty-seven years old who was suddenly seized during the night with severe pain in the suprapubic region and rigors, followed by pyrexia, vomiting, and a moderately profuse sanguineous vaginal discharge. She had been apparently in good health and spirits the day previous. The following morning a distinct bronzing of the skin was noted and there was marked dyspnea, tenderness in the suprapubic region, a temperature of 102° F., a quick, weak pulse, and a sense of great depression. She entered the Montreal General Hospital

the same evening. Her condition then was one of profound exhaustion; there was delirium, severe frontal headache, and great restlessness; the color of the skin had distinctly deepened. Moderate stimulation was employed. On examination the following morning the skin was everywhere of a light brown tint, resembling that of a mulatto; the conjunctivæ were suffused and much tinted. The thoracic organs appeared normal, and there was no increase in either hepatic or splenic dullness. A moderate degree of tympanites existed. The extremities were cool, and the temperature was 103° F. and very perceptible at the wrist. The respirations were between 40 and 50. The urine contained albumin, a few red blood cells, and numerous bacilli resembling the *Bacillus coli communis*. The blood examination showed 2,704,000 red cells, 79,200 whites, and 48 per cent. hemoglobin. The blood was dark, flowing with difficulty, and the serum was of a yellow tinge; crenation came on rapidly, the fibrin net forming in seven minutes. Under the microscope some fragments of red cells were seen in leucocytes and one fine needle of hemoglobin. Death occurred that same evening. Cultures from the blood ten hours after death gave a pure culture of the *Bacillus coli communis;* cultures from the ventricles of the heart, from spleen and kidney, and from the lining of the mucosa of the uterus, all gave a pure culture of a bacillus presenting the same morphological appearance and staining properties of the *Bacillus coli communis*. Cultures from the liver, gall-bladder, and brain remained sterile. Cultures from the urine before death gave the *Bacillus coli* in pure culture. The blood from the ventricles was of a deep chocolate tint, and gave the spectrum reaction for methemoglobin. The autopsy revealed a septicemia with hemolysis and methemoglobinemia, a subinvolution of the uterus, retained secundines, acute cystitis, hyperplasia of the spleen, healed tuberculous nodule at the apex of the right lung, cloudy swelling of the kidneys and a fatty liver.

Dr. E. G. Janeway of New York reported in this connection four cases of poisoning by bichloride of mercury, in one case by accident after confinement. The symptoms in all simulated those of dysentery—bloody discharges, etc.—and appendicitis was thought of in the first case. In the second case a lady took the drug by accident. In the third case the drug was used as a douche to prevent conception, and gave rise to the same dysenteric phenomena—intense abdominal pain, high temperature, etc.—recovery following. In the fourth case there was no salivation. He believed that poisoning by bichloride of mercury was more common than was generally supposed.

General George M. Sternberg, U. S. A., said that in the experimental injections in animals, as dogs, similar symptoms were obtained as described in the paper, although the blood was not disorganized to the same extent. The condition simulated yellow fever in the fatty changes and the changes in the kidneys. He said that he had obtained a pathogenic variety of colon bacillus from yellow fever patients while making experiments in Havana.

Dr. A. D. Blackader said that one of the most characteristic symptoms met with in poisoning by bichloride of mercury was the inflammation of the colon.

Hemochromatosis and Diabetes Mellitus. — Dr. Thomas B. Futcher of Baltimore read this paper, which dealt with the clinical features of hemochromatosis, and the cases in the literature in which the disease had gone on to the diabetic stage were reviewed to date. He called attention to the triad of symptoms in hemochromatosis, viz., the pigmentation of the skin and viscera, the hypertrophic cirrhosis of the liver, and the persistent diabetes in advanced cases. The first case reported was that of a man, forty-five years old, a heavy drinker, whose brother had died of diabetes. He had a diabetes which had lasted fifteen months. There was pigmentation of the skin, particularly on the exposed parts. The liver was very large. There was no enlargement of the spleen and no ascites. There was an 8 per cent. glycosuria and acidosis. The patient left the hospital and died. The second case reported was that of a man, fifty-three years old, with a striking pigmentation of the skin. He was not an alcoholic. The liver was enormously enlarged, and the spleen was enlarged. The sugar was 11.5 per cent., and there was acidosis. The diabetic symptoms lasted only six weeks previous to admission to hospital. This patient also left the hospital. Examination of the skin gave the characteristic iron reaction in the cells of the sweat glands and their ducts.

Dr. James B. Herrick of Chicago said that two weeks ago he had a patient under observation with the triad of symptoms Dr. Futcher referred to, and also tuberculosis of the lungs. At death, however, the autopsy showed cirrhosis of the liver, with pulmonary tuberculosis, but no pigmentation of the viscera. In looking back over the sequence of events, the history should have pointed against the diagnosis of hemochromatosis.

Universal Pruritus without Skin Lesion, Hematogenous Urobilinuria, Peculiar Erythrocytolysis.—Drs. John K. Mitchell and Alfred R. Allen of Philadelphia reported the case of a nervous individual, a medical student, who had suffered from chronic malaria poisoning. He first had a typical Raynaud's disease, and, four years later, he had an intense itching of the whole body, never wholly absent. With this there was insomnia. At no time was there any skin lesion. When he consulted the authors he had a typical Raynaud's disease neurasthenia, and this intolerable itching. The urinary and blood findings were interesting. There was a faint trace of albumin in the urine, and a few hyaline and granular casts. On standing, the urine became of port wine color. Urobilin was found, but did not come from the bilirubin (hepatic origin), but from the blood. In cases of urobilin being of hepatic origin he said there was always associated indican, and this was not found in this patient. The blood examination showed 58 per cent. hemoglobin, 19,000 leucocytes; lymphocytes, 35 per cent.; large mononuclears, 4 per cent.; transitionals, 4 per cent.; polymorphonuclears, 42 per cent.; and eosinophiles, 13 per cent. After two months of treatment the proportion of eosinophiles remained the same, but the hemoglobin rose as high as 79 per cent. Five months of treatment showed the leucocytes not above the normal, but the eosinophiles were 11.7 per cent. General improvement continued and the patient went to San Francisco, Cal., and reports some itching still. He believed the itching to be due to the presence of urobilin in the blood, caused by an erythrocytolysis resulting from malaria. The treatment was by the hot baths, to which starch water or bran was added, and by the internal use of iodides and mercury.

Dr. W. S. Thayer of Baltimore had seen two cases at the Johns Hopkins Hospital associated with Raynaud's disease.

Essential Pentosuria in Two Brothers.—Dr. Theodore C. Janeway of New York City presented this paper. He said that since Salkowski and Jastrowitz, in 1892, had observed in the urine an optically inactive sugar, which did not ferment with yeast, and identified it as pentose, seventeen undoubted cases of chronic pentosuria had been reported. No instance could be found in American, British, or French journals. He briefly reported two typical cases. The first was in a German Hebrew, twenty-eight years of age; he had three brothers and five sisters, all healthy except one brother. The patient had never been robust, was subject to severe headaches. He had been treated for mild diabetes for a year, and was refused life insurance on account of sugar in his urine. Physical examination was wholly negative. Urine, 1,050 c.c., 1,028 specific gravity, reducing Fehling's solution and giving a questionable bubble in the fermentation tube. After a months' observation the discrepancy between the uniform trace of sugar and the varied diet showed that the case was not one of glycosuria. Pentosuria was at once confirmed by the positive orcin test, and proof of optical inactivity and absence of fermentation, after 100 grams of glucose at a single dose. Preparation of the purified osazon

gave a melting point of 154°-158° C. and decided the diagnosis. The total pentose excretion estimated as dextrose by Pavey's method, varied between 2.5 and 4.2 grams in twenty-four hours. The second patient, brother of the first, aged twenty-seven, was almost the exact counterpart. He excreted the same quantity of pentose. The osazon from his urine had a melting point of 160°-162° C. At present three different types of pentosuria were known; alimentary, analogous to alimentary glycosuria, occurring when large amounts of vegetable pentoses were eaten; pentosuria in some severe diabetics, where the inability to burn sugars extended to the pentatomic ones; and true chronic pentosuria, of the type described, about which few facts were known. (1) The sugar in all cases (with one possible exception) had been inactive r-arabinose. This was the only known occurrence of an optically inactive sugar in nature. It could not therefore come from the vegetable pentose, nor from the l-xylose of the nucleins. (2) The power of burning all the hexoses, l-arabinose, and the pentose-containing nucleoproteids was unaltered. (3) The nuclear metabolism was not increased. (4) Family tendency seemed well marked, the nineteen reported cases containing four family groups. The malady had no connection with the diminished sugar combustion, but was rather an anomaly of intermediate metabolism somewhere, resulting in the synthesis of this abnormal sugar. It was analogous to cystinuria and alkaptonuria, rather than to diabetes. Any urine which reduced Fehling's solution only after a few moments' boiling and then with a sudden change of color to greenish or orange-yellow throughout, might be suspected. If it was optically inactive and non-fermentable, and if it responded well to the phenylhydrazin test, pentose was probably present; the orcin test with spectroscopic examination made the diagnosis almost absolute; a melting point of the osazon of about 160° C. settled the diagnosis definitely. The clinical treatment and the significance were mainly negative—the condition was not to be confused with diabetes. Restriction of the carbohydrate foods was not called for.

Aplastic Anemia, with Report of a Case.—Dr. R. Lavenson of Philadelphia reported the case of a woman, thirty-five years old, who had previously been healthy, and who without apparent cause developed a profound, rapidly fatal anemia. The prominent features of the blood analysis were oligocythemia, oligochromemia, a scarcity of normoblasts, an absence of megaloblasts, and a leucopenia, with relative lymphocytosis. At autopsy there was found an aplasia of the bone marrow. Dr. Lavenson then discussed the relation of aplastic anemia to progressive pernicious anemia, and to simple anemia.

Dr. Richard C. Cabot of Boston said that he had seen two such cases, but had not reported them because of absence as yet of autopsy.

Drs. A. Scott Warthin of Ann Arbor, Mich., Alfred Stengel of Philadelphia, W. S. Thayer of Baltimore, Shattuck of Boston, and Eugene L. Opie of New York discussed the paper.

Multiple Cerebral Hemorrhage in Leukemia.—Dr. James B. Herrick of Chicago reported a case of chronic myelogenous leukemia in which death was due to multiple, discreet, cerebral hemorrhages. The patient died suddenly, with delirium and hemiplegia. The specimen of the cerebrum was shown, and he said that a further study of it might cause him to change his diagnosis.

Exophthalmos in Leukemia.—Dr. Herrick also reported this case of acute leukemia, of mixed lymphatic and myelogenous type, in which bilateral exophthalmos was the striking feature. At autopsy a retrobulbar leukemic infiltration was found to explain the condition. There were no chloromatous masses.

Experiments on the Leucolytic Action of the X-Ray and the Injection of Leucolytic Serum in Leukemia.—Drs. Joseph A. Capps and J. F. Smith of Chicago reported some fruitful experiments they had done upon animals. A chart was shown of the effects of injecting this serum into a patient with leukemia. Before administering it the patient had not been under any treatment for three months. The leucocytes numbered 150,000 to 200,000 when 4 c.c. of the serum was given. Within twenty-four hours the count dropped from 160,000 to 124,000; within forty-eight hours, to 104,000. In other words, there was a fall of about 60,000 in forty-eight hours. In thirteen days the leucocyte count reached the point it was at the time of injection. A second injection of 5 c.c. was then given, and a drop occurred which was not so extensive as before and the recovery was more rapid, reaching the level in nine days. At the time of the third injection the count was 300,000, and he then gave 10 c.c.; in twenty-four hours the count fell to 215,000 and recovery then took but seven days. The leucolytic serum used was produced by the action of the *x*-ray in leukemia.

The Nucleus Test in Pancreatic Disease.—Dr. I. Dutton Steele of Philadelphia said that the nucleus test as suggested by Adolph Schmidt for the diagnosis of pancreatic disease confirmed the work of Wallenfang upon dogs, which showed that in complete lesions of the pancreas the muscle nuclei of ingested meat was not digested. A case of azotorrhea was reported, in which indigestion of muscle fiber was apparently dependent upon chronic appendicitis and not upon disease of the pancreas.

Notes on the Diagnosis of Pancreatic Disease.—Dr. John H. Musser of Philadelphia said that the diagnosis of pancreatic disease must only be suggestive, for there was no finality as to the result of examination of the urine and feces alone, except possibly by the methods Dr. Steele had pointed out, when there was a complete destruction of the organ. He said he was forced to the conclusion that the recognition of pancreatic disease depended not to the same degree upon laboratory methods as upon the study of the clinical course of the disease, and especially the previous history of the case and the objective signs.

Dr. D. L. Edsall of Philadelphia felt as Dr. Musser did, and referred to some work he had done in looking for the fat-splitting ferment in the urine.

Dr. W. S. Thayer of Baltimore referred to the case of a man, thirty years old, who gave indefinite digestive symptoms, and who developed glycosuria and pulmonary tuberculosis. The stools were enormous, sometimes amounting to a quart under an ordinary diet. The stools were followed by a gush of liquid fat that smelled like rancid butter. The diagnosis was made of probably pancreatic calculi, which was confirmed at autopsy, calcareous masses being found in the duct.

Some Experiments Upon the Digestive Activity of Pepsin in the Gastric Contents.—Drs. Joseph Sailer and C. F. Farr of Philadelphia gave a brief description of the methods employed in estimating the peptic activity. They called attention to the advantages and disadvantages of the Metts method and evidence of its accuracy. They called attention, too, to the accuracy of the law of square roots, that the degree of digestion corresponded to the square root of the amount of pepsin present, except in concentrated solutions. The more dilute the gastric juice, the greater became its digestive power. He then considered the effects of the various food preservatives upon peptic digestion. Benzoate of sodium and benzoic acid had strong inhibitory effects. Sodium salicylate was broken up into salicylic acid, the latter being precipitated as fine needles. Sodium sulphate had a strong inhibitory effect, as had sodium chloride in strong solution. Alcohol, on the other hand, in 66 per cent. strength, had but slight effect; when at a strength of 16 per cent., no effect at all was noted. Formalin had a slight inhibitory effect upon peptic digestion.

Report of a Case of Glandular Fever with Dermal Lesions Suggesting Syphilis.—Drs. Alfred Stengel, J. W. White, and J. S. Evans of Philadelphia reported the case of a medical student, twenty-six years old, whose disease suddenly developed with an intense itching of the skin and a tendency to urticaria. He also had at first an

icteroid condition of the skin, sore throat, and pain in the joints and substernum. There was some fever, and then the eruption became more distinct and florid. Enlarged glands, superficially situated, then developed all over the body. He had a gastrointestinal attack, which he attributed to the drinking of ice-water. There developed an atypical erythema multiforme. Photographs were shown, displaying the character of the eruption, some having been taken by Dr. Stellwagon. The juice of the lymphatic glands and the blood serum were examined for *Spirochæta pallida* by Dr. Kelly, but none were found. He had had three injections of bichloride of mercury into the buttocks, but without any effect upon the eruption or symptoms. There was a leucocytosis. Cultures from the blood, glands, and tonsils resulted in finding a streptococcus resembling *Streptococcus equi*, found by veterinary pathologists in the glandular fever and epidemic coryza of horses. There was a gradual improvement in the patient without specific treatment.

An Experimental Study of Cerebrospinal Meningitis.—Drs. Simon Flexner and Henry S. Houghton of New York told of the Commission that had been appointed by the New York Board of Health for the purpose of making certain investigations regarding this epidemic disease. It fell upon Dr. Flexner to experiment with animals to see if they could be immunized, and also to try to produce a serum. The lower animals, he said, were not well adapted for experimental reproduction of the lesions occurring in cerebrospinal meningitis. Thirty or forty monkeys were made use of, and a few facts were learned which had a direct bearing upon the pathology of the disease, and which might have some value in the study of the disase as it occurred in man. These findings would be published later.

Internal Hydrocephalus Complicating and Following Cerebrospinal Meningitis.—Dr. Henry Koplik presenttd this communication. He spoke of the paucity of the literature on this subject, and briefly called attention to the symptoms that marked the three principal types of the disease. He emphasized the importance of the tympanic percussion note in cases of fluid in the ventricles of the brain. He thought they should formulate some form of procedure in cases of cerebrospinal meningitis, crystallizing their views on the therapy of the disease, having some definite procedure. There were cases of cerebrospinal meningitis that recovered without any interference; these were the cases with but little pressure on the brain, a simple infection, and got well because they were self-limited. There were other cases in which there was a marked distention, which must be relieved at once. If the infection was very great, one could not rely very much upon puncture. In the subacute cases puncturing at the right moment could save the cerebral structures from damage.

Experimental Arterial Degeneration.—Dr. Joseph L. Miller of Chicago gave a lantern-slide demonstration of the changes produced chiefly by substances increasing blood pressure, as adrenalin, digitalis, nicotine, physostigmine, barium chloride, etc. Similar changes, however, might be produced by substances that either did not affect or lowered the blood pressure, such as phloridzin and lead carbonate. The causes of the vascular changes after the use of adrenalin, he said, were either increased blood pressure or toxic influences.

Nature of Spirochætæ.—Dr. F. G. Novy of Ann Arbor gave a lantern-slide demonstration in which was well marked the transverse and not the longitudinal division of this organism.

Relapsing Fever.—Dr. F. G. Novy gave a lantern-slide demonstration of the spirillum of Obermeier.

Thrombophlebitis of the Splenic and Portal Veins and Its Relation to Splenic Anemia.—Dr. Alfred Scott Warthin of Ann Arbor said that he and Dr. George Dock had reported three cases of splenic anemia, showing at autopsy splenic fibrosis associated with stenosis or obstruction of the portal or splenic veins, due to an old thrombophlebitis. A fourth case was now reported of relatively acute splenic thrombophlebitis following pneumonia, and which presented features of secondary anemia and splenic fibrosis. The results of experimental work were given, and an attempt was made to establish the clinical and pathological entity of splenic and portal thrombophlebitis as a variety of splenic anemia. Lantern slides were shown.

A Histological Study of Two Cases of Sudden Death Associated with Hypertrophy of the Thymus; One Case with General Lymphatic Enlargement, the Other Without.—Dr. Alfred Scott Warthin of Ann Arbor gave the results of a pathological study of the autopsy material from two cases of sudden death in children, associated with thymic hypertrophy. In one case the lymph glands were enlarged, in the other they were small, but the same condition was found in both cases, viz., atrophy and disappearance of the lymphoid elements, endothelial and fibrous hyperplasia, etc. Similar changes were found in the spleen and bone marrow. The thymus in both cases showed a lymphoid hyperplasia, eosinophilia, etc. The findings were interpreted as a toxemia resulting in a lymphoid exhaustion of the lymph glands, bone marrow, and spleen, and a compensatory hypertrophy of the thymus. A possible relationship to Hodgkins' disease was also discussed and a lantern-slide demonstration was given.

Histological Notes on a Case of Leukemic Hodgkins' Disease.—Dr. Warthin also reported a case with the clinical picture of Hodgkins' disease, but with a blood picture of lymphemia, showing changes in the lymph glands, spleen, bone marrow, and liver, corresponding to the "epithelioid" type of Hodgkins instead of the lymphoid hyperplasia (lymphocytoma) characteristic of lymphocytic leukemia. The possible relationship of Hodgkins' disease to the group of aleukemic and leukemic hyperplasia was discussed and lantern slides were exhibited.

Acute Dilatation of the Stomach and Its Relation to Mesenteric Obstruction of the Duodenum.—Dr. Lewis A. Connor of New York reported a case of acute dilatation of the stomach and duodenum, with complete occlusion of the lower end of the latter by pressure of root of mesentery and its contained superior mesenteric artery. An analysis of ninety cases of acute dilatation of the stomach was made. Dilatation of the duodenum was found in 60 per cent. of the fatal cases. Mesenteric obstruction was demonstrated in nineteen cases, and was probably present in many more. There was difficulty in determining whether the mesenteric obstruction or the gastric dilatation was the primary condition. Acute dilatation of the stomach was probably due, in most cases, to one of the several forms of obstruction in the duodenum, of which mesenteric compression was the most important. Satisfactory results of postural treatment in several cases of severe gastric dilatation in which such mesenteric compression was assumed to exist were to be had. A lantern-slide exhibition was given.

Clinical Notes on Exophthalmic Goiter.—Dr. W. Gilman Thompson of New York read a paper which was based upon a study of upward of eighty cases. In a large proportion of the cases an acute febrile toxemia developed, in which, in addition to the cardinal symptoms of goiter, tremor, tachycardia, and exophthalmos, the following symptoms were noted: Fever, acute dilatation of the heart, cardiac murmurs, dyspnea, precordial, thoracic, or abdominal pain, edema of the legs, erythema, and sweating. The increased temperature (which was usually not described in connection with these exacerbations) frequently reached 104° or more, and might continue for several days. It was particularly these toxic exacerbations which he said might be influenced by the new cytotoxic serum. The cause of the sudden toxic exacerbations often appeared to be an intercurrent mild infection, such as an attack of tonsillitis, influenza, bronchitis, or an attack of gastro-

intestinal disturbance. He considered the relative frequency of the various symptoms, the causes of death, and the possibility of mistaking the condition for acute septicemia or malignant endocarditis. Of the 43 patients coming into the hospital with acute symptoms and very active, 39 were females. Exophthalmos was present in 28; tremors in 36; sweating in 17; edema in 23; tonsillitis, etc., in 16; gastrointestinal disturbances in 16; emaciation in 16; erythema in 7; heart from 4 to 6 1-2 inches in 24, under 4 inches in 19; murmurs in 31; temperature between 101° and 104° in 13, 104° or over in 7, above 99° in only 4. The mortality was 7 per cent.

Treatment of Exophthalmic Goiter by a Specific Cytotoxin.—Dr. JOHN ROGERS of New York presented this part of the symposium, for a detailed account of which see the MEDICAL RECORD of February 24, 1906, page 322.

Preparation of a Specific Cytoxin for Exophthalmic Goiter.—Dr. S. P. BEEBE of New York described this. (See the MEDICAL RECORD of February 24, 1906, page 322.)

Dr. S. J. MELTZER of New York presented two photographs of children, whose ages were nine and ten years, with Graves' disease. The exophthalmos and goiter diminished during the use of thymus gland, given accidentally. One of the patients had been absolutely cured, remaining so for nine years. Sodium phosphate had also been advised, based upon the theory that Graves' disease had its origin in disturbances in the medulla oblongata, and this salt was of benefit in disease of the medulla oblongata. He considered Drs. Rogers' and Beebe's discovery one of the most remarkable of the times, if their claims could be verified.

Dr. FORCHHEIMER of Cincinnati reported thirty-one cases, all but one occurring in females, which he had collected from his private practice in thirty years. His method of treatment was to administer five grains of hydrobromate of quinine with one grain of ergotin, three or four times daily. Twenty-seven of these cases were completely restored to health and in four the method failed.

Dr. W. G. MACCALLUM of Baltimore had had an opportunity of examining twenty-nine glands in exophthalmic goiter, and was able to make out a more or less specific change in them. The important point was to remember that this specific change was in the direction of a hypertrophy, a compensatory hypertrophy. The parathyroids were found to be normal in nine or ten of the cases.

Dr. A. SCOTT WARTHIN of Ann Arbor asked Dr. Ewing if he had ever examined the thyroids in cases of eclampsia.

Dr. W. GILMAN THOMPSON of New York said that he had seen cases improve by simply rest in bed. He thought it rather premature to express adverse judgment upon the experimental work of Rogers and Beebe, for they certainly had gotten hold of something in the line of serum therapy.

Dr. JAMES EWING of New York said that he had examined a number of thyroids and parathyroids in cases of eclampsia, and they were quite intersting in showing a variation in the quantity of colloid material present.

The Enzymes in Phagocytic Cells of Inflammatory Exudates.—Dr. EUGENE L. OPIE of New York said that phagocytic cells, which had a part in the resolution of inflammatory exudates, digested bacteria and various cellular elements by means of two proteolytic enzymes, one of which, contained in the polynuclear leucocytes (like trypsin), digested actively in an alkaline medium, while the other, contained in the large mononuclear phagocytes or macrophages (like pepsin), digested only in an acid medium.

Some Experiments in Psychotherapy.—Dr. L. F. BARKER of Baltimore read this paper, which contained a plea for the more systematic, conscious application of psychic treatment in the management of functional disorders of the nervous system. He reported many illustrative cases. Psychotherapy should always be applied to the simple cases. Persuasion, occupation, and education were the main features in this treatment. Psychoneurotic conditions responded best to psychotherapy. He detailed the difference between suggestion and persuasion. More than eighty cases had been treated at the Johns Hopkins Hospital in which the psychotherapy was the mainstay. He then considered the abuse of this treatment.

Use of the X-Ray in Unresolved Pneumonia and the Nature of the Toxic Reaction to X-Ray, with Observations on Metabolism.—Drs. D. L. EDSALL and RALPH PEMBERTON of Philadelphia presented this communication, in which they said that several cases of unresolved pneumonia in which the *x*-rays were used on account of the authors' view that the *x*-ray stimulated autolysis by acting as an accelerator of ferment-action, showed more or less striking and rapid improvement, with conditions of metabolism similar to those at the crisis in pneumonia. In one case, in which a severe toxic reaction occurred immediately after the *x*-ray exposure, and in another in which a similar but milder reaction occurred, striking disturbances in metabolism were noted, and these appeared to make clearer the nature of such a reaction, and some of the dangers associated with the use of the *x*-rays.

Immunity in Tuberculosis.—Dr. SIMON FLEXNER, New York, delivered this address at a joint meeting of this Association and the National Association for the Study and Prevention of Tuberculosis. He said the first successful inoculation had been made in 1843 by Klemper, but his investigations had not been pursued and were soon forgotten. At this time the opponents of the infection theory had endeavored to prove that tuberculosis could be produced by the injection of nontuberculous material. Conheim had brought out the method of introducing the infection into the rabbit's eye which had the advantage that the whole process could be watched and that spontaneous tuberculosis had never been known to occur in the rabbit's eye. Koch in 1882 had demonstrated the organism and secured cultures of the bacillus free from extraneous matter and was able to reproduce the disease in domestic animals. He thought that it did not detract from his work that he had failed to distinguish between the different forms of tuberculous disease in fowls, animals and man. Now several distinct kinds were recognized, classified into human, bovine, and avian. The close relationship of these made the study of the disease in animals of great advantage, and the problem of the suppression of tuberculosis had to take into account the possibility of danger of infection from one to the other. Avian tubercle bacilli occurred rarely in man, and the speaker thought all forms of human tuberculosis were caused by the mammalian or bovine bacilli. It had been shown that the bacilli could gain entrance through the intestinal walls and lymphatics and he thought that the limitation of the disease must depend upon our knowledge of its mode of entrance. A marked reduction in the mortality from tuberculosis had been going on in various countries due to the régime of education and improvement of the condition of the poor. Vaccination by means of the dead bacilli and of living attenuated bacilli promised much and tuberculin as a diagnostic measure at least was of great value. The first successful efforts had been those of Dr. Trudeau in injecting animals with the avian bacilli. While tuberculosis claimed in death one in every seven persons the morbidity was much greater than this indicated and autopsies indicated that 90 per cent. of persons have at some time of life been the victims of this infection. From this it was to be assumed that the human organism had a natural tendency to immunity and it was to be believed that a degree of immunity might be acquired by man. Vaccination of cattle was now being successfully practised. He called attention to the fact that Dr. Leonard Pearson of the Phipps Institute had concluded that different cultures of the human bacillus possessed different immunizing values and it had been definitely shown that vaccination could be practised in animals, though not always without danger. The question of the duration of immunity was still an open one; it had been shown to last a year, but there was no proof that it would last for an entire lifetime and

the immunity could be overcome by the injection of large quantities of active bacilli. It remained to be learned how long the bacilli survived after vaccination. He said investigators should not in any way relax their efforts to secure an immunity for man against tuberculosis and held that there was certainly great hope for the future treatment of the disease in man. He believed that further researches along the line of securing such immunity would in time stay the ravages of the disease.

Election of Officers.—*President,* Dr. Francis B. Kinnicutt of New York; *Vice-President,* Dr. James Tyson of Philadelphia; *Secretary,* Dr. Henry Hunt of Washington, D. C.; *Recorder,* Dr. Solomon Solis-Cohen of Philadelphia; *Treasurer,* Dr. J. P. Crozier Griffith of Philadelphia; *Councillor,* Dr. L. F. Barker of Baltimore; *Active Members,* Drs. W. M. L. Coplin, S. W. Lambert, and G. H. Weaver; *Associate Members,* Drs. A. A. Eshner, R. G. Freeman, I. P. Lyon, M. J. Rosenau, Jno. S. Billings, Jr., Edward R. Baldwin, and Herbert C. Moffitt.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, April 9, 1906.

THE PRESIDENT, DR. THOMAS E. SATTERTHWAITE, IN THE CHAIR.

Minute on the Death of Dr. George R. Fowler.—The Secretary read this minute, as follows: "The death of our distinguished fellow member, Dr. George Ryerson Fowler, has been felt by all of us, not only as a personal loss, but as a loss to the ranks of able and progressive surgeons. He had lived and worked long enough to establish his rank. He was among that small class of ceaselessly active, thoroughly grounded, splendidly trained, and self-disciplined surgeons who have reached a time of life where every act tells for good. He would have disdained to be considered in a class by himself, but, rather, regarded it as his greatest privilege and noblest duty to work shoulder to shoulder with his comrades in science. Those who knew him best as a teacher loved and venerated his wise and experienced words. Those who watched his surgical work noted his originality and unerring correctness of action. Those who knew him as a man saw, throughout his life, devotion to principle and quick response to every call of duty, regardless of personal sacrifice. Never considering himself first, he served not only his profession, but his school, his State, and his country. His personal qualities of buoyancy, modesty, and truthfulness excited a pleasant interest in all his public utterances. Never speculative, and always eminently practical, he was always fearless and ready with his pen. When his views were matured, his writings always rang true, and bore the stamp of large experience tempered by unusual wisdom. Those who were fortunate enough to be associated with him in hospital work found him ever watchful of details in his operating room and a most severe teacher of strict asepsis. His influence on the surgical work of his generation will stand among the strongest of the workers of his time. As was written on the tomb of Charles Wesley in Westminster, 'God buries his workmen, but continues his work.'

"ROBERT ABBE,
"CHARLES JEWETT,
"ROBERT T. MORRIS,
"*Committee.*"

The order of the evening was a discussion on indications and methods in diseases of the intestines and peritoneum.

A Comparison of the Results of Treatment of Tuberculosis of the Peritoneum by Surgical and by the Conservative or Expectant Method.—Dr. JOHN C. HEMMETER of Baltimore, Md., said that in enumerating the various forms of peritonitis that might be confused with tuberculosis, he would for the sake of brevity pass over those forms that were due to infection, (1) through the genital tract in the female; (2) those due to infection from the digestive tract; and (3) those due to infection or extension of the inflammation from the biliary apparatus, as well as those forms of peritonitis which occurred secondarily during the course of chronic heart and kidney affections. The more important left for consideration were the following: 1. When peritoneal tuberculosis gradually developed with the clinical picture of simple ascites, it was sometimes difficult to distinguish from the ascites due to cirrhosis of the liver. Both diseases might occur together, and in such cases the diagnosis was extremely difficult. 2. Infectious diseases like measles, typhoid fever, and dysentery were sometimes found associated with ascites. 3. Malignant tumors of the peritoneum, intestine, gall-bladder or pancreas might be very difficult to differentiate from the tumor form of tuberculous peritonitis 4. There was a type of ascites that occurred in young girls during the period of adolescence called by French writers *"ascite des jeunes filles."* This was not due to an inflammation, but was supposed to be caused by hyperemic and hypersecretory conditions of the peritoneal regions approximate to the inner genitalia. It disappeared spontaneously after the first menstruations had occurred. 5. Traumatic peritonitis. Chronic exudative peritonitis that was not tuberculous might occur after injuries to the abdomen. 6. In 1884 Curschmann described a chronic inflammation of the peritoneum of a very peculiar type and of nontuberculous nature which he called "chronic fibrous polyserositis." It was always associated with a perihepatitis of the same peculiar type, giving the peritoneal and abdominal organs the appearance of being inclosed in a cast of opaque sugar. The cause of this condition was not known. It had been observed after various infectious diseases, and after circumscribed forms of peritonitis. Curschmann stated that the disease was characterized by two features, namely, a much reduced, small, hard liver, cylindrical at its edge, and by a very protracted course, lasting from two to sixteen years. The disease was very rare. 7. Idiopathic chronic peritonitis. Dr. Hemmeter said he had never seen a case of this type, and he doubted its occurrence. Nothnagel claimed that a genuine idiopathic peritonitis had not yet been demonstrated. In speaking of the differential diagnosis of the various forms of peritonitis, the speaker said he would simply emphasize three methods by the aid of which we were enabled to determine at least what was a tubercular peritonitis and what was not. They might almost be called specific reactions of tuberculosis. The first was the introperitoneal injection of some of the peritoneal exudate into guinea pigs; the second was the injection of Koch's tuberculin, and the third was the diazo reaction of Ehrlich. After a careful review of the treatment of tuberculous peritonitis, and as the result of his own experience, Dr. Hemmeter said that while he could not confirm the statement of the surgeon Borchgrevink that more cases were cured under a purely conservative medical treatment than under operation, he was nevertheless convinced that at least as many cases recovered under the expectant or conservative treatment as would recover after an operation.

Recent Advances in Intestinal Surgery.—Dr. ALGERNON T. BRISTOW of Brooklyn, N. Y., reviewed briefly the history of intestinal surgery, and said that the advances that had been made in this field in recent years might be classified as follows: Improvements in the methods of suture, in apparatus, and in general technique. Some additions had also been made to our methods of diagnosis, particularly in obscure cases of appendicitis, which sometimes presented themselves without much pain or tenderness, and even with a normal pulse and temperature. Referring more particularly to improved methods of suture, Dr. Bristow said that speed was a prime requisite in all surgical work on the intestines, and that that suture was the best which secured accurate coaptation with the least liability to leakage, and yet which did not require much time to introduce. Connell's suture seemed to fulfil those conditions better than any other stitch which was at present described in surgical works. It was a through-and-through suture. The only

objection to it was that it was somewhat difficult to learn. If, instead of the suture, the surgeon had a fancy for apparatus, there had never been invented anything more ingenious than the Murphy button. It was particularly useful to the surgeon whose experience was limited in this field of work. The ring clamps of La Place were also excellent devices, which had this advantage over the button, in that they were withdrawn after the suture was complete, and hence avoided leaving a foreign body in the lumen of the gut. In considering the improvements in general technique, the speaker said we were forced to the conclusion that the tendency among all surgeons who did much intestinal surgery was to simplify the technique. The surgeon who adopted for his motto the time-honored precept, *"non nocere,"* would always score the greatest number of successes in this field of work.

What Has Surgery Left to Medicine in the Treatment of Peritonitis in Adults and Children?— Dr. HENRY W. BERG read this paper. (See page 1044.)

Surgery of the Peritoneum.— Dr. LEWIS STEPHEN PILCHER of Brooklyn, N. Y., said the surgery of the peritoneum was so closely involved in the surgery of the organs which it enveloped and of the walls of the cavities which it lined that it was difficult to disassociate it from them. There was, however, a propriety in considering the peritoneum as a distinct entity and as having a surgery of its own, for on the recognition of the peculiarities of the peritoneum and its reaction to surgical conditions depended largely the ability of the surgeon to deal successfully with the organs which it enveloped. One of the most notable peculiarities of the peritoneum was the rapidity with which, when exposed to wound or irritation, it threw out an abundant supply of fibrinous lymph, which protected the serous surface from further irritation, united adjacent surfaces, and thus repaired wounds or closed in areas of infection. Surgeons had learned that the peritoneum, while it was peculiarly liable to infection, possessed in a very marked degree the ability to resist infection and to rid itself of the products of infection, so that notwithstanding very imperfect applications of the laws guarding against infection in the course of surgical procedures in which it was involved, ultimate recovery of the patient not infrequently still occurred. Surgeons had learned further that the great capacity for regeneration possessed by the peritoneum was more than an offset for its easy vulnerability, so that if in any given case conditions could be secured which were reasonably favorable for its reparative energy to be exercised, recovery from severe traumatism or extensive infection might be expected. Upon those two qualities of the peritoneum—rapidity of repair and resistance to infection—depended the success of most of the intraabdominal surgery of to-day; just as the individual surgeon adopted methods which promoted the one, and reduced the need of the other to a minimum, would his results be the most satisfactory. This regenerative power of the peritoneum, however, had also its unfavorable side, for, in the more or less extensive adhesions which remained as the result of attempts to repair traumatisms or overcome infection, there were created conditions which might entail disability, interfere with functions, produce pain, and limit and render extra hazardous subsequent attempts at surgical relief. For the production of adhesions, it was simply necessary that two damaged peritoneal surfaces should be in contact for a time. The firmness of those adhesions would depend upon the depth to which the serous surfaces had been destroyed; slightly damaged serosa, in contact with healthy serosa, might cause a weak, mayhap an evanescent adhesion; serous surfaces from both of which a superficial exfoliation of endothelium had occurred might become united by fairly strong adhesions, through which, however, a line of cleavage might subsequently be readily formed by the surgeon's effort, with easy separation of the adherent surfaces. The most dense adhesions resulted when a damaged serous surface came in contact with a raw surface, as of denuded muscle or fascia. It was from such dense adhesions as these that, by the continual tug caused by attempts at motion in the adherent organs, intraperitoneal bands were developed. In the surgery of the peritoneum, the possibility of adhesions, with their more or less remote disadvantages and dangers, must always engage the attention of the surgeon: first, from the standpoint of prevention; second, if already present, to loosen the bound-down organs from their bonds; and, third, after detachment, to prevent their reformation. In speaking of peritoneal infection, Dr. Pilcher said its malignancy depended, first, on the virulence and amount of the organisms that were introduced; and, second, upon the energy and extent of the local leucocytic reaction which it awakened, whereby was determined either the localization of the process, or its progressive diffusion. The proportion of recovery, even in advanced cases, that had rewarded surgical effort, had steadily increased during the past ten years from one of practically nothing at the beginning of that period, to one of more than 50, possibly of 75 per cent. at the present date. This had been due to improvements in operative methods, and in after-treatment, as a better understanding had been reached as to the reaction of the peritoneum to sepsis and to traumatism. Nothing had contributed more to this great improvement that the demonstration of the value of the elevated trunk, or semi-sitting position after operation, coupled with drainage from the pelvis. This we owed largely to the late Dr. George R. Fowler. A second important factor had been the abandonment of time-consuming, shock-producing efforts at cleansing the peritoneal cavity; such efforts inevitably inflicted much traumatism upon the peritoneal surfaces, and lessened their ability to carry on the further contest with infection, not only by the traumatism inflicted, but also by opening up increased surfaces for the absorption of toxins, just in proportion as the sheets of lymph were washed away from their areas of attachment. For these measures were substituted simply the relief from pressure afforded by a free incision of the abdominal wall, and the spontaneous escape of all fluids under pressure. The peritoneum was left to its own undisturbed resources to deal with infection, and the function of the surgeon was thus largely limited, after the removal, if possible, of the original source of infection, to providing by proper means of drainage against the further accumulation of secretions under pressure. A precious resource yet remained, and one of the highest value in supporting the peritoneum in its struggle; namely, surcharging the vascular system with water, whereby toxins were diluted, elimination, especially through the skin and kidneys, was stimulated, and the lymphatic current was changed from one of absorption to one of secretion. An intravenous infusion of physiological saline solution on the table as a part of the primary operation inaugurated this branch of the treatment, and it was continued thereafter by frequent rectal enemata of the same fluid, or by the continuous slow installation of the solution into the rectum, as suggested and practised by Murphy. The final feature of the practice of to-day was the suppression of peristalsis as far as possible; all foods and liquids by the mouth were withheld; lavage was resorted to for emptying the stomach of accumulations of putrid fluids that might regurgitate into it, and morphine was administered as might be borne.

Dr. ROBERT T. MORRIS, in referring to Dr. Bristow's remarks in regard to the operative treatment of ameboid dysentery, said he recently saw a woman from Panama who was suffering from that disease, and who, in order to get the benefit of a rapid cure, did not hesitate to have the abdomen opened, so that the bowel could be flushed from above through the appendix, rather than by the older and slower method from below. The speaker said he fully agreed with Dr. Berg's statement that palpation of the abdomen in typhoid fever could be carried to a dangerous extent, and the expert should know how much and how little to palpate. In dealing with acute cholelithiasis, Dr. Morris said he rather favored a radical operation in order to prevent the formation of adhesions which would otherwise result, and which often gave rise to much discomfort.

In puerperal peritonitis, he agreed with Dr. Berg that an operation would not remove the bacteria that were circulating in the blood, but it *would* remove the focus which was the source of the bacterial invasion, and by doing this, the scale was sometimes turned in the patient's favor. In tuberculous peritonitis he was inclined to accept the theory that the beneficial effects of the operation were due to the hyperleucocytosis that resulted from opening the abdominal cavity. In peritonitis from appendicitis or other local cause, the indications were to remove the focus of infection, and trust to leucocytosis to do the rest. The peritoneum, as Dr. Pilcher brought out, had a surgery of its own and had its own powers of resistance. For example, a man who received a slight stab-wound of the peritoneum was in much greater danger of developing a general peritonitis, in spite of operation and every aseptic precaution, than he would be if he had a malignant growth, the removal of which would require an extensive resection of the gut. In the latter case, in spite of careless handling of the bowel, primary union would doubtless follow, because the malignant focus had already called out the kind of protection which guarded against bacterial invasion, while the small stab-wound in the former case afforded no such protection. In speaking of the value of Cargile membrane in abdominal work, Dr. Morris said that while it had its limitations, there were certain cases in which it could be used to decided advantage. In many cases where he had used it to relieve the discomforts caused by adhesions, the patients had been much gratified with the result, and in some of the more extensive cases, where the adhesions could not be relieved at one sitting, they had voluntarily returned for further operative work. The same was true of cases where the membrane had become absorbed, and the adhesions had reformed. In properly selected cases, one operation was usually sufficient, but in extensive cases it might be necessary to do the work piecemeal. The willingness of patients to return for repeated operations was pretty good evidence of their appreciation of its influence, and counted far more than negative testimony gained from experiments of Craig and Ellis on dogs. Dogs are apt to have more severe peritoneal reaction than rabbits, and rabbits more than the human species.

Dr. A. Ernest Gallant, referring to tuberculous peritonitis, said he recalled two cases which illustrated the marked differences in the condition of the peritoneum. The first was the case of an emaciated woman, with a tensely distended abdomen, and with several large masses above the umbilicus. When the abdomen was opened these proved to be made up of intestine and tuberculous material inclosing fluid. The sac was opened, and the whole cavity washed out with saline solution. The patient did badly; the abdomen refilled at once, and the woman died four days later. Perhaps, if there had been less handling and irrigation, this patient might have lived. The second case was one of miliary involvement of the entire peritoneal surface, visceral and parietal. This patient had a leakage through the wound which was purposely kept open for nearly eight months. Her weight was now nearly double that at the time of operation, and she did the housework for the entire family. The great difference between perforative and non-perforative peritonitis seemed to lie in the fact that time had been or could be allowed the peritoneum to adapt itself to the invasion of its domain, and withstand surgical manipulation. In peritonitis in young girls, one should always suspect vaginal gonorrhea. The greatest advantage of the Trendelenburg posture lay in the fact that it removed the intestines from the field of operation, and minimized handling and trauma.

Dr. Albert A. Berg said that the points brought out by Dr. Pilcher concerning the handling of the peritoneum could not be too strongly emphasized. The surgeon of the beginning of the twentieth century was but little in advance of his colleague at the beginning of the aseptic era in the method of handling the peritoneum, and the great advances of the future would be along the lines suggested by Dr. Pilcher; namely, greater care in manipulation, less traumatism, less interference with the protective power of the peritoneum, quicker work, and more careful asepsis. Dr. Berg said he did not agree with Dr. Morris that under certain conditions the peritoneal cavity could be invaded with comparatively little danger as regarded the occurrence of sepsis, and he thought that every possible safeguard in that connection should be taken. As regarded intestinal anastomosis, the speaker expressed the belief that all mechanical devices, especially the Murphy button, would ultimately be the resort of beginners in surgery, while the more experienced would confine themselves to the suture operation, which could be done at the expense of only a few minutes' more time, and was not open to any of the objections that had been raised against the use of a mechanical device. During the past five years, Dr. Berg said, he had seen four fatal cases of necrosis of the bowel followed by perforation produced by pressure from the Murphy button.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 19, 1906.

The President, Dr. Charles L. Dana, in the Chair.

Concerning Neurofibrils (with Lantern-Slide Demonstrations).—Dr. Charles I. Lambert, of the State Pathological Institute, in presenting this subject, spoke briefly of the several fibril methods at our disposal to-day, of their application in normal and pathological conditions of the nervous system, and the alterations observed. Bethe's and Donaggio's methods depended upon mordanting and subsequent staining with a weak solution of toludin blue; Cajal's and Bielschowsky's depended essentially upon silver nitrate impregnation and subsequent reduction with a pyro-formalin mixture and toning. For normal histology, Donaggio's and Cajal's methods were preferred; for neuropathology, Bielschowsky's was more adaptable. Lantern-slide views were shown illustrating the nerve cell reactions occurring in normal as well as abnormal states. The several fibril methods produced a closely similar picture in normal cells of the same type. It consisted of a very delicate fibrillar network pervading the entire cell body, the fibrils anastomosing less freely in the peripheral parts and lying quite parallel within the dendrites. Illustrations were given of the termination of foreign nerve fibers on the surface of the cell body, the so-called "*end füsse*," and current opinions of their significance were expressed. The neurofibril reactions in a number of the more familiar cell alterations were demonstrated. In fever changes, artificially excited, there was produced an apparent dissolution of the Nissl stainable substance. The fibril picture was better preserved. In severe pyrexia the Nissl bodies appeared dissolved, and the fibrils showed similarly advanced changes. In central neuritis, described by Dr. Adolf Meyer, in *Brain*, 1901, as a parenchymatous alteration of the larger nerve elements, mainly of central distribution, was found the typical axonal reaction, with or without other superimposed cell changes. As in the Nissl picture, there was a dissolution of the stainable substance, with more or less swelling of the region usually opposite the origin of the axone, displacement of the nucleus toward the surface and even beyond the normal contour of the cell, with more or less persistence of the peripheral Nissl bodies, and preservation of the spindles in the dendrites; so in Bielschowsky's equivalent there was a coincident disappearance and preservation of the fibrils corresponding to the Nissl picture, the severity of the cell alteration being equally apparent in both, and of like distribution. Certain cells in central neuritis showed a striking whirlpool arrangement of the Nissl bodies, the nucleus usu-

ally being at the center of the vortex formations. In general paralysis the cortex disturbance and the incipient and end stages of cell death were demonstrated. In senile conditions, which represented an atrophy and not an inflammatory reaction, the architectonic of the cortex was well preserved, as well as the outer form of the cell and its dendrites, and the fibril destruction was less severe. The pigment and its reticular net was well rendered by the fibril methods. In certain conditions of diffuse cortical sclerosis, resembling Sach's amaurotic idiocy, many of the cells presented a peculiar inflation of the cell body protoplasm, a simple net production without plain pigment formation, and partial preservation of the dendrite fibrils. In conclusion, Dr. Lambert said there was need for further control studies of neurofibrils in their reaction to definite and known experimental conditions.

Dr. Adolf Meyer said the problem of the neurofibrils had naturally excited a great deal of attention of late years in connection with the conflict between the neuronists and the antineuronists, while Dr. Lambert had given an excellent exposition of the actual material that had been thus far obtained from the study of neuropathology in the human being. These histological studies offered a splendid field for further research and appeared more important than disputes regarding points which were beyond the safe realm of the microscope. It had first been claimed that the neurofibrils were individual structures; that they did not anastomose, and that they occasionally exchanged smaller elementary fibrils, and thus merely simulated a net. Concerning all these points the histological study of human material gave no conclusive evidence. It had also been demonstrated by Bethe that in the neurofibrils there was a special chemical substance, and where functional interruption took place, the neurofibrils showed a well circumscribed defect of its primary stainability; his method, however, was inappropriate for ordinary work. While the investigator in neuropathology had to restrict himself largely to the Bielschowsky method, the demonstration by Dr. Lambert gave evidence of the decided gains made by the new methods, and also of the desirability of abstaining from too much hypothetical construction as long as there was not more harmony on the nature of the fibrils.

Disturbances of Sensation in Visceral Disease.—Dr. Joseph Fraenkel, in presenting this paper, said the subject was a very extensive one, and its theoretical foundation was still complicated. It was important because it was of decided aid at the bedside, and frequently, ill-defined and vague symptoms received considerable illumination by making use of the simple method which was elaborated so thoroughly and brilliantly by Head. Dr. Fraenkel said his own contribution to the subject could be summed up in a few words: He had made use of the examination of skin sensibility in visceral diseases, and had received occasional diagnostic help and frequent illuminating suggestions therefrom. It was somewhat astonishing, he thought, that so simple and promising a method had thus far been neglected by the profession in general.

Evidence collected in the physiological laboratory and during operations seemed to show that the viscera had no capacity for pain sensation. Pain sensation was shown only by the external integument, *i.e.* the skin, then by another integumental layer, the fasciæ of the muscles, the tendon sheaths, the periosteum, the synovial membranes, and finally, by the third envelope layer, the serous membranes, the pleura, pericardium, peritoneum, and meninges. The organs themselves, the brain, lung, heart, stomach, liver, etc., could be handled without giving pain or causing any definite sensation. It was also well to keep in mind the fact that when the centripetal innervation of a certain area was disturbed, the impression conveyed was received by the central organs, but would be falsely localized. By studying carefully the areas of distribution of herpes zoster eruptions and the areas of hyperesthesia in visceral disease, Head succeeded in marking on the skin areas which correspond to the innervation of the segments of the cord. Dr. Charles L. Dana was the first to draw attention to the cephalic areas, by associating the location of a headache with its possible visceral origin (ocular, uterine, vesical, stomachic, etc.). Long and painstaking labor had enabled Head to assign the various viscera to corresponding cord segments.

When confronted with that unfortunately not infrequent symptom, pain, a difference between local and reflected pain could be established by the influence of local pressure over the painful area. Pain arising from an infiltration of the skin, from an inflammation of the periosteum, or from local disease of the peritoneum or pleura or meninges became aggravated by pressure, and contrary, a reflected pain became mitigated. The reflex hyperesthesia was elicited by pinching the skin or stroking it with a needle or with the smooth end of a pin, or testing it with hot water or ice; or finally, with a small electrode attached to a faradic current. One would find either in the entire area or at the maximum points certain subjective and objective expressions of hyperesthesia. Often the objective expressions were very striking and would serve as a welcome diagnostic aid in differentiating between structural and functional conditions. The hyperesthetic findings would be most marked in strictly localized and acute conditions. When they became chronic, or when the diseased process had extended, the findings of hyperesthesia would become blurred, or disappeared entirely, or might even be replaced by areas of diminished sensation.

Dr. M. Allen Starr said that when Head's original paper on this subject first appeared he had been much interested in it, although it had excited in him a certain amount of hostility because of the fact that no mention was made of the work of Dr. Dana along this same line, the results of which had been published at least three years before. With the aid of Drs. McBurney and Peabody, at Roosevelt Hospital, Dr. Starr said he had attempted to confirm these zones of hyperesthesia in various regions of the body, and he was unable to do so excepting in about 12 per cent. of the cases. The cases tested were those in which there were gross visceral lesions, and included a number of surgical cases. Dr. Starr said his experience with the method had led him to believe that while in certain cases it was of value, it could not be generally applied with any satisfactory results.

Dr. William H. Thomson said that after reading Head's article in *Brain* regarding the disturbances of sensation in visceral disease he had taken the work up at Roosevelt Hospital and had tested a great many cases. Occasionally the results were very striking, particularly in one case of stone in the kidney, but on the whole, his experience with the method was very similar to that of Dr. Starr. The method, Dr. Thomson said, might be put upon the same plane as the Widal reaction in typhoid fever, but was even less satisfactory. When a positive result was obtained, the information it gave was very valuable, but its negative results could not be relied on. In one case of thoracic aneurysm in which the diagnosis was beyond question, the results of the tests were negative.

Dr. J. Ramsay Hunt said that he had utilized the so-called Head zones of hyperesthesia in visceral disease and could testify to their practical importance in the recognition of abdominal conditions. He referred to obscure cases of gastric ulcer and gallstones in neurotic individuals in which the presence of this symptom had aided materially in the diagnosis.

The President, Dr. Dana, said that one factor which had detracted from the value of the method was that the technique of its application was not well understood. It was of no value whatsoever in the diagnosis of chronic diseases, but in certain acute conditions the method was of some service.

The Significance of Jacksonian Epilepsy in Focal Diagnosis, with Some Discussion of the Site and Nature of the Lesions and Disorders Causing This Form of Spasm.—Dr. Charles K. Mills of Philadelphia said that, with the exception of monoplegia or hemiplegia, probably no single symptom or symptom complex was so often made use of by the diagnostician in his efforts to fix the site of a tumor for the purpose of operation as Jacksonian epilepsy. The term was here used in a broad sense, as meaning monospasm or hemispasm due to cortical or cortico-subcortical discharge, a spasm which usually exhibited, if closely studied, an initial symptom and a serial order of phenomena. As originally and as commonly employed, the mere use of the term was supposed to predicate the existence of a focal lesion of the motor cortex, and it was sometimes defined as a spasm limited to a single group of muscles, or at least to a few muscular groups. Irritation or instability of portions of the cerebral motor area was, in by far the largest number of cases of Jacksonian spasm, as here defined, a direct or indirect cause of this form of epilepsy, but it was by no means true that it was always or even nearly always due to gross lesion of the motor zone. A distinction was at times necessary between Jacksonian epilepsy and hemiepilepsy. Some of the latter cases belonged to the category of Jacksonian epilepsy, but they were not all to be relegated to it. The convulsive attacks following hemiplegia were frequently unilateral, but they might begin on the paralyzed side and become general. Occasionally, they were confined to a portion of one side of the body. Frequently, probably usually, they were of cortical origin. When, as was so often the case, the hemiplegia, especially in childhood and youth, was due to softening from thrombosis, the convolutional areas surrounding or in the neighborhood of the parts destroyed were often the seat of deep congestion and punctiform hemorrhages. These rendered the cortical centers unstable, and convulsive discharges ensued, which might be confined to the limbs and face of one side, or might be unilateral, or become general. The monospasm or unilateral convulsions which occurred in cases of this description sometimes simulated very closely those which were due to brain tumor in the motor cortex or subcortex. They had the same mechanism as the Jacksonian spasms of tumor or other lesion; namely, irritation or instability of cortical motor cells. Hemiepilepsy might, however, in some instances, be due to an irritative lesion well removed from the cortex, or to some toxic state.

Dr. Mills then reported in detail a few cases in which Jacksonian spasm had been an important or a deciding symptom in successfully fixing the site for operation in dealing with cerebral tumor. In connection with such cases, he emphasized the following points: 1. That tumors situated in other parts of the brain than the motor cortex might cause Jacksonian epilepsy. 2. That other lesions besides tumors situated in the motor cortex might cause this form of spasm. 3. That it might occur in toxic and other diseases in which no demonstrable focal lesions were present. 4. That a spasm closely counterparting the Jacksonian type might be observed as a reflex or hysterical disorder. 5. That Jacksonian epilepsy might be simply an integral part of the entire expression of a case of idiopathic epilepsy. Jacksonian epilepsy due to cortical discharge might occur as the result of tumors in other parts of the brain than the motor zone. The irritation, owing to its intensity, spread to the motor cortex, and it was probable, also, that in some of these cases, unusual instability of the motor cells played some part. A midfrontal or even a prefrontal tumor not infrequently invaded caudally until the motor region was grazed or implicated, Jacksonian spasm of typical form, showing itself after psychical graphic and speech disorders, had become prominent. In some instances Jacksonian epilepsy, apparently of the usual motor area type, was observed in tumors of the cerebellopontine angle, or of the cerebellum. In two cases which had come under the speaker's observation, cerebellopontine tumors caused Jacksonian epilepsy, or what appeared to be that affection. The gross lesions of the motor area which caused monospasm or hemispasm, counterparting that produced by neoplasm, were (1) depressed fractures; (2) localized meningitis; (3) meningeal or cortical hemorrhage; (4) focal hemorrhagic encephalitis or cortical polioencephalitis; (5) focal necrosis occurring from embolism or thrombosis, including cases associated with generalized arteriosclerosis.

Dr. Edward D. Fisher said he judged from Dr. Mills' paper that he included under the term Jacksonian epilepsy everything that corresponded to a localized convulsive seizure, irrespective of the condition of consciousness. He apparently disregarded the latter factor, taking a broader view of localized or focal seizures. The usual idea in describing Jacksonian epilepsy had been that in such an attack the convulsive seizure began, for example, in one hand, then passing to the arm and face, and finally becoming general. During the onset of such an attack the patient might remain conscious, and even be able to describe certain features of it, but consciousness was lost as the convulsion became general. Exactly such a case, Dr. Fisher said, recently came under his observation. The patient would say, "I am going to have an attack"; then the hand would close, the forearm would become flexed, and the arm raised from the side of the body; then, as the convulsion became general, unconsciousness would supervene. In that case an operation revealed a small, tuberculous tumor in the hand center, anterior to the fissure of Rolando. Dr. Fisher said he did not believe there was much more to be learned in regard to the motor area of the brain. Future investigations might show some slight differences in regard to the exact distribution of the functional motor areas, but nothing more, and it would prove of slight practical importance, from either a medical or surgical point of view, to learn that the various centers overlapped to a slight degree. In regard to the diagnosis of brain tumor, one of the most important symptoms was the motor disturbance, with or without resulting paralysis. The general symptoms, which Dr. Mills had described so fully, might be absent entirely. In the case of tuberculous tumor, to which he had already referred, there were no sensory disturbances at all, and it was not positive that a tumor existed until it was actually demonstrated at the time of operation. Even with slow-growing brain tumors of considerable size very few symptoms might be present. In speaking of convulsions as a diagnostic feature of brain tumor, Dr. Fisher said he thought there was considerable difference in the facies of a patient who had epileptic convulsions resulting from brain tumor, and one who was suffering from idiopathic epilepsy. The mental appearance accompanying Jacksonian epilepsy was better than that in idiopathic epilepsy; the former patient was in no sense demented; between the attacks his mind was entirely clear, whereas in advanced cases of idiopathic epilepsy that was not so.

Dr. Starr said he was inclined to agree with Dr. Mills that the neurologist had perhaps been too ready to base

a diagnosis of brain tumor upon the history of a Jacksonian attack. From his own experience, the speaker said he was now somewhat reluctant to make a diagnosis of tumor in the motor zone in a case in which Jacksonian epilepsy was the only manifestation: with tumors in that region, we should have not only local irritation, but also, as the tumor progressed, we should get evidences of destruction of tissue, giving rise to some form of paralysis in connection with or following the spasm, and that paralysis would naturally become more pronounced as the growth increased in size. Dr. Starr said he realized that Jacksonian epilepsy could be caused by tumors both in front of and behind the motor zone. He reported such a case that recently came under his observation. In another case which he saw, typical Jacksonian fits were apparently due to uremia, as nothing was found in the brain either at the time of operation, or subsequently at post mortem. Jacksonian epilepsy might also occur in old people in connection with apoplectic attacks.

Dr. Dana said he thought idiopathic epilepsy of the Jacksonian type was extremely rare, but it was the only type in which it was wise to operate, even if no tumor or organic lesion was suspected. He recalled one such case in which the patient was relieved of his attacks for two years by excision of the cortex. In another case, which was also relieved, the patient was lost sight of. He said he was rather skeptical in regard to the cases reported by Dr. Mills in which Jacksonian fits were produced by cerebellopontine tumors, and he was inclined to believe that the convulsions were the result of direct irritation of the seventh nerve and not a cortical discharge.

Dr. L. Pierce Clark said it was well known that a certain number of cases of idiopathic epilepsy were masked as Jacksonian epilepsy. In his study upon exhaustion paralysis in epilepsy at the Craig Colony he had found that these cases were by no means rare. They formed about two per cent. of the total admissions. In differentiating between the two types of epilepsy, one should not only take into consideration the character of the spasm itself, but also the absence or presence of the mental stigmata of idiopathic epilepsy, and the imperfect and slow loss of consciousness of Jacksonian epilepsy. The weakness in parts previously convulsed was different in the two types: in idiopathic epilepsy it was very transient; in Jacksonian epilepsy it was more or less permanent. The other symptoms of brain tumor would make diagnosis easy in Jacksonian spasm if all the cases were due to neoplasm, but unfortunately the great majority of the cases difficult of diagnosis were those due to small cortical hemorrhage and local meningoencephalitis. It was particularly difficult to differentiate the latter class from true idiopathic epilepsy. The diagnosis would not be so important if we ceased to urge operation in the local encephalitis cases, and the speaker said he had never seen such a case permanently benefited by operation. There were not a few permanent residents at the Craig Colony illustrating that view point.

The discussion was continued by Dr. T. P. Prout, and closed by Dr. Mills.

College of Physicians of Philadelphia; Section on General Medicine.

At a stated meeting held April 9, Dr. T. L. Coley exhibited a girl, about fifteen years old, who presented a tumefaction in the epigastric and umbilical regions, yielding dullness on percussion in its upper portion and a tympanitic note below. There was also a certain amount of lordosis in the lumbar region. The formation was thought to be a neoplasm and an exploratory operation was contemplated. Under ether narcosis, however, the mass disappeared entirely. The conclusion was now reached that the condition was dependent upon contraction of portions of the abdominal recti muscles, due perhaps to faulty posture. It was found that the phenomena reappeared on the return of consciousness, although they could be dissipated by removal of the lordosis through placing a pillow beneath the lumbar spine. There were no other stigmata of hysteria, and the patient was a bright-cheeked, red-lipped, well-nourished girl. Dr. H. A. Hare reported "A Fatal Case of Acute Dilatation of the Stomach." The patient was a man suffering from an attack of typhoid fever, who, while under observation it was discovered had been habituated to the use of morphine. Hyoscin was administered in effective doses every two hours, and the man appeared to be doing well, when suddenly in the night without warning he died. On post-mortem examination the stomach was found enormously dilated and occupying almost the entire abdominal cavity. Dr. D. J. Milton Miller presented a communication entitled "Some Accidental Eruptions in the Course of Typhoid Fever." In observations made in a series of 250 cases of typhoid fever he had encountered a variety of accidental rashes in 16, some erythematous, others papular, still others vesicular. Dr. Norman B. Gwyn read a paper entitled "Orchitis in Typhoid Fever, with a Report of Two Cases." The association is believed to be a rare one, as only a comparatively small number of cases is recorded in the literature. In some cases the affection is due to lodgment in structures of testicle or epididymis of typhoid bacilli brought by way of the bloodstream. Suppuration sometimes takes place, with partial destruction of tissue.

Philadelphia County Medical Society.

At a stated meeting held April 11, Dr. George E. Pfahler exhibited "A Modification of Benoist's Penetrometer," an instrument for measuring the intensity and penetrating power of the *x*-ray. Dr. William M. Angney demonstrated "A First-aid Dressing Adopted by the Police Department of Philadelphia." This consisted of several strips of borosalicylated gauze of different lengths enclosed in a sealed and sterile receptacle, that can be used as pads and bandages. Dr. James M. Anders delivered "The Address of the Retiring President," in which he reviewed the more important work accomplished by the Society during the preceding year. He also pointed out directions in which he thought the Society might take up new work in the way of lectures, demonstrations, addresses, the offering of prizes, the institution of collective investigations. He strongly commended the establishment of branches of the central society, with occasional joint meetings, both scientific and social. He committed himself to the policy of extending membership to all reputable practitioners of medicine, regardless of their school of graduation, provided, however, they abjured sectarian practice and designation. Dr. Albert P. Francine read a paper entitled "The Treatment of Gastroptosis," in which he detailed mechanical and medicinal measures that have proved serviceable in the relief of the condition named. Dr. Henry D. Beyea read a paper entitled "The Surgical Treatment of Gastroptosis." He described the method of procedure that he devised some eight years ago and that he has now practised in a moderate number of cases with admirable success, namely, plication of the gastrohepatic ligament.

Professional Amenities.—A writer in the *British Medical Journal* notes that no love was lost between Scarpa and Rasori, who were contemporary teachers at Pavia. One day Scarpa was standing under the portico of the university when Rasori, who happened to pass, let fly a jibe at his brother professor. Scarpa replied: "Some time or other the *razor* must lose its edge.' To which came the retort from Rasori: "It will always be sharp enough to cut a *shoe*" (*scarpa*).

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Standard of Requirements Raised.—At a meeting of the Illinois State Board of Health, recently held at the Great Northern Hotel, Chicago, the President of the Board, Dr. George W. Webster, introduced a resolution, which was unanimously adopted, requiring all applicants for entry to medical colleges to have completed a nine months' course in chemistry, biology, physics, and languages, in addition to the requirements for obtaining their regular grammar and high school diplomas. This lengthens the regular course a full year. These new subjects may be taken from any recognized institution teaching these subjects in regular course. This resolution does not go into effect until 1910.

Reciprocity in Vermont.—It is announced that hereafter the Board of Medical Registration of Vermont will issue licenses without examination to reputable physicians and surgeons who appear personally and present a certified copy of certificate of registration, or license, which has been issued to said applicant in another State where the requirements for registration are deemed equivalent to those of Vermont, provided such State accords a like privilege to holders of a license granted under the laws of Vermont. Each applicant for such license must pay a registration fee of ten dollars.

Mississippi.—At the spring examination, held in Jackson, there were 231 candidates, of which number 118 passed and 113 failed to pass.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 23, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	396	177
Diphtheria	288	16
Measles	611	20
Scarlet Fever	160	4
Smallpox	4	—
Varicella	110	—
Typhoid Fever	33	2
Whooping Cough	35	4
Cerebrospinal Meningitis	8	9
Malarial Fever	.....	....
Totals	1,645	232

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending June 23, 1906.

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Alaska, Nome	June 14–15	6	On Schr. *Monterey.*
California, Los Angeles	June 2–9	1	..
Florida, General	June 9–16	6	.
Jacksonville	June 9–16	3	
Georgia, Augusta	June 4–11	3	
Sapolo Island	To June 12	6	.
Louisiana, New Orleans	July 9–16	5	
Michigan, Detroit	June 9–16	2	..
Montana, General	May 1–31	6	
New York, Monroe	June 19	1	
Saratoga Springs	June 19	1	
New York	June 9–16	4	
North Dakota, General	Apr. 1–30	25	4
Ohio, Cincinnati	June 8–15	12	.
Hamilton	May 12–19	1	.
Youngstown	May 16–June 15	3	
Oklahoma Territory, Oklahoma	June 2–9	8	1
Oregon, General	May 1–31	36	1
Pennsylvania, Allegheny	June 9–16	1	..
Pittsburg	May 26–June 9	5	3
Tennessee, Knoxville	June 9–16	1	
Memphis	June 2–16	5	.
Utah, General	May 1–31	70	.
Wisconsin, Appleton	June 9–16	2	..

SMALLPOX—FOREIGN.

Africa, Cape Town	May 5–12	4	
Freetown	May 14	.	Present.
Belgium, Liege	May 10–26	1	1
Brazil, Pernambuco	May 8–15	.	5
Chile, Antofagasta	May 20	.	Present
Coquimbo	May 20	.	Present.
Iquique	May 20	.	Epidemic.
Talkahuana	May 20	.	Present.
France, Paris	May 12–26	16	..
Gibraltar	May 27–June 3	2	..
Great Britain, Liverpool	May 26–June 2	2	..
London	May 26–June 2	3	.
India, Bombay	May 15–22	.	5
Calcutta	May 6–12	.	57
Karachi	May 13–20	15	11
Madras	May 12–18	.	11
Rangoon	May 6–12	.	23
Italy, General	May 25–31	27	..
Peru, Callao	May 12–19	1	..

CHOLERA.

India, Bombay	May 15–22	.	20
Calcutta	May 6–12	.	42
Rangoon	May 6–12	.	4

YELLOW FEVER.

Costa Rica, Limon	June 20	1	.
Cuba, Habana	June 18–21	2	.
Honduras, Pimienta	May 19–23	20	..
*Mexico, Merida	May 27–June 9	3	1

*Case reported at Coatzacoalcos in report for June 8, 1905, found not to be yellow fever.

PLAGUE—INSULAR.

Hawaii, Honolulu	June 15	.	1

PLAGUE—FOREIGN.

Australia, Brisbane	Apr. 28–May 5	1	1
Rockhampton	Apr. 28–May 5	1	..
Brazil, Pernambuco	May 1–15	.	1
Egypt, General	May 17–31	34	12
Alexandria	May 29	1	..
Port Said	May 26	2	1
India, Bombay	May 15–22	..	511
Calcutta	May 6–12	..	92
Karachi	May 13–20	144	135
Rangoon	May 6–12	..	69
Peru, Lambayeque	May 6–13	2	..
Lima	Apr. 30–May 13	9	..

INDEX.

A.

Aaser, illness of Dr., 633.
Abbe, Robert, explosion of a radium tube, 615.
Abdomen, contusions of the, 189.
Abdominal cavity, irrigation of the, 482; pain, diagnosis of affections characterized by, 763; pain, medical treatment of, 112; puncture, diagnostic, 193; section, convalescence following, 200; symptoms, acute, from chronic conditions, 982; wounds, overlapping the aponeuroses in closing, 82.
Abortion, criminal, 985.
Abraham, Joseph H., syphilitic empyema of the accessory sinuses of the nose with a report of four cases, 345.
Absinthe, 267; in Belgium, 477.
Academy of Medicine, popular lecture at the, 22.
Acetanilid, 428.
Acetone imbedding methods, 115.
Acetonuria in pelvic diseases, 1016; postanesthetic, 940.
Achondroplasia, 561; a case of, 277.
Acne, a new treatment for, 60.
Actinomycosis of the urinary tract, 481.
Addison's disease, 774.
Adenitis, in appendicitis, 12.
Adenoids, 406; and deafness in children, 724.
Adrenalin in Werlhof's disease, 995.
Agglutination for the practitioner, 273.
Air, clean, 165, 203; de luxe, 181; passages, symposium on the diseases of the upper, 406; the entrance of, into the circulation, 305; the therapeutic value of warm moist, and hot dry, in children's diseases, 131.
Alabama State Medical Association, 719.
Albuminuria, orthostatic, 849; prostatic, 397.
Albumoses, observations on, in urine, 233.
Alcohol, a bill for free, 266, 552, 674, 718, 931, 978; death from wood, 266; distaste for, in the Antarctic regions; 349; the effect of on the heart, 941; venereal disease and tuberculosis problems, 857, 902.
Alcoholic beverages in Germany, 633.
Alcoholism, hospital for the treatment of acute, 552; in Munich, 766; the study of, 633.
Alien act, a new, in Great Britain, 630.
Alimentary canal, rhythmic sounds in the, 152.
Aluminum instruments, sterilizing, 38.
Ambulance accident, 144; chasing, 553.
Am Ende, C., causation of the stimulus of the heart, 1058.
American Academy of Medicine, the, 799, 978.
American Climatological Association, 801.
American Dermatological Association, 23, 932.
American Gastroenterological association, 1019.
American Editors' Association, 977.
American Laryngological, Rhinological and Otological Society, 393.
American Medical Association, finances of the, 1052; officers of sections, 977; orators of the, 1018; the Boston meeting of the, 974.
American Medical Directory, the, 837.
American Medicine to be issued monthly, 510.
"American Practice of Surgery," 800.
American Urological Association, 510, 1019.
Amputation below the knee, 271.
Anal fissure, the office treatment of, 656.
Anemia, observations on, 315; of parasitic origin, 194; pernicious, successfully treated, 767; relation of chronic intestinal putrefaction to, 606.
Anesthesia, a device for, in resection of the jaw, 906; advantages of mixed, 1026; a suggestion for a combination, 631; local, 154; local, in surgery of the ear, 727; lung complications after, 940; some points in, 685; spinal, combined with scopolamine-morphine, 686; vapor, 65; the history of spinal, 1026; with the Roth-Dräger apparatus, 940.
Aneurysm, rupture of thoracic into the vena cava, 896; treatment of, by direct arterial closure, 436; treatment of, by intrasaccular suture, 82, 517, 693.
Angina, and stomatitis, ulceromembranous, 313.
Angina pectoris, position as a diagnostic sign in, 155; the nature of, 1033; the relation of to an arteriocardiac reflex, 360; without circulatory disease, 726.
Angioma, gluteal cavernous, 150.
Ankylostomiasis, eucalyptus oil in, 314.
Annals of Gynecology and Pediatrics, 308.
Anterior poliomyelitis, 773.
Anthrax, primary intestinal in man, 892.
Antibodies, passage of, into the blood of infants, 155.
Anticomplements, action of the, 273.
Antigonococcus serum in gonorrheal rheumatism, 101.
Antivivisection at length, 308.
Antrum, abscess of, causing acute rheumatism, 313.
Anus, fissure of the, 151.
Aorta, disease of the, in congenital syphilis, 518.
Aortic valves, mechanism of the, 714.
Aponeuroses, overlapping the, in closing abdominal wounds, 82.
Apoplexy, cerebellar, 743, 774.
Appendectomy during pregnancy, 853.
Appendicitis, 122, 157, 158, 416, 598, 774; adenitis in, 12; and ascaris lumbricoides, 600; and hernia, combined operation for, 692; and obstruction of the ileocolic valve, 691; alleged epidemicity of, 1053; improved method of suturing in, 846; medical sufferers from, 186; neglected, 123; or colitis, 976; pin worms as a cause of, 350; tape worm simulating, 358; the indications for operation in, 726; the muscles splitting incision in, 69; the prevention of, 71; the treatment of, 558; traumatism as a cause of, 868; tuberculous, 985; when to operate in, 435.
Appendicostomy, 273, 690, 772, 995.
Appendix, bilharzia infection of the, 359; mucocele of the, 313; primary cancer of the, 716, 1024; reflex neuroses with reference to the, 111; the, 117; tuberculosis of the, 233, 700.
Aperients, effects of on peristalsis, 1029.
Archives of Pediatrics, 65.
Arctic climate, the, 233.
Arizona State Medical Association, 759.
Arkansas State Medical Association, 886.
Army medical bill, the, 977.
Army Medical Corps examinations, 306, 885.
Army medical schools, 630.
Arterial pressure, the diagnostic significance of high, 522, 1028; tension, constitutional low, 845.
Arteries, results of occlusion of large, 992.
Arteriosclerosis, 360; and cardiac neurosis following trauma, 806; arterial poisons and the etiology of, 985; as a general disease, 270; a statistical study of, 521; from alimentary toxins, 897; in surgery, 639; mental diseases and cerebral, 140; the increased arterial pressure of, 400; the treatment of, 235.
Arthritis, bacteriology of infectious, 74; differential diagnosis of, 1034; gonorrheal, 1034; pneumococcic, 806; toxic, 201; treatment of chronic, 1035.
Arytenoid cartilage, a case of congenital luxation of the, 865.
Asepsis in operation wounds, 727; maintenance of, 151.
Association of American Medical Colleges, 511.
Association of American Physicians, 841.
Association of the Surgeons of the Southern Railway, 932.
Asthma, clinical features of spasmodic, 40; the mechanism and treatment of spasmodic, 426; the vasomotor factor in, 637.
Athletes, deaths of in athletic games, 870.
Atlantic City Academy of Medicine, 885.
Aural cases in general practice, 315.
Austrian physicians' strike, 146.
Authors' clinic, an, 931.
Auto speeding by physicians, 430.
Autolysis, 481.
Autopsy dispute, 64; question, the, 885.

B.

Bacillus chlorhydrici, 358.
Bacteria, action of high tension electrical currents on, 939; a method for staining in sections, 73.
Bactericidal power of the organism, 155.
Balsam of Peru in castor oil as a surgical dressing, 480.
Bandler, Samuel W., some clinical observations on salpingitis and parametritis in nulliparæ, 916; what is the climacterium? 209.
Bangs, L. Bolton, some observations on prostatectomy, 997.
Bardes, Albert, earache, 101.
Barkan, L., a few suggestions in reference to consumption, 302.
Barlow's disease, operation in, 985.
Barstow, Donald M., a case of tympanic and mastoid cholesteatoma; extradural abscess; sinus thrombosis; prolonged pyemic temperature without metastases; recovery, 217.
Baruch, Simon, the medical discovery of Oliver Wendell Holmes, 228.
Bath, the warm in gynecological examinations, 515.
Beard, John, trypsin and amylopsin in cancer, 1020.
Beck, Carl, the modern treatment of fractures, 449.
Beef question, a pathological study of the, 1018.
Behring's tuberculosis cure, 759.
Bell, W. Duffield, some obstetrical methods practised in the Philippines, 136.
Belladonna, intolerance of, 482.
Bellevue Hospital, appointments at, 144; paid internes at, 430; plans, 840, 978; the new, 145, 799, 886.
Bellevue Training School for Nurses, 106.
Benedict, A. L., the relaxing warm bath in gynecological examinations, 515.
Bennett's fracture, 1024.
Benzin poisoning, and its postmortem appearances, 483.
Benzoic and salicylic acids in foods, 394.
Berg, Albert A., the diagnosis of surgical diseases of the kidney, 582.
Berg, Henry W., what has surgery left to medicine in the treatment of peritonitis in adults and children? 1044.
Berlin, letters from, 23, 231, 513, 803.
Beth Israel Hospital Association, 107.

Bier's treatment, the state of the blood during, 799.
Bile acids as a remedy, 724; pigments, a reaction for, 559.
Bilharziosis of the appendix, 517.
Biliary tract, diagnosis and operations on the, 397.
Bill, a silly, in Ohio, 184.
Billings, Jr., J. S., sanitary supervision of pulmonary tuberculosis and other communicable diseases by the Department of Health of the City of New York, 790; the administration of diphtheria antitoxin and performance of intubation by the Department of Health of New York City, 258.
Birchmore, Woodbridge Hall, the pseudouremia of childhood, 133.
Bishop, Louis F., the occurrence and prognosis of pneumonia as studied at the Lincoln Hospital, 835.
Bladder, over distention of the , 234; the operative treatment of tumors of the, 439.
Blair, Louis E., literary gems from the medical essays of Oliver Wendell Holmes, 375.
Blastomycetic dermatitis, 603.
Blind, to help the, 64.
Blindness with astereognosis, 160.
Blood, a test for, in feces, 234; clinical chemistry of the, in various diseases, 605; clot dressing, the, 558; corpuscles, diffusion of through agar, 847; cultures in children, 988; effect of temperature on the viscosity of, 475; forensic identification of, 235; platelets, 30, 436, 599, 1015; preparations, the value of unstained, 806; pressure and pulse as affected by altitude, 380; pressure changes in mitral insufficiency, 896; pressure, effect of intestinal extract on, 776; pressure, effect on, of the removal of fluid from the thorax, 952; researches on the viscosity of the, 304, 893; vessels, advances in surgery of the, 806.
Bloomfield, M. D., a phonendoscope attachment, 736.
Boas, a testimonial to Dr., 552.
Bone marrow, anemia without regeneration of the, 848.
Bones, subcutaneous fissures of the, 483.
Book Notices.
Albumins, chemistry of the, by S. B. Schryver, 850.
Anatomists, the World's, by D. W. H. Kemper, 986.
Anatomy and physiology for nurses, by Le Roy Lewis, 34.
Anatomy, clinical applied, by Charles R. Box and W. M. Eccles, 895.
Anatomy, descriptive and surgical, by Henry Gray, edited by T. Pickering Pick, 401.
Anatomy, text-book of, edited by E. J. Cunningham, 34.
Anatomy, the Edinburgh stereoscopic atlas of, by J. R. Cunningham and David Waterston, 601.
Animal parasites of man, the, by Max Braun, translated by Pauline Falcke, 728.
Autointoxication in disease, lectures on, by Ch. Bouchard, 275.
Bacteriology, a manual of, by Herbert U. Williams and B. M. Bolton, 640.
Behandlung der Krankheiten der Nase und des Nasenrachens, by D. A. Onodi and A. Rosenberg, 942.
Berliner Arzneiverordnungen, by Paul Reckzeh, 440.
Biographic clinics, by George M. Gould, 75.
Blakiston's quiz compend: A compend of medical chemistry, by Henry Leffmann, 401.
Bodily deformities, by E. J. Chance, edited by John Poland, 601.
Case teaching in medicine, by Richard C. Cabot, 1027.
Chemical analysis of inorganic and organic substances, a systematic course of, by Henry W. Schimpf, 640.
Chemistry, a laboratory manual of physiological, 562.
Chemistry, a manual of organic and inorganic, by Arthur P. Luff and Frederic J. M. Page, 116.
Chemistry, a text-book of medical and pharmaceutical, by Elias H. Bartley, 34.

Borderline diseases, duties of practitioners in relation to, 901.
Borgias, poison of the, 477.
Bottini's operation, the value of, 765.
Bowditch, the case of Dr., 107, 226; resignation of Dr. H. P., 800.
Bowel infection in infants, bacteriological and blood findings in, 988.
Brachialgia, 115.
Bradley, C. Cole, trachoma in children, 178.
Bradycardia with epileptiform seizures, 806.
Brain and skull, traumatic lesions of the, 771; surgery, two cases of, 687; tumor, a case of, 161.
Breast, amputation, a new technique for, 121, 200, 435; axillary and pectoral scars following removal of the, 70; diagnosis and treatment of swellings of the, 272; feeding, 1017; mixed tumors of the, 807; tumors of the, in a man, 274.
Breuer, Max, the Bier treatment by hyperemia, 290.
Broad ligaments, the preservation of the functions of the, 991.
Bronchopneumonia and pyemia, 892.
Bronx, a new hospital in the, 24.
Brooks, Paul B., the examination of the spinal fluid in dementia paralytica, 1048.
Brow ague, 724.
Bryant, W. Sohier, operative technique and after-treatment for mastoiditis with epidural complications, 502.
Bulkley, Dr. L. Duncan, lectures by, 430.
Bullous affections and their classification, 366; eruption of the face, a case of recurrent, 367.
Burnham, Melvin P., the State and tuberculosis sanatoria, 746.
Burns, pathology of, 1053.

C.

Calcareous degeneration, 61.
California Board of Medical Examiners, 64.
California, for our medical brethren in, 800.
Camphor, poisonous and fatal action of, 426.
Cancer, abdominal hysterectomy for, 437; a defense of the parasitic theory of, 19; a device in radical operations for, 982; as a cause of death in assured lives, 488; causes and cure of, 516; Doyen's serum in, 685; in the United States, 725; investigation, experimental, 765; metabolism in, 359; medical treatment of, 1030; of the breast, early recognition of, 984; of the breast, medical aspects of, 153; of the colon, a method of removing, 398; of the head and neck, treatment of, 80; of the stomach, 598; of the stomach, *x*-ray examination of the stomach in, 315; of the tongue, early conditions in, 984; of the tongue, two cases of, 442; of the uterus, 284; of the uterus, pathology and surgical treatment of, 990; of the uterus, the radical operation for, 714; problems, notes on the, 559; propagated, 984; retropharyngeal, 161; the early diagnosis of gastric, 312; the law of accelerating risk in, 439; treatment of, by a bacterial vaccine, 685; treatment of mediastinal with *x*-rays, 270; trypsin in, 983, 1020; use of the *x*-rays in, 124, 439.
Canteen bill, the, in Congress, 19.
Carbolic poisoning, alcohol in, 482.
Card index, the value of a therapeutic, 144.
Cardiac murmurs, effect of posture on, 397; murmurs, experimental studies of, 896; pathology, advances in, 276; stimulation, by digital manipulation, 995.
Carotid gland, tumors of the, 993.
Carpenter, Dudley N., fever in tertiary syphilis, 412.
Carstens, J. H., the principles of ethics, 269.
Carter, H. R., yellow fever contracted during the daytime, 683.
Cartwright lectures, the, 105, 185.
Casts in the urine, the clinical significance of, 882.
Cat, the case against the, 929.
Cataphoresis, vacuum electrode for, 735.
Cataract extraction, success in, 438; the operation for, 598.
Catgut, dry iodine, 73; sterilization, a new method of, 984.
Catheters, the sterilization of, 856.
Cecum, volvulus of the, treated by operation, 805.
Cell, selective absorption by the, 10.
Celluloid plates for cranial defects, 356.
Cerebellum, tumor of the, 112, 603.
Cerebral disease, symptoms in, 725; segmentation, 878; seizures due to multiple aneurysms, 515; tumor, mental symptoms of, 597.
Cerebrospinal fluid, some notes on the, 219; hemorrhages, lumbar puncture in, 561.
Cervical rib, three cases of, 775.
Cesarean section, 389; for intestinal obstruction, 1026; post-mortem, 893; the popularity of, 508; vaginal, 655; vaginal, is it justifiable? 602.
Chancre of the eyelid, 115; the treatment of soft, 143.
Charaka Club, the, 633.
Charity, bequests to, 476.
Charities Federation, 510.
Charities, State Board of, 633.
Chauffeur's fracture, a new, 637.
Cheek, plastic operation for cancer of the, 689.
Chemistry, International Congress of, at Rome, 718.
Chest, diameters of the normal and phthisical, 30.
Chicago, health conditions in, 66, 632, 673, 886, 978; home for destitute crippled children, 800; hospital internes in, 674; schools, sanitary rules for, 65.
Children, to study physically deficient, 510.
Children's bureau, for a, 106; diseases, warm moist, and hot dry, air in the treatment of, 131.
Chloroform, dosage of, in the blood, 361; in consumption, 517; poisoning, delayed, 231.
Chlorosis, the gastric juice in, 807.
Cholecystectomy, 397, 770.
Cholera, a remedy for, 234; flies in,

33; quinine in, 269; saline injections in, 983.
Cholesteatoma, a case of tympanic and mastoid with complications, 217.
Cholin injections, effect of, on the leucocytes, 154.
Chorea and some disorders simulating it, 547; chronic progressive in youth, 360; diphtheria antitoxin in, 972; Huntington's, 316; mental disorders in, 898; the heart in, 1032.
Chorionepitheliomatous proliferations in teratomata, 190.
Christian science, in England, 800, 841; in the jury box, 225.
Christian scientist held, 931.
Chronic conditions, remarks on, 773.
Churches, hygiene of Spanish, 100.
Cigarette law, Indiana, 719.
Cincinnati Academy of Medicine, 477.
Circulation, interrupted as a therapeutic agent, 271; the physiology of the, 1032.
Circulatory current, the reversal of the, 755; disorders, strychnine and nitroglycerin in, 113.
Circumcision, 909.
City seaside park, 932.
Civil Service examinations, 354, 392, 552, 977.
Clark, J. Bayard, some necessary principles in the diagnosis of surgical conditions of the upper urinary tract, 255.

Hospital Saturday and Sunday Association, 107, 633.
Hospitals *vs.* libraries, 476.
Housemaid's knee, new treatment for, 272.
Howard, William Lee, football and moral health, 546.
Howe, Louis, tick fever, 311.
Humerus, nailing the head of the, for a fracture, 15.
Hunt, Edward L., Korsakoff's disease; a report of four cases, 387.
Hutchinson, Woods, the heart in tuberculosis, 335.
Hydrocephalus and rachitis, radiotherapy in, 404.
Hydrochloric acid, the determination of the absence of, by a stool examination, 667.
Hydrotherapy, lectures on, 673, 758.
Hygiene and sanitation, readjustment of education and research in, 233; a summer course in, 511.
Hyperemia, Bier's in acute suppurations of the ear, 361; Bier's, in eye diseases, 193; the Bier treatment by, 290; the treatment of acute suppurative processes with Bier's, 361.
Hyperpyrexia following traumatism, 114.
Hypnotic, death from a synthetic, 145.
Hysterectomy, 854; technique of, 894.
Hysteroepilepsy, 854.
Hysterical manifestations by imitation, 767.

I.

Icterus, neonatorum, a series of cases of, 153.
Idiocy, amaurotic family, 152.
Illinois, health statistics of, 64; training school for nurses, 758.
Illinois State Medical Association, 886.
Immigrants, to raise the standard of, 592.
Immigration law, new, 886.
Income, the physician's, 264.
Incurables, painless death for, 64.
Index medicus, 840.
Inebriety often a form of moral insanity, 383.
Infancy, the anemia of, 941.
Infant feeding, 70, 1017; during hot weather, 1001; sodium citrate in, 989; the trend of opinion concerning, 989; the scientific principles underlying the use of milk in, 50.
Infants, intoxication arising from medication in, 236; mortality of, an institution to combat, 306; the stools in starch fed, 989.
Infectious diseases, notification of, 107.
Inflammation, anesthetics in the treatment of, 848; a new view in regard to, 590; congestion and pressure treatment in, 848; the treatment of by hyperemia, 686.
Influenza, symptoms, treatment, and bacteriology of, 563.
Innocents, slaughter of the, 472.
Insane, a plea for the convict, 30; causes of injuries among the, 805; operation for pelvic disease, in the, 767.
Insanity, a common form of, 659; as a result of hysterotomy and oophorectomy, 241.
Insects, the relation of, to disease, 629.
Insomnia, professional treatment for, 597.
Institutions, care of the sick outside of, 138.
Insurance organizations and healthful living, 648.
Intercostal pain, relief of by injections of water, 223.
International Food Exhibit, 308.
International Medical Congress, 226, 266, 308, 353, 393, 476, 592, 672, 717, 842, 887, 933, 980, 1022.
Intestinal obstruction, abdominal disorders which resemble acute, 399; acute, 636; a new form of, 693; produced by the appendix, 399.
Intestinal sand, 114; parasites, eggs of, 193; perforation due to a fish bone, 853; ulcers, iliosigmoidostomy for, 684.
Intestine, congenital stenosis of the small, 984; sacular dilatation of the small, 308; strangulation of, through a slit in the omentum, 713, 729; subcutaneous rupture of the, cured by operation, 273; the lower, 117; volvulus of the small, two cases of, 692.
Iodine in surgery, 637; the action of, on adrenalin arterionecrosis, 807.
Iodism and thyroiditis, 438.
Iowa State Medical Society, 932.
Isaacs, A. E., appendicitis, 461.
Isthmus, health conditions on the, 308.
Ivy poisoning, 426.

Trypanosomiasis, treatment of human, 847.
Trypsin in cancer, 983, 1020.
Tubercle bacilli, antagonistic action of normal and therapeutic serum against, 155; the virulence of, 559; parasitism of, 724.
Tuberculides, the, with a report of cases, 1012.
Tuberculin therapy, the principles of, 900.
Tuberculosis, albuminuria in, 894; al-

cohol and venereal disease problems, 857, 902; among federal employees, 429; and patent medicines, 398; a note on, 194; blue ointment, in, 71; cerebral manifestations of, 847; chloroform in pulmonary, 272; congenital, 204; contractile processes in the lung as a result of pulmonary, 270; cure, a new, 632; diagnosis of, 1054; diagnosis of genitourinary, 151; early *x*-ray diagnosis of, 321; experiments on apes in regard to, 154; home sanatorium treatment of pulmonary, 358; human and bovine, 150, 648; immunization in, 85, 1069; immunization of cattle against, 260; in Germany, 931; intestinal and its surgery, 603; ionization in the treatment of, 921; miliary, 154; of joints, treatment of, in the open air, 396; of the heart, a case of, 766; of the mesenteric glands, surgical treatment of, 71; of the thoracic duct and acute miliary tuberculosis, 70; of the urinary system, treatment of, by tuberculin, 31; of the urinary tract in women, 955; open-air treatment of bone, 150; problem, the teacher's part in the, 245; prognosis in, 70; pulmonary, and other communicable diseases, supervision of, by the New York Department of Health, 790; pulmonary congestion as a forerunner of, 115; pulmonary, home treatment of, 65; pulmonary, in school children, 639; pulmonary, more conservative examination in cases of, 542; raw meat in, 72; results of sanatorium treatment of pulmonary, 200; sanatoria and the State, 746; sanatoria; do they pay? 183; sanatorium, New York City, 632; sanatorium, opposition to the Staten Island, 306; specific treatment of, 43; suggestions in reference to pulmonary, 302; suppression of, in dairy herds, 151; the county sanatorium for the treatment of pulmonary, 646; the curability of, 417; the diagnosis and treatment of, 774; the heart in, 335; the leucocyte formula of, 767; the methods of distribution of pulmonary, 519; the open-air treatment of, 480; the pathogenesis of pulmonary, 474; the portal of infection in, 686; the sanatorium treatment of, 358; the treatment of, 893; the treatment of joint, 639; the treatment of pulmonary by artificial pneumothorax, 639; the treatment of with Marmoreck's serum, 272, 437; the value of throat examinations in pulmonary, 480; urinary chlorides in, 194; Wright's method of treating, 191.

Tuberculosis exhibition, 226, 354, 477; for the slums, 107; in Boston, 66, 107; in Chicago, 632.

Tuberculous cattle killed, 106; children, results obtained at the Herold Hospital for, 881; dangers to the healthy in resorts for the, 937; the psychology of the, 482.

Tumors, endothelial, 359.

Turbinectomy, 585.

Typhoid bacilli, cultivation of the from the blood, 1025; bacilli, proliferation of, in the gall-bladder; 62; bacilluria, 549; bacillus, the Conradi-Drigalski medium for the isolation of the, 557; gangrene, 448; serum, obtained from the goat, 765; spine and spondylitis, 897.

Typhoid fever, acute symptoms from inflamed mesenteric glands in, 314; a more liberal diet in, 414; and pulmonary gangrene, 894; complicated by mesenteric thrombosis, 78; feeding in, 1029; incubation and reincubation cycles of, 197; in infants, 29; of children, septicemia in, 33; pathological physiology of 111; prognosis in, 559; protective inoculation against, 224; saline beverages in, 579; the epidemiology of, 114; the management of, 662; treatment of, 873; with jaundice, 604.

Typhus fever in Mexico, 931.

U.

Ulceration, chronic, in the pubic region, 367.

Ulcus rodens (Mooren), 505.

United States Civil Service Commission, 267.

Uremia, etiology and treatment of, 1031.

Ureter and kidney, traumatism of the, 81; rectal anastomosis of the, 890.

Urethra, endoscopy of the, 360; rupture of the, 646; to remove foreign bodies from the, 819.

Urethral discharges, diagnosis of chronic, 358.

Urethritis, chronic, the treatment of, 397.

Uric acid and the xanthin bases in leukemia treated by the *x*-rays, 315; elimination of, by the feces, 274; the formation of, 516.

Urinary casts, staining methods for, 839; examinations, deductive value of, 230; incontinence, a new operation for, 955; tract, diagnosis of surgical conditions of the upper, 255.

Urine, small quantities of sugar and albumin in the, 235.

Urogenital diaphragm, destroying the, to relieve prostatic ischuria, 439.

Utah State Medical Association, 841.

Uterus, a new method of ventral fixation of the, 72; and vagina, removal of, for prolapsus uteri, 853; antifixation of the, and protracted gestation, 400; complete inversion of the, 795; enucleation of fibromyoma of the, during pregnancy, 517; fibroid tumors of the, 954; fibroids of the, treatment of, 772; hysterectomy for fibroids of the, complicating pregnancy, 1023; medical treatment of fibroids of the, 113; myomata of the, and cancer, 436; penetrating wounds of the, 894; polypus of the, extraction of a, after labor, 561; removal of the for chronic inflammation, 646; rupture of the, during parturition, 363; spontaneous rupture of the, in the seventh month of pregnancy, 363; surgical treatment of prolapse of the, 603; treatment of retrodisplacements of the, 811; wandering fibroid tumors of the, 80.

V.

Vaccination in Paterson, 552; in Philadelphia, 750; revolts, 267.

Vaccina, aberrant, 314.

Vaccine treatment in surgery, 764.

Vaginapexy, 270.

Vaginal cesarean section and the surgical era in gynecology, 315; cysts, 517.

Valk, Francis, the formation of a cul-de-sac for an artificial eye, 712.

Valvular lesions, the indirect effects of, 645.

Van der Poel, John, conservatism in the treatment of senile hypertrophy of the prostate, 827.

Varicocele, radical cure of, 33.

Varicose veins, treatment of, 121.

Vascular spasm and fibrosis, 302.

Veins and organs, transplantation of, 230.

Venereal disease, alcohol and tuberculosis problems, 857, 902; the need of publicity in the prophylaxis of, 863; the prophylaxis of, 593.

Venous blood pressure, experiments on, 806; obstruction, 775.

Ventrofixation, 638.

Version, delivery of the arm in, 32.

Vestibule, operation on the, for vertigo, 152.

Vienna, letters from, 68, 434, 479, 722, 844, 889.

Vineberg, Hiram N., a contribution to the diagnosis and treatment of ectopic pregnancy, 1007.

Vinton, C. C., medical educational needs in Korea, 396.

Virginia doctors, to remove State tax on, 477.

Visceral disease, disturbances of sensation in, 1073.

Vitreous opacities in young girls, 1024.

Vomiting, chronic and periodic, 294.

Von Noorden, Prof. Carl, appointment of, 257.

Von Raitz, F., the treatment of tabes dorsalis, 786.

Von Ruck, Karl, immunization in tuberculosis, 85.

W.

Wadsworth, Augustus, the practical significance of our knowledge of bacteria in their relation to pneumonia, 699.

Wainwright, John W., exercise, 706.

Wallian, Samuel S., eyes and ears that might be saved, 12.

War, International Medical Association for the Suppression of, 633.

Warning, a, 841.

Warren triennial prize, 307.

Warts, 321.

Wasson, W. L., atrophic cirrhosis of the liver with report of two cases, 748.

Water as a local anesthetic, 69; filtration, public, in Massachusetts, 471, 485; supply of New York City, the problems of the, 485; supplies, filtration of public, 468, 485; the commercial value of clean, 487; of New York, pollution of the tidal, 590.

Watters, W. H., sutures and their preparation, 16.

Waugh, William F., selective absorpton by the cell, 10; treatment of pneumonia, 1011.

Weaver, H. B., pneumonia, 212.

Weil's disease, 32.

West Virginia State Medical Association, 674.

Western Surgical and Gynecological Association, 66.

Wheel injuries, 690.

White, honors to Dr. J. H., 593.

Whitlow and its treatment, 437.

Widener Home for Crippled Children, 394.

Williams, Linsly R., fresh-air homes and medical work in connection with them, 923.

Wilson, the late Dr. Ezra H., 227.

Wise, Fred, observations on the use of the *x*-ray in the treatment of certain diseases of the skin, 98.

Wolbarst, A. L., the three-glass catheter test; an improved method for the identification and separation of urethral and bladder deposits in urethritis, 627.

Wood, Wallace, cerebral segmentation, 878.

Word blindness, 182.

Wounded, care of the, on the battlefield, 687, 1054.

Wounds, the treatment of extensive gunshot, 983; treatment of, 32.

Wright, George S., professional treatment for insomnia, 597.

Wrist and ankle, clinical significance of variations of, 995.

Wyeth, John A., celluloid plates for cranial defects, 356.

X.

X-ray therapy, 617, 643. See also *Radiotherapy* and *Roentgen ray*.

Y.

Yaws and syphilis, 475.

Yellow fever, 476; at Havana, 66, 146; at New Orleans, 145, 553; at Panama, 511, 1019; blood parasites in, 399; contracted during the daytime, 683; cost of the outbreak of, in Mississippi, 266; in Cuba, 841; older views in regard to, 427.

Yerkes hospital, the, 65.

Youth, the instruction of, in sexual matters, 111.

Z.

Zabriskie, G. E., neurons and neurofibrils, 957.

Ziegler's successor, 674.
